These findings demonstrate that embedding SDEAs into footwear can provide meaningful plantarflexion assistance while remaining lightweight, silent, and unobtrusive. The device can partially restore push-off power in children with ankle control deficits and represents a promising step toward shoe-integrated soft robotic assistance. Current limitations include the modest strain capacity of SDEAs (~11%) and the need for a low-power (~1 W) but high-voltage (~1200 V) driver, which constrains the availability of portable electronics suitable for wearable use. Future work will focus on redesigning the midsole to improve SDEA integration, optimizing actuator placement beneath the heel to maximize push-off moment, and incorporating gait-synchronized control to enable real-world walking assistance.

Introduction

Evidence suggests that the visual fidelity (i.e., visual realism) and cognitive demand (i.e., psychological realism) of a virtual reality (VR) rehabilitation paradigm may influence motor learning [1]. However, the combined effects of these features on learning and real-world transfer remain untested; a crucial gap given that variability in VR fidelity may underlie mixed reports of VR training efficacy. Thus, the purpose of this study is to determine how these VR design features impact reaching biomechanics during learning and real-world transfer of a novel arm prosthesis control task.

Methods

Participants with and without a transradial amputation (anticipated *n* = 40 without and *n* = 10 with amputation) are being recruited for this ongoing study. Each participant learns to perform a block sorting task using a custom foot-controlled below-elbow prosthesis. After a real-world baseline assessment, participants practice this task twice per week for five weeks in a virtual environment that differs in terms of visual fidelity (high (HV) or low (LV)) and cognitive demand (high (HC) or low (HC)). All participants then perform a real-world transfer test. Inertial measurement units (IMUs) placed on the trunk and arm are used to calculate sagittal-plane reaching kinematics as well as forearm linear jerk.

Results

Preliminary results (*n* = 4, all without amputation) indicate that training in HV/HC VR resulted in large changes in reaching kinematics between baseline and transfer, including a large decrease in shoulder flexion and a large increase in elbow extension compared to the other groups. Moreover, this group demonstrated a drastic increase in forearm linear jerk during transfer, indicating a less smooth reaching strategy.

Discussion

These results indicate that high-fidelity (instead of highly realistic) VR conditions (both visual and cognitive) alter (or modify) participants' reaching strategies. Across groups, VR training also promoted a more distal, elbow-dominant control strategy. Preliminary results indicate that VR design features modify motor learning and biomechanical behavior, reinforcing the need for rehabilitation protocols to consider how fidelity levels influence movement quality and real-world transfer.

Hands-On vs. Teleoperated Assistance: Exploratory Findings from a Single Therapist Training Artificially Impaired Treadmill Walkers

Dr. Julia Manczurowsky PT, DPT, PhD[1], Ms. Samantha Steer[2], Mr. Om Prajapati[2], Dr. Sheng-Che Yen PT, PhD[2], Dr. Lester Leung MD, MSc[3,4], Dr. Peter Whitney PhD[2], Dr. Charles Hillman PhD[2,5], Dr. Christopher Hasson PhD[2]

[4]Tufts University School of Medicine, Boston, MA, United States. [5]Institute for Cognitive and Brain Health, Boston, MA, United States

Introduction

During rehabilitation, physical therapists vary assistive forces to facilitate motor adaptation, yet assistance is subjectively described as minimal, moderate, or maximal, making skilled strategies hard to interpret. Quantifying assistance is essential for improving clinical practice and robotic systems, which currently rely on algorithms agnostic to therapist behavior. To address this gap, we analyzed one therapist's assistance forces across two similar gait-training studies: hands-on through an instrumented leg brace and teleoperated through a robotic arm attached to the leg. We examined whether assistance modality or visual feedback modulated these forces.

Methods

Interaction forces were extracted from two assisted gait-training datasets involving healthy adults treadmill-walking with an artificial impairment of elastic resistance and hamstring stimulation to disrupt right leg swing (N= 35 hands-on; N = 23 telerobotic). Across four 2.5-minute trials and 1 trial the next day, the same therapist assisted participants to increase stride length and reach a mechanical work target. Visual feedback, assigned randomly, showed either participant and therapist summed work (control), or their work relative to the therapist (comparative). Feedback of stride-length accuracy helped the therapist adjust assistance. Anterior-posterior forces were averaged per trial and group. A linear mixed model tested effects of assistance modality, time, and feedback on mean force, with participant identity as a random effect and AR1 for repeated time.

Results

Assistance forces were less frequent and more discrete with telerobotics, reflected by a main modality effect on average force ($p < .001$). Target stride length was equally achieved in both studies. Although programmed to closely follow participants' leg motion, a small baseline resistance from the robotic arm produced negative mean forces during swing. Feedback also interacted with modality ($p = .005$): hands-on assistance was greater for control participants, whereas feedback type did not affect assistance during teleoperation.

Discussion

Therapeutic assistance is shaped by how participants and therapists adapt, how they are physically connected, and the feedback provided. Physical proximity may change engagement, while robotic constraints may temper therapist forces but increase participant effort. The observed assistance differences with a single therapist are hypothesis-generating for testing factors that could enhance or impede motor adaptation in gait retraining.

Quantifying Play Interactions: Implementation of a Digital Switch-Accessible Play Kit for Young Children Receiving Early Intervention Services

Mia Hoffman PhD[1], Ms. Alisha Bose[1], Ms. Riley Bernas[2], Ms. Kate Bokowy BS[1], Dr. Heather Feldner PhD, PT, PCS Emeritus[1], Dr. Katherine Steele PhD[1]

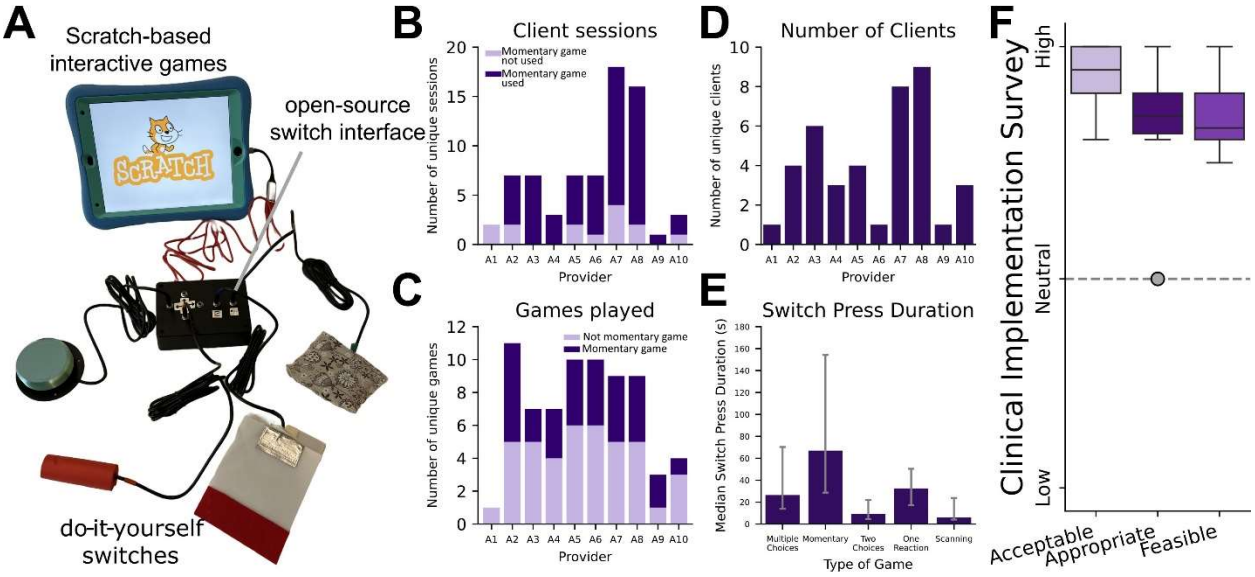
[1]University of Washington, Seattle, WA, United States. [2]University of Connecticut, Mansfield, CT, United States

Introduction

Play-based therapeutic activities are essential for young children with disabilities, yet accessible play options remain limited due to market constraints and financial barriers [1]. We collaborated with clinical and family stakeholders to develop the Switch Kit, an open-source switch interface compatible with homemade, low-cost switches and interactive Scratch-based games. This study aimed to understand and measure how early interventions providers integrated the Switch Kit into their practice.

Methods

Ten early intervention service providers (3 – 22 years' experience) received a Switch Kit to use for 4-6 weeks with clients. A data logger embedded in Scratch games tracked device usage and interaction metrics for each switch press. These data were combined with provider-completed logs detailing client characteristics and activities. At study completion, each provider completed clinical-implementation surveys and a semi-structured interview.



Results

Providers used the Switch Kit with one to nine clients (ages: 9 months – 4 years) with diagnoses including cerebral palsy and autism spectrum disorder. Momentary games, which played music during switch activation, were the most frequently selected. This game type also yielded the longest median press duration (67.5 seconds) and highest median presses (80.1) compared to other game types. All providers rated the Switch Kit as acceptable and feasible for classroom, outpatient, and in-home settings. All but one provider deemed it appropriate for their clients. Providers reported that the Switch Kit offered insights into each child's preferences, cognitive abilities, and readiness for other assistive technologies, such as augmentative and alternative communication.

Discussion

Providers used the Switch Kit to promote play participation for children with sensory challenges or significant motor involvement. Providers reported using the Switch Kit more frequently and with more clients than other switch-adapted toys, echoing prior findings that children engaged more with socially-assistive robots than switch-adapted toys [2]. The Switch Kit provides a practical, low-cost, and open-source solution (https://miahoffmannd.github.io/switchkit/) for integrating assistive technology into early intervention. By expanding access to play and offering insights into developmental readiness, it addresses a critical gap in technology use for young children with disabilities and supports clinicians in tailoring future interventions.

The Effects of Spasticity on Gait: A Comparison Between Predictive Simulations and Expert Consensus

Ms. Stefanie de Jager MSc[1,2], Dr. Niels Waterval PhD[1,3], Dr. Ajay Seth PhD[2], Dr. Kirsten Veerkamp PhD[4,3,1], Dr. Marjolein van der Krogt PhD[1,3]

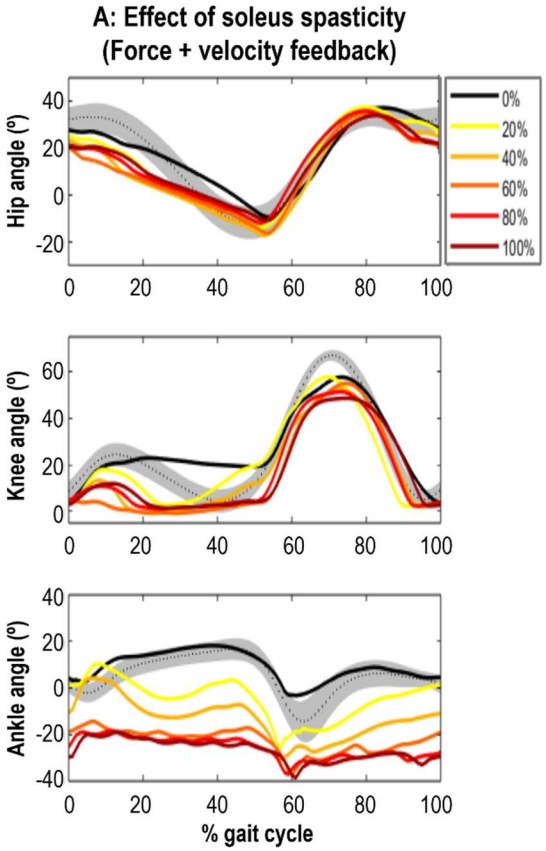
[1]Amsterdam UMC, Department of Rehabilitation Medicine, Amsterdam, NH, Netherlands. [2]Delft University of Technology, Department of Biomechanical Engineering, Delft, SH, Netherlands. [3]Amsterdam Movement Sciences, Rehabilitation & Development, Amsterdam, NH, Netherlands. [4]Vrije Universiteit Amsterdam, Department of Behavioural and Movement Sciences, Amsterdam, NH, Netherlands

Introduction

Spasticity can have a detrimental impact on gait [1], but the specific effects of individual muscle spasticity on gait kinematics are poorly understood. Here we compare two approaches that attempt to elucidate this effect, i.e. predictive simulations of gait and expert consensus. By comparing these approaches, we intend to gain further insight in the effect of spasticity on gait and obtain confidence in each of these methods.

Methods

We employed a predictive simulation framework [2], using a planar neuromusculoskeletal model, featuring nine musculotendon units per leg [3]. Muscles were activated by reflex-based controllers, while minimizing cost of transport, head movements, and foot-ground impacts [4]. Spasticity was modelled for the soleus, gastrocnemius, hamstrings, and rectus femoris muscles separately, by increasing velocity-dependent or force-dependent reflexes [3], or a combination of both, with five increasing gain values. Kinematic deviations from the unperturbed simulation were compared against spasticity-related gait features based on expert consensus, as previously obtained using a Delphi study [5].



Results

The combined force+velocity-dependent simulations showed the best match with expert consensus, followed by velocity-dependent reflexes alone. The simulations of soleus and gastrocnemius muscles matched well with expert consensus for most gait features (7/8 and 8/8, respectively, Fig.1). Simulations with hamstrings and rectus femoris spasticity did not match as well (1/3 and 1/2 features, respectively) and showed additional gait features that were not expected by experts.

Discussion

Our findings indicate that spasticity may be best represented by multi-factorial reflex pathways, rather than by purely velocity- or force-dependent reflexes. The mismatches found may be due to compensations by the model to prevent the muscles from stretching or producing force not typically seen in patients. In addition, length-dependent reflex activity was absent in our model but may play a significant role particularly in more proximal muscles [6]. Ultimately, predictive simulations may help to further refine clinical understanding by yielding deeper insight in the mechanisms underlying spasticity and its impact on gait.

Mechanical Demand Shapes Anticipatory Kinematic Adjustments in Landing From a Countermovement Jump: Evidence From a Microgravity Paradigm

Dr Romain Bechet[1], Prof Benedicte Schepens[2], Dr Clement Gambelli[3,2]

[1]Institut de Biomécanique Humaine Georges Charpak, Paris, Ile de France, France. [2]Laboratoire de Physiologie et biomécanique de la Locomotion, Institute of NeuroScience, Université catholique de Louvain, Louvain-la- Neuve, Brabant Wallon, Belgium. [3]Physical Activity, Sport and Recreation Research Focus Area (PhASRec), North-West University (NWU), Potchefstroom, North-West, South Africa

Introduction

Landing from a jump presents distinct challenges that require the integration of sensory information to accurately predict both the timing of ground contact and the characteristics of the forthcoming impact forces, to generate the appropriate motor command. Gravity is central to these predictions, as the central nervous system (CNS) relies on internal models assuming constancy to overcome sensory feedback delays. When gravity changes, touchdown (TD) joint angles and muscle activity adjust, suggesting sensory reweighting [1]. Yet, the mechanisms guiding pre-landing kinematic adjustments remain unclear.

Methods

Six participants performed countermovement jumps (CMJ) under simulated microgravity (0.2g, 0.4g, 0.6g, 1g) during parabolic flights, using a subject loading system to apply downward force in weightlessness (0g). Ground reaction forces and sagittal plane kinematics were recorded and used to compute hip, knee, and ankle joint angles and angular velocities, computed from a left derivative. The onset of joint flexion was defined as the first moment angular velocity became positive and remained so until TD. A linear mixed model examined the effect of gravity.

Results

The *p*-values, mean and standard deviation (SD) of flight time (FT), flexion onsets, relative flexion onsets (expressed as a percentage of FT) and joint velocities at TD are presented in Table 1. Gravity significantly altered FT, with longer FT in lower gravity. It also significantly altered hip and knee flexion onsets, with earlier onsets in lower gravity. In contrast, gravity had the inverse effect for relative joint onset, with later relative onsets in lower gravity.

Gravity also significantly affected hip, knee and ankle velocities at TD, with lower angular velocities in lower gravity.

Discussion

Earlier absolute but later relative onsets in lower gravity indicate that the CNS does not rely on a fixed timing reference to adjust joint angular velocity at touchdown. Instead, pre-landing control appears to be flexibly scaled to the mechanical constraints imposed by reduced gravity.

Elevated Mediolateral Slip Risk through Comprehensive Friction Demands during Walking in Unilateral Transfemoral Amputees

Mr. Shunta Kobayashi B.Sc.[1], Mr. Kai Kobayashi B.Sc.[1], Prof. Chien-Chi Chang Ph.D.[2], Prof. Takeshi Yamaguchi Ph.D.[3], Assoc. Prof. Hiroaki Hobara Ph.D.[1]

[1]Tokyo University of Scinence, Tokyo, Tokyo, Japan. [2]National Tsing Hua University, Hsinchu, Hsinchu, Taiwan. [3]Tohoku, Sendai, Miyagi, Japan

Introduction

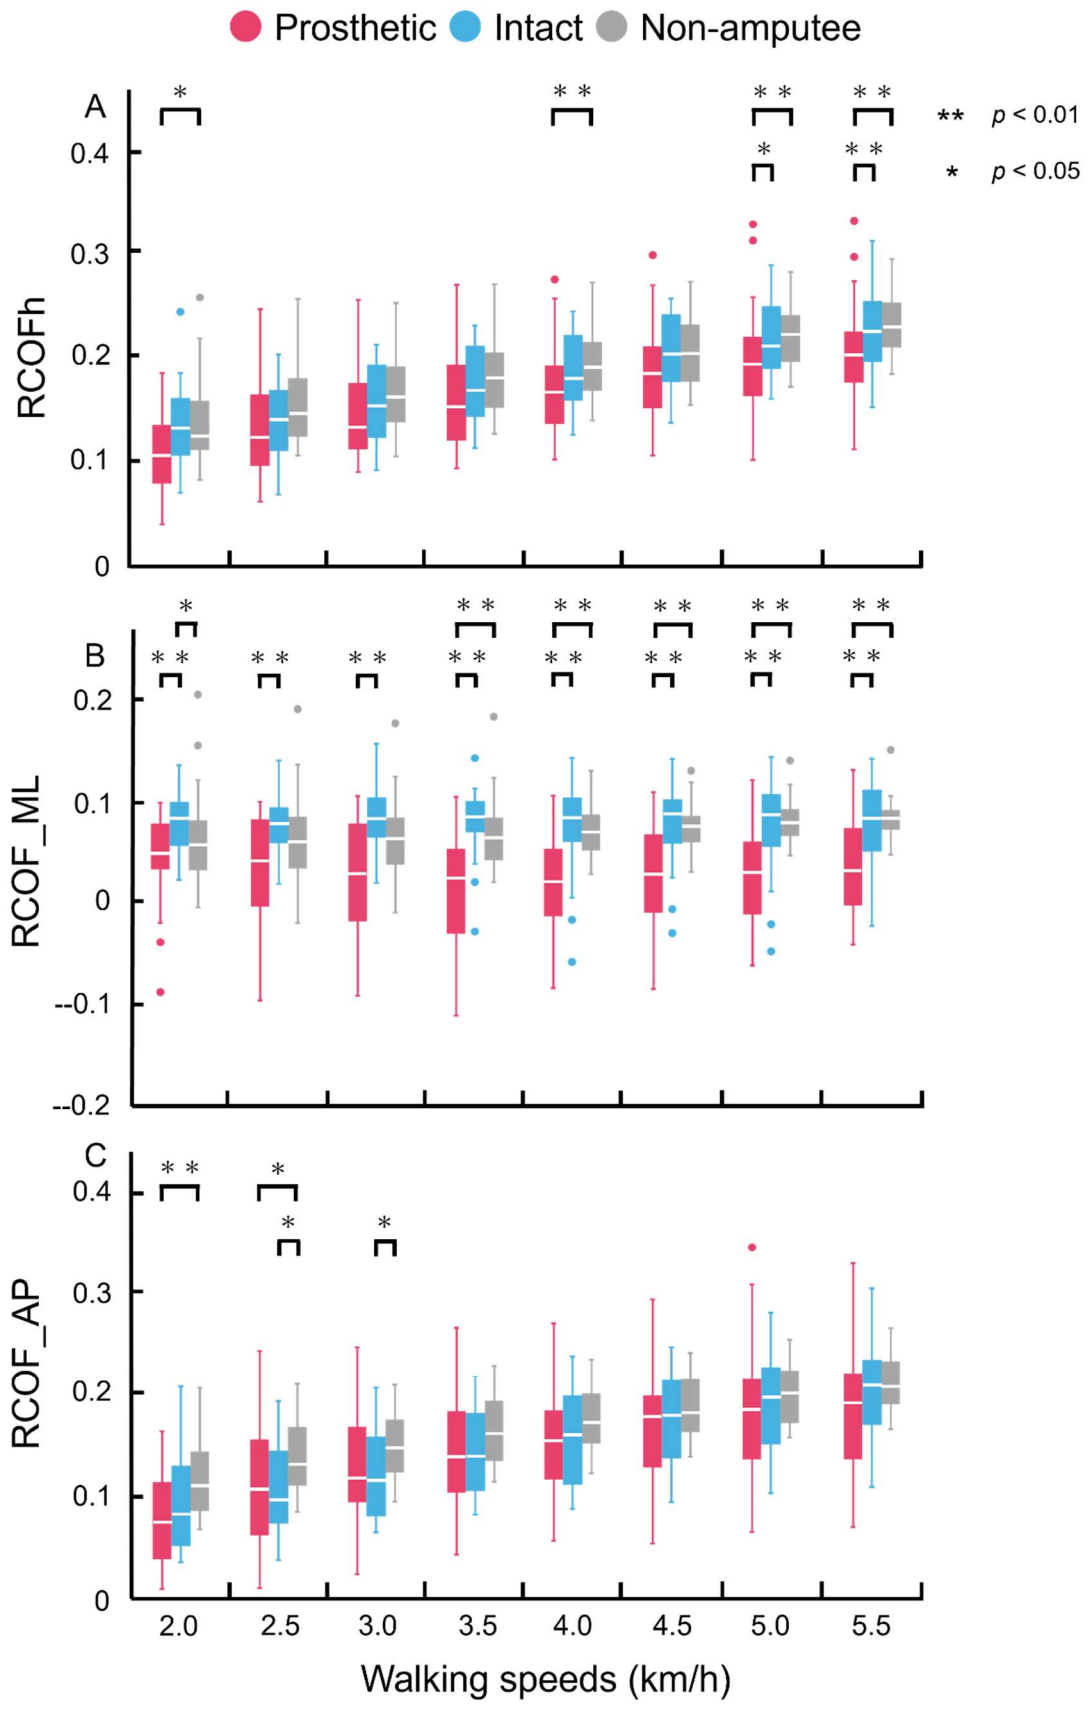
Individuals with unilateral transfemoral amputation (uTFA) exhibit an elevated fall risk than non-amputees, and slipping is a major factor in both populations [1, 2]. The required coefficient of friction (RCOF)—the minimum shoe–floor friction needed to prevent slipping—has been characterized in non-amputees' gait. In contrast, research on RCOF in individuals with uTFA remains limited, particularly regarding its dependence on walking speed. To address this gap, the present study compares RCOF between individuals with uTFA and non-amputees across multiple controlled walking speeds.

Methods

Thirty individuals with uTFA and thirty sex-, age-, and body mass-matched non-amputees were recruited. All participants walked at eight prescribed speeds (2.0–5.5 km/h) on an instrumented split-belt treadmill, and ground reaction forces (GRFs) were collected at 1 kHz. RCOFh was defined as the ratio of the resultants GRF to the vertical GRF (Fh/Fz), where

$$Fh = \sqrt{(Fx^2 + Fy^2)}$$

Higher RCOF reflects greater frictional demand and increased slip risk, whereas lower RCOF indicates reduced slipping potential. For each trial, the peak RCOF (RCOFh) and its mediolateral and anteroposterior components (RCOF_ML and RCOF_AP) were calculated as Fx/Fz and Fy/Fz at the instant of peak RCOF during the braking phase [3]. Normality was assessed using the Shapiro–Wilk test; when assumptions were violated, the Friedman test and Kruskal–Wallis test were applied ($p < 0.05$).



Results

RCOFh was higher in the non-amputee limb than in the prosthetic limb at 2.0, 4.0, 5.0, and 5.5 km/h, and higher in the intact limb than in the prosthetic limb at 5.0–5.5 km/h. RCOF_ML was higher in the intact limb than in the prosthetic limb across all speeds, and higher in the non-amputee limb at 2.0 and 3.5–5.5 km/h. RCOF_AP was higher in the non-amputee limb at 2.0–2.5 km/h and higher in the intact limb at 2.5–3.0 km/h.

Discussion

These results suggest that individuals with uTFA may benefit from asymmetric outsoles designed to enhance slip-resistance in the lateral direction.

Visuospatial Attention and Trip Avoidance Throughout Pregnancy

Dr. Robert Catena PhD[1], Dr. Jason Moore DPhil[2], MS. Xueying Wu BEng[1], Dr. Pegah Jamali PhD[1], Dr. Alan Godfrey PhD[2], Dr. Lisa Fournier PhD[1]

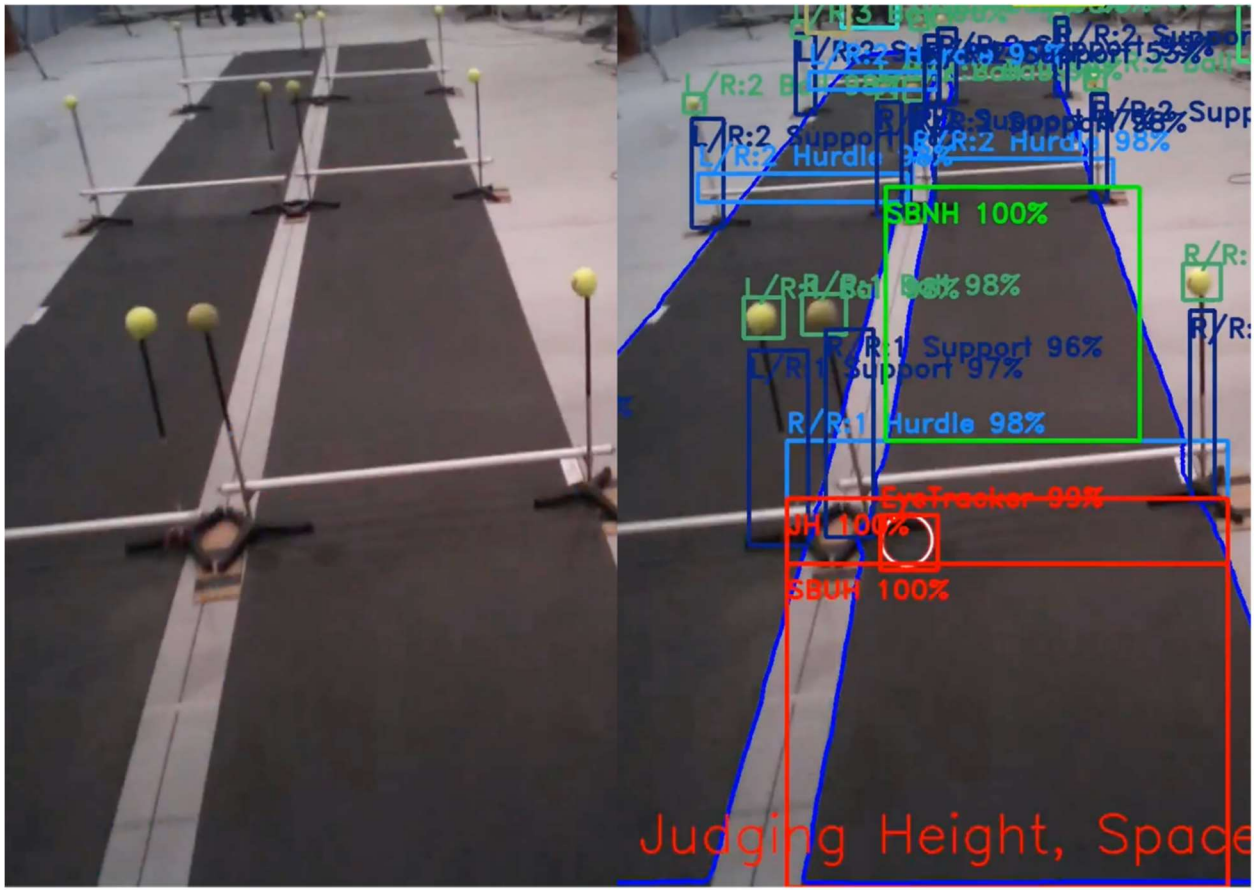
[1]Washington State University, Pullman, WA, United States. [2]Northumbria University, Newcastle, Tyne and Wear, United Kingdom

Introduction

The fall rate at seven months gestation is 25x greater than the first month [1]. An introspective shift of attention [2] may sacrifice needed extrospective attention to trip hazards. Our aim was to determine if visuospatial attention allocation to obstacle avoidance changes during pregnancy to explain some of the increase in fall risk.

Methods

Seventeen healthy pregnant participants were tested at ~13, ~19, ~25, ~31, and ~37 weeks of gestation. They walked continuous laps for 2 minutes through a 24m obstacle course consisting of six obstacles between 5% and 12.5% of body height (figure 1 left). Pupil kinematics and scene video were tracked with a mobile eye tracker. A YoloV8 algorithm classified scene objects and gaze overlap with objects to measure gaze distances relative to obstacle- and distractor-related scene information (figure 1 right) [3]. An 11-camera motion capture system tracked Euclidian distances between feet and obstacles [4]. Linear mixed models statistically analyzed changes over gestational time.



Results

Attention magnitude (blink rate, pupil size) did not change throughout pregnancy. Through the 2nd trimester, attention location (gaze distance) moves 10% closer to the current obstacle being crossed ($p=0.05$) and time spent attending to future obstacles decreased by 75% ($p=0.05$), allowing for 15% reduction in foot crossing heights ($p=0.03$). These changes suggest a safer and more energy efficient crossing strategy in the 2nd trimester. However, by week 31, visuospatial attention shifts away from the current trip hazard, while at the same time, crossing height further decreased by 20%, suggesting a riskier crossing strategy in the early 3rd trimester.

Discussion

With reduced attention allocated to the current trip hazard and low crossing heights, trip risk is greatest in week 31 (~7 months) of pregnancy. This timepoint also corresponds with degraded balance control [5] and degraded perception of obstacle heights [4], suggesting a combination of cognitive and mechanical reasons for the increased trip rates at 7 months gestation [1].

Whole-Body Balance Control Strategies During Obstacle Negotiation in Older Adults with Mild Cognitive Impairment

Dr. Shiuan-Huei Lu[1,2,3], Prof. Yi-Chun Kuan[1,2], Prof. Kuan-Wen Wu[1], Prof. Ting-Ming Wang[1], Prof. Tung-Wu Lu[1]

[1]National Taiwan University, Taipei, Taiwan, Taiwan. [2]Taipei Medical University, Taipei, Taiwan, Taiwan. [3]Purdue University, West Lafayette, Indiana, United States

Introduction

Mild cognitive impairment (MCI) represents a transitional stage between normal aging and dementia and is associated with deficits in executive function, attention, and motor coordination. These impairments challenge dynamic balance regulation during complex locomotor tasks such as obstacle negotiation. Whole-body balance control, quantified through center of mass-center of pressure (COM-COP) inclination angle (IA) and its rate of change (RCIA), provides a mechanistic framework for understanding fall-prone gait patterns. This study examined whole-body balance control strategies in older adults with MCI across obstacles of varying heights.

Methods

Eighteen adults with MCI (8 males, 10 females; 67.5 ± 4.2 years) and 18 healthy controls (10 males, 8 females; 67.8 ± 4.5 years) walked at preferred speed and crossed obstacles set at 10, 20, and 30% of leg length. Whole-body kinematics were recorded using a Vicon motion system, and ground reaction forces were measured using forceplates. COM position was estimated as the weighted sum of body-segment centres of mass, and COP position was derived from forceplate measurements. IA and RCIA were calculated in sagittal and frontal planes. Crossing speed and endpoint parameters, IA, and RCIA were analyzed using two-way mixed-design ANOVA with group as the between-subject factor and obstacle height as the within-subject factor.

Results

Crossing speed and endpoint parameters, including toe-obstacle clearance, did not differ between groups. However, the MCI group demonstrated increased sagittal-plane posterior IA and RCIA during double-limb support (DLS) and increased anterior RCIA during leading-limb swing ($p<0.05$). In the frontal plane, the MCI group exhibited increased medial IA and RCIA during swing and the first half of DLS ($p<0.05$).

Discussion

The phase-specific increases in IA and RCIA suggest impaired neuromechanical regulation of the inverted-pendulum-like COM-COP system in MCI, reflecting deficits in both anticipatory and reactive balance mechanisms. Although toe clearance was preserved, compensatory adjustments were required to maintain stability, potentially narrowing the margin of stability and elevating fall susceptibility. These results establish a biomechanical signature of instability in MCI and highlight COM–COP dynamics as sensitive indicators for early detection of impaired obstacle negotiation. Future work incorporating control-theoretic modeling and neuromusculoskeletal simulations may further elucidate the mechanistic pathways linking cognitive decline to gait instability.

Organic Bone Matrix Predictors of Fracture Toughness in Type 2 and Non-diabetic Cortical bone from Cadaveric, Femoral Midshafts

Ms. Emily Berestesky BS[1], Mr. Sasidhar Uppuganti MS[2], Dr. Paul Voziyan PhD[2], Dr. Thomas Willett PhD[3], Dr. Jeffry Nyman PhD[2]

[1]Vanderbilt University, Nashville, Tennessee, United States. [2]Vanderbilt University Medical Center, Nashville, Tennessee, United States. [3]University of Waterloo, Waterloo, Ontario, Canada

Ms. Emily Berestesky

Introduction

The risk for fragility fracture is assessed by Dual-energy x-ray absorptiometry (DXA) scans, which measure bone mineral density (BMD). T2D patients are at a greater risk of sustaining a fracture than non-diabetic age, sex & BMD-matched adults suggesting T2D weakens bone matrix quality. However, we recently reported that fracture toughness (FT) of human cortical bone is not different between donors with T2D (≥ 10 years) and without diabetes despite thermal stability of the organic matrix being higher with T2D [1]. Since matrix properties and porosity influence FT of cortical bone, we hypothesized that T2D affects the relationship between FT and matrix- and structural-related properties of the mechanical specimen while accounting for sex and age of the donor.

Methods

Single-edge notched beams (SENBs) from 120 cadaveric femoral midshafts (60 with T2D, 60 non-diabetic; sex-equivalence) were scanned by μCT (cortical porosity, Ct.Po; volumetric BMD, Ct.vBMD) and ^{1}H nuclear magnetic resonance relaxometry (bound water volume fraction, BW) [2] before micro-notch fracture toughness testing (crack initiation toughness, K_{init}; total crack energy dissipation, J_f) [3]. SENB sections underwent high performance liquid chromatography (pentosidine, PE; pyridinoline, PYD) and differential scanning calorimetry (temperature at maximum recorded heat flow, T_{peak}). To test the hypothesis, the ability of either Ct.Po, Ct.vBMD, PE, PYD, BW, or T_{peak} to predict FT properties was assessed with linear regression models, which included covariates: donor group (Non-diabetic/T2D), age, and sex. Group and each predictor interaction was not significant ($p > 0.3$), therefore excluded.

Results

Disproving our hypothesis, diabetic status was not a significant covariate of any FT property (Table). Only BW and Ct.Po were significant predictors of K_{init} and J_f. Female donors had higher FT for a given bone property than males. J_f but not K_{init} significantly depended on age.

Discussion

Present results suggests that fracture risk would benefit from measurements of Ct.Po and BW in long bones of patients since these properties could predict bone's ability to resist crack growth. The high-than-expected fracture risk in T2D cannot be attributed to alterations in how porosity and the matrix confer fracture toughness.

Images (Optional)

Table. Estimates (β) and p-values from linear regression models of Fracture Toughness properties and matrix- and structural-related properties.

Dr Stephan Zeiter

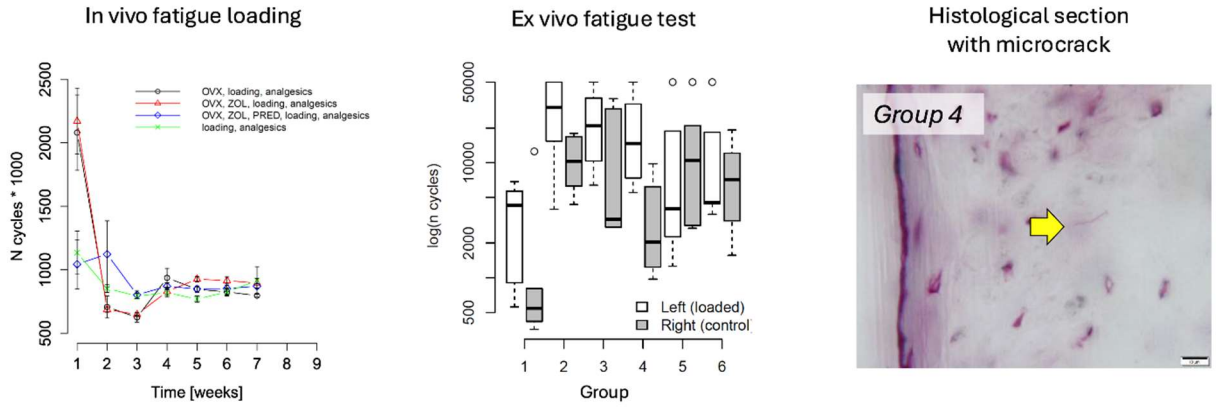
Introduction

The causes of stress fractures are not yet fully understood. Stress fractures likely develop from the accumulation of microdamage caused by repetitive loading. Under normal circumstances, bone cells continuously renew damaged bone; however, changes in physical activity, estrogen deficiency, and the use of corticosteroids (CS) or antiresorptive medications like bisphosphonates (BP) can disrupt this process. The study aimed to develop a murine model to investigate the response of bone to pathological fatigue loading, assess microcrack accumulation, and evaluate the role of CS/BP on resistance to fatigue.

Methods

Eighty-four 10 weeks old female C57BL6 mice were divided into 6 groups (Table 1). Animals in groups 1 to 3 underwent ovariectomy at week 12. From w20 on, groups 2 and 3 received BP (zoledronic acid weekly). Group 3 received CS (Prednisolone pellets - PRED). From w25 on, the left tibia in groups 1-4 were axially loaded (3-18N, 0.5Hz until 140% deformation). Group 4-5 were not loaded. Group 5 received analgesics only. The tibias were scanned bi-weekly with microCT. After sacrifice 6 tibias per group were tested in axial fatigue, the others were reserved for histology.

Results



The number of loading cycles until 140% deformation was very variable at w1 (1500±1000 cycles) but by W4 all groups had converged to 860±100. Groups 3 and 4 exhibited the most notable increases in cortical thickness (ct.th) and bone volume (BV) at proximal ROIs, reaching or surpassing the control levels. However, no significant changes were observed at the distal ROIs.

Imaging revealed that bone formation was greater in loaded tibias compared to non-loaded ones, while bone resorption showed only minor changes. Significant formation of woven bone was observed in the proximal region of the loaded tibias, and mechanical tests demonstrated that these tibias were significantly more resistant to fatigue than the non-loaded controls. Only 3 microcracks were observed in all histological slides (Fig. 1).

Discussion

The increased strength and absence of microdamage in the bones under fatigue loading indicates that mouse tibias adapt to mechanical loading even under intense weekly fatigue stress regardless of estrogen levels or CS/BP exposure.

Micromechanical Properties of Human Femoral Neck Compact Bone - Influence of Age, Sex and Anatomical Site

BSc Alex Bieri[1], BSc Simon Walker[2], MSc Jorge de Oliveira[3], Dr Christian Minnert[3], Dr Kevin Both[3], MSc Valeria Zanrè[3], Prof Beat Neuenschwander[2], Dr Jakob Schwiedrzik[3], Prof Philippe Zysset[1], Dr Tatiana Kochetkova[1]

[2]Institute for Applied Laser, Photonics and Surface Technologies ALPS, Bern University of Applied Sciences, Burgdorf, BE, Switzerland. [3]Empa, Swiss Federal Laboratories for Materials Science and Technology, Dübendorf, ZH, Switzerland

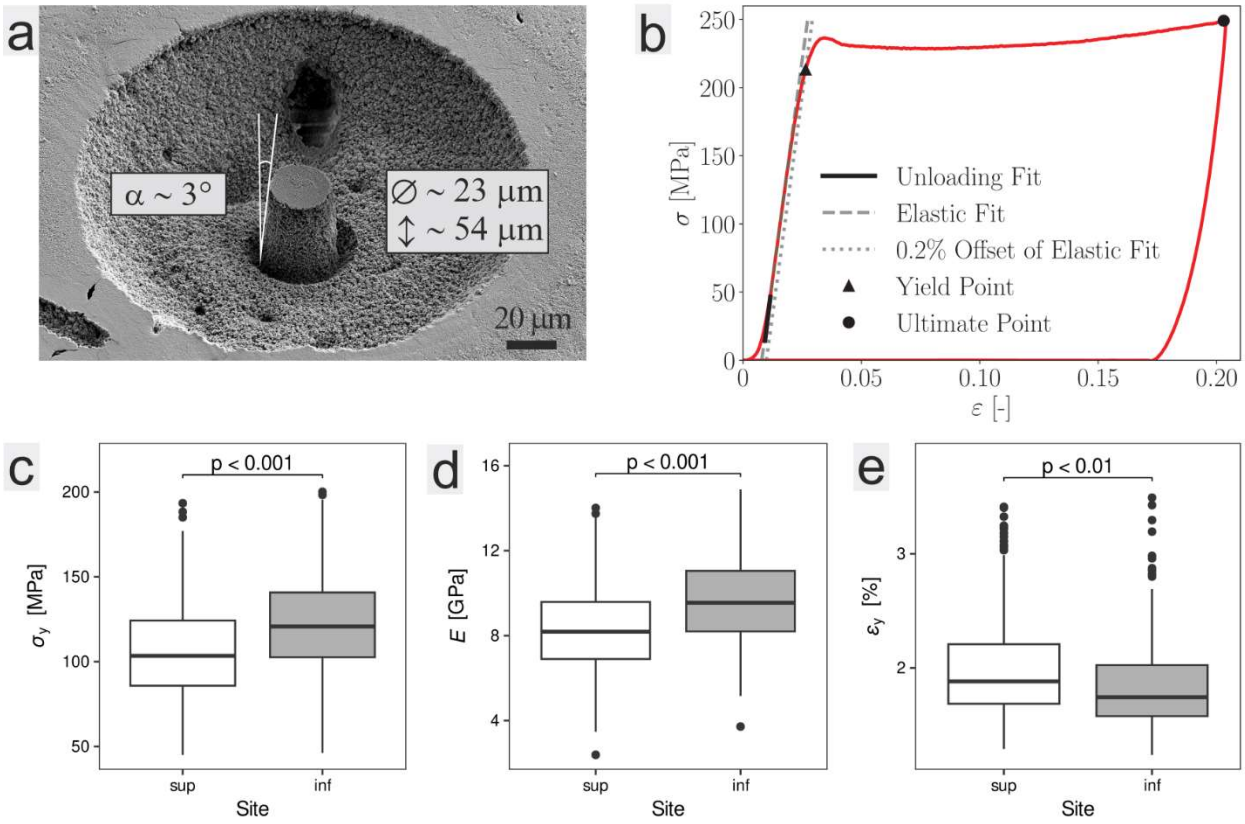
Introduction

The femoral neck site is the most burdensome location of fragility fractures. Anatomically, this site has a thicker inferior cortex compared to the thinner superior counterpart, the latter being the nucleation point for the majority of femoral neck fractures. While numerous studies focused on macro- and microarchitectural differences within the neck quadrants, there is limited data addressing their mechanical properties at the tissue level. We are interested in comparing the elastic, yield and post-yield mechanical properties of the inferior versus superior quadrants in ageing. This knowledge is relevant for understanding the fracture mechanism that leads to whole-organ failure.

Methods

Inferior and superior quadrants were cut from the femoral neck sections of 40 donors (24 female and 16 male, 57-96y.o.). In each quadrant, 12-20 bone micropillars were fabricated using the refined laser ablation protocol, providing, for the first time, sufficiently straight micropillars (~3° taper) in a high-throughput manner without exposing the sample to vacuum (fig-a). Micropillars were compressed under ambient conditions using an *ex-situ* indenter setup in a displacement-controlled quasi-static loading protocol with an intermittent unloading segment, to assess elastic, yield and post-yield properties (fig-b). A total of 1053 micropillars were compressed, with 1028 included in the final analysis.

Results



Inferior cortex exhibited 16-18% higher tissue-level E, σ_y, and 8% lower ε_y, in comparison to the superior quadrant (fig-c-e-d). All mechanical properties were largely constant across the examined donors' ages and sex, as anticipated [1]. Four types of failure modes were identified for both quadrants: homogeneous deformation (39%), mushrooming (21%), and

a combination of the first two with shear localization (34% and 6%), consistent with existing observations from ion-milled micropillar compressions [2].

Discussion

Observed variations in the femoral neck quadrants' tissue-level mechanical properties are attributed to the different mineralization levels [3] and/or internal lamellar organization, both of which are to be investigated with polarized Raman spectroscopy and second harmonic generation microscopy. Combined data will shed light on the microscale structure-property relationship within the inferior and superior femoral neck quadrants.

Evaluating Regional Bone Loss in Patients With Brachial Plexus Injury

Dr. Karyne Rabey PhD, Ms. Nikala Bochinski, Ms. Takeisha Wang, Dr. Mithun Rajshekar PhD, Ms. Stephanie Ramage, Dr. Matthew Curran MD, Dr. Ming Chan MD

University of Alberta, Edmonton, Alberta, Canada

Introduction

Peripheral nerve injuries can render an affected limb flaccid and insensate. Our rodent models have shown that there is a significant loss of bone mineral density (BMD), bone innervation, and bone strength post injury. Whether these peripheral nerve injuries also lead to BMD loss in humans, has not yet been tested. This represents a major knowledge gap as untreated bone loss in an arm already lacking motor and sensory protection could increase the risk of fractures and further exacerbate functional decline.

Methods

Twenty-eight adult participants (22 males and 6 females) with a brachial plexus injury resulting in shoulder and/or elbow deficits were recruited. Time since their injury ranged from 6 months to 17 years. Each patient underwent a full body DEXA scan using General Electric iDXA encore-based X-ray Bone Densitometer (Fig 1A). Results from the region of interest (ROI) in the injured humerus were compared to those from the uninjured arm.

Results

Results revealed a significant decrease in both BMD (82 ± 13%) and lean tissue mass (83 ± 9%) with an increase in fat tissue mass (157 ± 45%) in the injured arm. All changes began 1 year since injury and persisted over time. There were no differences in BMD between patients with motor recovery and patients with little to no motor recovery. Data indicated that male and female patients were classified to have either regional osteopenia (T-score between -1.0 and -2.5) or regional osteoporosis (T-score -2.5 and below) (Fig 1B-C).

Discussion

Patients with peripheral nerve injuries have significant loss of BMD and lean tissue mass, accompanied by infiltration of fat tissue, in the region of their injury. These findings are persistent even in those with motor recovery and those who are 10+ years post injury. This suggests that loss of BMD is not due to weakness or lack of arm use. Rather, recent data from our animal studies show an intimate relationship between sensory and sympathetic

nerves and bone turnover. This highlights the importance of early detection and early integration of osteoporosis management into the treatment of nerve injuries to prevent irreversible bone loss and to minimize the risk of fractures.

Images (Optional)

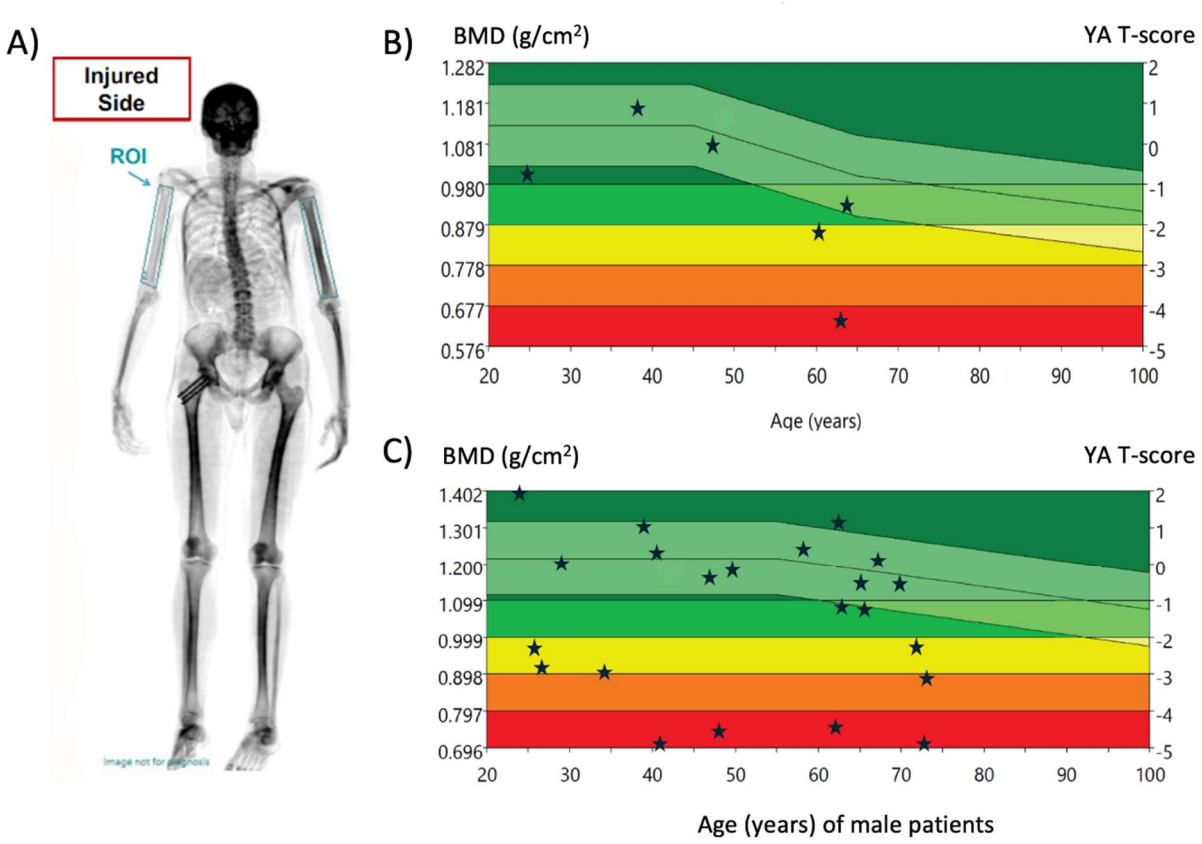

Figure 1: **A**) DEXA scan image showing the humeral regions of interest (ROI – blue boxes) used for comparison. **B-C**) Bone mineral density (BMD) of injured arm in female (**B**) and male (**C**) participants as related to their sex-matched T-scores to predict future fracture risk. Reference database classified 2 female patients and 4 male patients with regional osteopenia (T-score -1.0 to -2.5); 1 female patient and 7 male patients classified with regional osteoporosis (T-score -2.5 and below).

Chemomechanical Modeling of Time-Delayed Feedback in Cell–ECM Adhesion Regulation

Mr Eiji Matsumoto PhD student, Mr Shinji Deguchi Professor

Graduate School of Engineering Science, The University of osaka, Toyonaka, Osaka, Japan

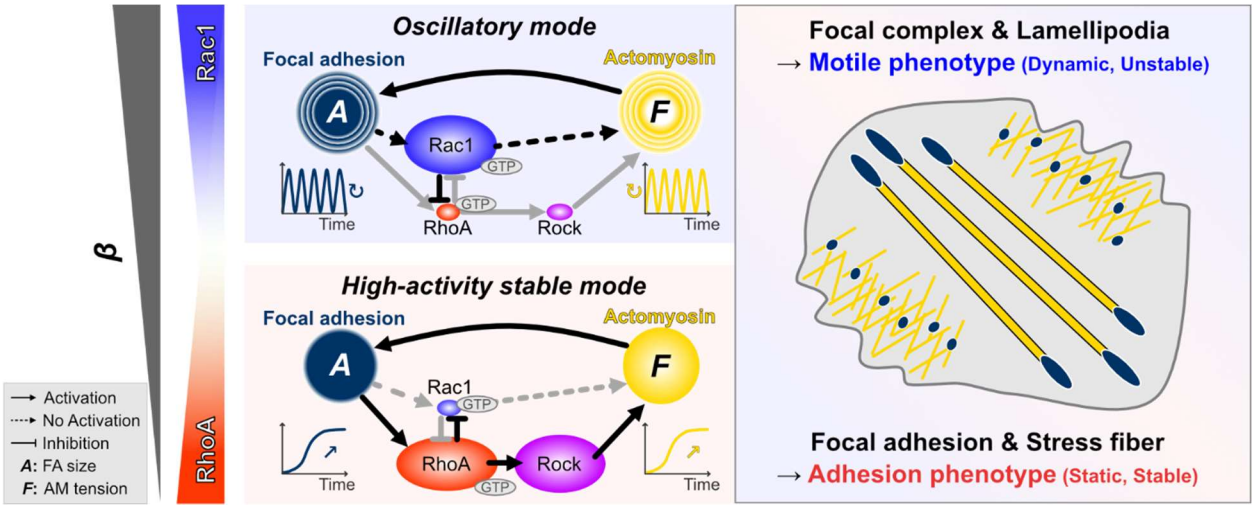
Introduction

Cell–ECM adhesion plays a central role in how cells integrate mechanical forces and biochemical signals to regulate their behavior. This interaction is mediated by focal adhesions (FAs), which physically link the extracellular matrix (ECM) to actomyosin fibers (AMs), the contractile structures that generate intracellular tension, thereby enabling chemomechanical coupling. Dysregulation of this adhesion process contributes to pathological conditions such as fibrosis and atherosclerosis, highlighting the need to understand its regulatory principles. Although the relevant biochemical cascades have been well characterized, a fundamental question remains unresolved: how diverse adhesion dynamics can coexist within a single cell. This study aims to elucidate the minimal chemomechanical principle that accounts for the coexistence of distinct adhesion dynamics.

Methods

Live imaging of FA-associated proteins combined with traction force microscopy revealed two distinct dynamical modes coexisting within single cells: a stable mode and an oscillatory mode. To clarify the chemomechanical origin of these dual modes, we developed a minimal chemomechanical model that captures the key feedback loops coupling FA size and AM tension. The model incorporates tension-dependent FA maturation and the antagonistic RhoA–Rac1 signaling pathway, formulated as a bidirectional feedback system with an effective time delay. This delay acts as a coarse-grained representation of the reaction-time delays accumulated within biochemical signaling cascades.

Results



The model yields a dynamical phase diagram that predicts the coexistence of stable and oscillatory regimes, reproducing time-course behaviors consistent with experimental observations. The oscillatory period follows a scaling relationship determined by the chemomechanical feedback strength, and the phase lag between FA size and AM tension

remains robustly locked at 90 degrees. Oscillation amplitudes are regulated hierarchically by model parameters, revealing how biochemical and mechanical factors together shape adhesion dynamics.

Discussion

The model provides a physical mechanism suggesting that time-delayed chemomechanical feedback acts as the essential driver of both stable and oscillatory adhesion behaviors. This framework generalizes beyond adhesion dynamics to broader chemomechanical regulation and provides a mechanistic basis for interpreting pharmacological perturbations as modifications of underlying bifurcation structures. By connecting chemomechanical control of adhesion to pathological phenotypes, the model offers a conceptual foundation for therapeutic strategies targeting cell–ECM mechanics.

Type V Collagen Regulates Nascent Matrix Templating and Cell-Mediated Reorganization in Embryonic Meniscus

Mr. Neil Patel[1], Dr. Meghan Kupratis PhD[2], Dr. Karen Xu PhD[2], Mr. Thomas Li[1], Dr. Eiki Koyama PhD[3], Dr. Nathaniel Dyment PhD[2], Dr. Robert Mauck PhD[2], Dr. Lin Han PhD[1]

[1]Drexel University, Philadelphia, PA, United States. [2]University of Pennsylvania, Philadelphia, PA, United States. [3]The Children's Hospital of Philadelphia, Philadelphia, PA, United States

Introduction

Meniscus injury often leads to the onset of post-traumatic osteoarthritis, but there is limited success in meniscus repair due to poor understanding of its fibrocartilaginous matrix and cell-matrix cross-talk. Our prior work showed collagen V plays key roles in the initial establishment of meniscus matrix and mechanosensitive signaling of meniscal cells in vivo. This study investigates how collagen V directs embryonic meniscal cell–matrix interactions under well-controlled in vitro scenarios.

Methods

Meniscal cells were harvested from E84 pigs and were transfected with *Col5a1*-siRNA to reduce Col5a1 expression. Cell-derived matrices (CDMs) were generated at 7-10 days to assess mechanical properties via AFM-nanoindentation and architecture (fibril alignment and density). Additionally, cell-mediated matrix contraction was evaluated in collagen I gels with and without the addition of exogenous collagen V. Cell level fibril reorganization was assessed via second harmonic generation (SHG).

Results

The reduction of Col5a1 expression by siRNA was validated up to 3-5 days by qPCR and immunofluorescence imaging (**Fig. 1a,b**). As a result, the production CDM was significantly impacted. At day 7, siRNA-CDMs exhibited reduced fibril alignment and density (**Fig. 1c**), which was recovered by day 10. However, AFM-nanoindentation found significantly lower micromodulus for siRNA-CDMs compared to the controls, indicating impaired matrix assembly (**Fig. 1d**). Meanwhile, Col5a1 knockdown led to significant delay in cell-mediated gel contraction (**Fig. 1e**) and reduced collagen I fibril organization at the cell-gel interface via SHG (**Fig. 1f**). Conversely, treatment of exogenous collagen V was able to partially restore gel contraction (**Fig. 1e**) and cell-mediated reorganization (**Fig. 1f**).

Discussion

This study highlights a pivotal role of collagen V in regulating meniscus matrix functional elaboration and cell-mediated matrix organization. This is supported by the impairment of CDMs, delayed gel contraction and diminished collagen fibril reorganization by siRNA-treated embryonic meniscal cells. Meanwhile, such effects caused by a loss of endogenous collagen V can be partially rescued by exogenous collagen V. Therefore, our results also indicate the therapeutic potential of applying collagen V for improving meniscus repair by augmenting matrix assembly and cell-matrix interactions.

Critical Cell Spacing Governs Mechanical Communication via Strain-Stiffened Tension Bands in Fibrous ECM

Prof Guy Genin[1], Dr Xiangjun Peng[2], Mr Yuxuan Huang[1], Dr Wenyu Kong[2], Prof Yanan Du[2], Prof Elliot Elson[1], Prof Xi-Qiao Feng[2]

[1]Washington University, St. Louis, MO, United States. [2]Tsinghua University, Beijing, Beijing, China

Introduction

Cells communicate mechanically through the extracellular matrix (ECM), influencing neighbors' contractility, polarization, and migration during wound healing, fibrosis, and cancer progression. However, the physical principles governing the range of this mechanical communication remain unclear. Understanding what determines whether cells can "sense" each other through the matrix is essential for predicting collective cell behavior and developing mechanical interventions for fibrotic disorders.

Methods

We developed a bio-chemo-mechanical model integrating three components: (1) a motor-clutch framework for cell contractility, incorporating actin polymerization, myosin motor activity, and integrin-mediated adhesion; (2) nonlinear fibrous ECM mechanics capturing strain-stiffening behavior through a fiber recruitment model; and (3) mechanosensitive signaling via YAP/TAZ nuclear translocation. We simulated cell pairs at varying separations and ECM properties, then extended the model to multicellular systems to examine collective behavior.

Results

Mechanical communication between cells exhibited a nonmonotonic dependence on ECM stiffness: communication was optimized at intermediate stiffness values where cells could both generate sufficient contractile forces and create strain-stiffened tension bands in the ECM. This balance established a critical cell spacing threshold of approximately 100-200 μm, which was remarkably conserved across different cell types and collagen densities, consistent with experimental observations. The critical stretch ratio at which fibrous networks transition from compliant to strain-stiffening governed this threshold through tension band formation between neighboring cells. In multicellular simulations, these mechanical communication networks drove a collective phase transition from disordered

to ordered polarization states when cell density exceeded an effective percolation threshold.

Discussion

Our model provides a mechanistic explanation for the experimentally observed phenomena of "optimal ECM rigidity" and "paratensile signaling," revealing how microscale cell-ECM interactions control emergent tissue-level mechanical properties. The conserved critical spacing offers a quantitative design parameter for tissue engineering and suggests that manipulating ECM mechanics or cell density near this threshold may enable more effective treatments for chronic wounds, fibrosis, and cancer invasion.

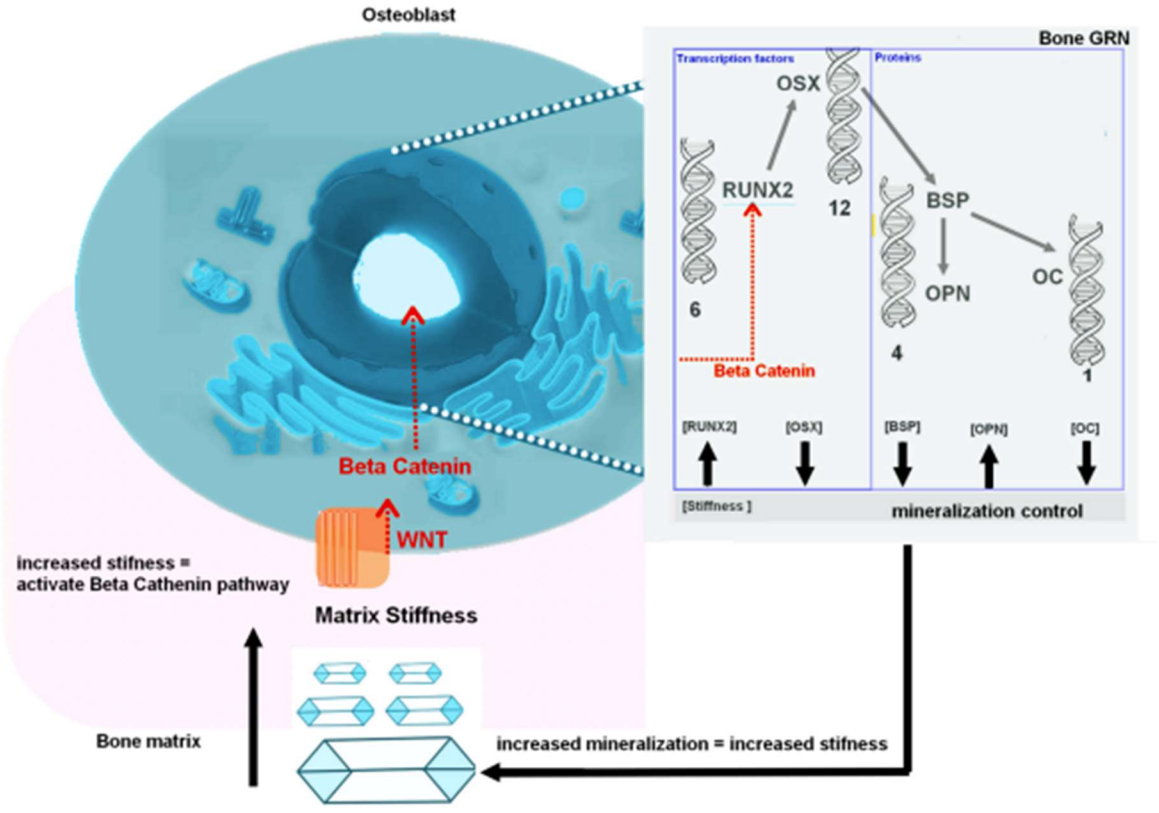
Introduction

Bone is a dynamic, load-responsive tissue whose structure and function are shaped by mechanical forces. Through mechanotransduction, osteogenic cells convert mechanical cues such as stiffness, strain, and fluid shear into biochemical signals that regulate proliferation, differentiation, and matrix mineralization. In mesenchymal stem cells, these signals modulate the bone Gene Regulatory Network (GRN), directing lineage commitment and the expression of key osteogenic proteins. Understanding how mechanical inputs interface with gene regulatory mechanisms is essential for explaining bone adaptation, pathological remodeling, and the design of biomaterials that exploit mechanically guided osteogenesis. The aim of our study was to determine how a defined segment of the bone GRN governs mineralization in response to stiffness. We hypothesized that a system of differential equations could model stiffness-sensitive gene regulation in human mesenchymal stem cells by capturing the epistatic interactions between stiffness-activated pathways (e.g., WNT–β-catenin) and five major transcription factors and bone proteins (RUNX2, BSP, OSX, OC, and OPN)

Methods

To test this hypothesis, we (i) performed in-vitro experiments culturing bone cells on different stiffness, (i) adapted our previously published model from being continuously time-dependent to continuously stiffness-sensitive, and (iii) simulated protein production in function of stiffness and other protein production from the best estimate of parameters coming from the experimental work.



Results

Our experiments show a non-parametric relationship between stiffness and RUNX2 expression, with no clear linear trends for the other proteins. The modeling results indicate that continuous changes in stiffness allow accurate simulation of bone-GRN gene expression and fit our new experimental dataset. In particular, the model predicts maximal OPN production at low stiffness (8 kPa), whereas RUNX2, OSX, and OC reach their highest expression at higher stiffness (64 kPa). This agreement highlights the model's ability to reproduce the experimental observations

Discussion

Our model predicts that WNT–β-catenin activation enhances OPN and BSP production. It also identifies a negative feedback–like interaction between OC and BSP. Variations in stiffness exert a strong influence on OC and BSP expression and a moderate effect on OPN. By incorporating stiffness-dependent gene regulation, the approach provides mechanistic insight into mineralization patterns through the predicted dynamics of bone protein expression.

OA127-02

Impact of Stent-Graft Compliance on Regional Aortic Remodeling

Dr. Ramin Shahbad[1], Ms. Sivapriya Kuniyil[1], Dr. Jason MacTaggart[2], Dr. Anastasia Desyatova[1]

[1]University of Nebraska Omaha, Omaha, NE, United States. [2]University of Nebraska Medical Center, Omaha, NE, United States

Introduction

Endovascular aortic repair is the first-line therapy for treating aortic pathologies such as aneurysm, dissection, and blunt thoracic injury. However, implantation of currently available stent-grafts introduces a substantial compliance mismatch with the native aorta, which can disrupt wall biomechanics, promote pathological remodeling, and contribute to long-term cardiovascular complications. To investigate the impact of this compliance mismatch, we compared aortic remodeling four months after implantation of a conventional stiff stent-graft (CS-SG) with a newly developed compliant nanofibrillar stent-graft (NF-SG) designed to mimic native vessel properties.

Methods

Aortas were harvested from 20 porcine animals that underwent endovascular surgery 18 weeks earlier to receive either a stiff polyethylene terephthalate stent-graft (CS-SG, N=8), a compliant nanofibrillar stent-graft (NF-SG, N=5), or sham-operated (control, N=7). Tissue samples were collected from proximal, stented, and distal aortic regions. Post-sacrifice analyses included planar biaxial mechanical testing to quantify intrinsic wall stiffness and nonlinearity, and histological assessment of elastin, collagen, and smooth muscle cell densities across the medial depth using Movat's Pentachrome and Masson's Trichrome (MTC) stains. These metrics were compared between treatment groups and across anatomical locations (proximal, stented, and distal segments) to characterize regional remodeling patterns.

Results

Remodeling in the CS-SG group was mainly localized to regions in direct contact with the stent-graft and was characterized by marked collagen accumulation (~25–30% vs. ~15% in the inner media), elastin fiber compaction, substantial SMC loss (~10–15% vs. ~20–25% in the inner media), and formation of a thick neointima. These structural changes corresponded to increased aortic stiffness (0.47 MPa vs. 0.37 MPa) and reduced non-linearity, most notably in the distal stented segments, while non-stented remote regions showed minimal alterations. In contrast, NF-SG implantation resulted in significantly

milder remodeling, with preserved SMC density, less collagen compaction, minimal neointima, and greater compliance in both stented and neighboring regions.

Discussion

A compliant stent-graft reduced wall loading at stent–tissue contact, limiting excessive remodeling and preventing early stiffening. In contrast, the stiff graft restricted expansion and generated higher localized stresses that promoted maladaptive structural changes. These findings highlight the importance of compliance-matching of stent-grafts in maintaining healthy aortic biomechanics.

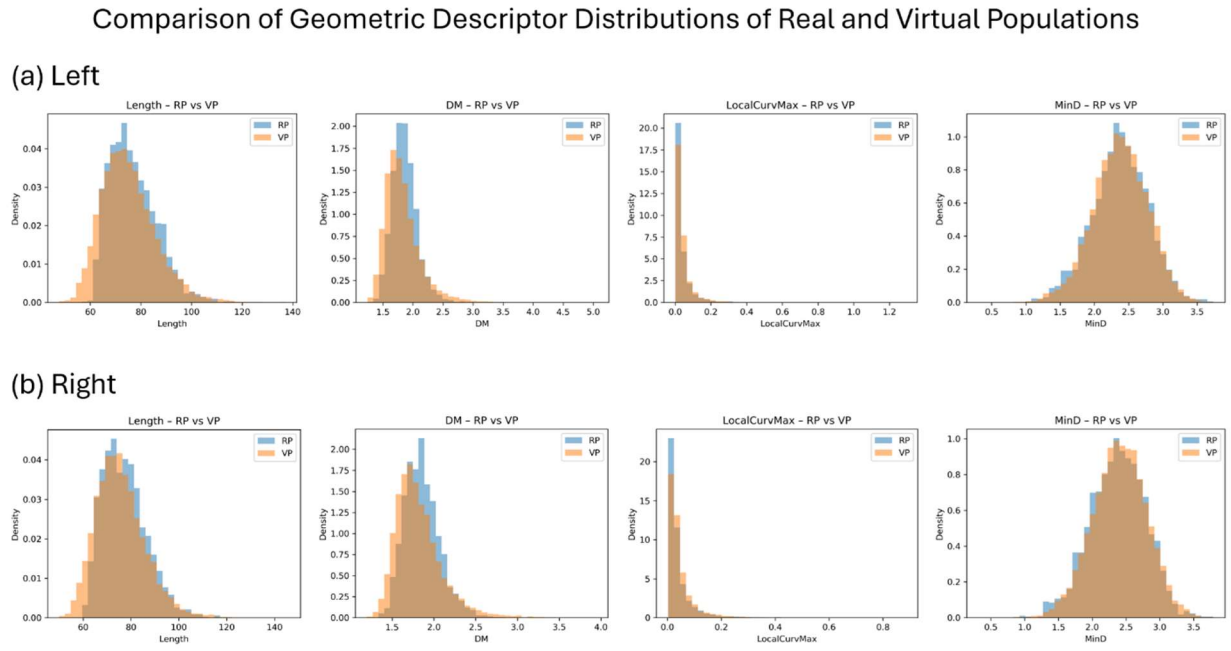
Introduction

The geometry of the internal carotid artery (ICA) strongly influences flow patterns and the initiation of vascular diseases. Large ICA datasets support data-driven analysis, yet are challenging to obtain because of ethical and cost constraints. Previous studies have proposed Multivariate Normal Distribution (MVND) based artery virtual population generation [1], but these efforts relied on limited datasets (<20 ICAs), restricting their ability to represent natural anatomical variability. In this study, we extend the virtual population approach to a substantially larger and more diverse community dataset. ICA data from the Nagahama cohort (1,883 left and 1,927 right) were analyzed to construct a large-scale, statistically grounded virtual ICA population that better captures population-level shape diversity for downstream vascular research.

Methods

ICA centerlines and diameter profiles were extracted, resampled, and smoothed from the Nagahama MR images. The 3D coordinates and corresponding diameter values of each landmark points were used as the input for MVND modeling, from which 10,000 virtual ICA samples were generated. Geometric descriptors, including vessel length, distance metrics, local maximum curvature, and minimum diameter, were then computed for both real and virtual populations. Distributional similarity between real and virtual populations was quantified using Kullback–Leibler (KL) divergence for each geometric descriptor. All procedures were performed separately for left and right ICAs to preserve laterality-specific anatomical characteristics.

Results



The distributions of key geometric descriptors in the virtual population closely matched those of the real Nagahama dataset. Similar trends were observed for both left and right ICAs. KL divergence values were consistently low to moderate, with <0.10 for minimum

diameter and local curvature maxima, ~0.29–0.39 for distance metrics, and ~0.58–0.90 for vessel length, indicating good agreement between real and virtual populations. The model faithfully reproduced major ICA morphological trends and variability patterns observed in the cohort.

Discussion

This work demonstrates that a large community-based cohort enables construction of a statistically representative virtual ICA population with significantly greater anatomical diversity than prior small-sample models. The resulting virtual population provides a robust foundation for uncertainty quantification, large-scale flow simulations, and future studies on ICA-related cerebrovascular risk.

Abluminal Watertight Lining in Porcine Carotid Arteries: Biomechanical Role and Impact on Decellularization Efficiency

Prof. Jin-Jia Hu, Mr. Yi-Jing Chen

Department of Mechanical Engineering, National Yang Ming Chiao Tung University, Hsinchu, Taiwan, Taiwan

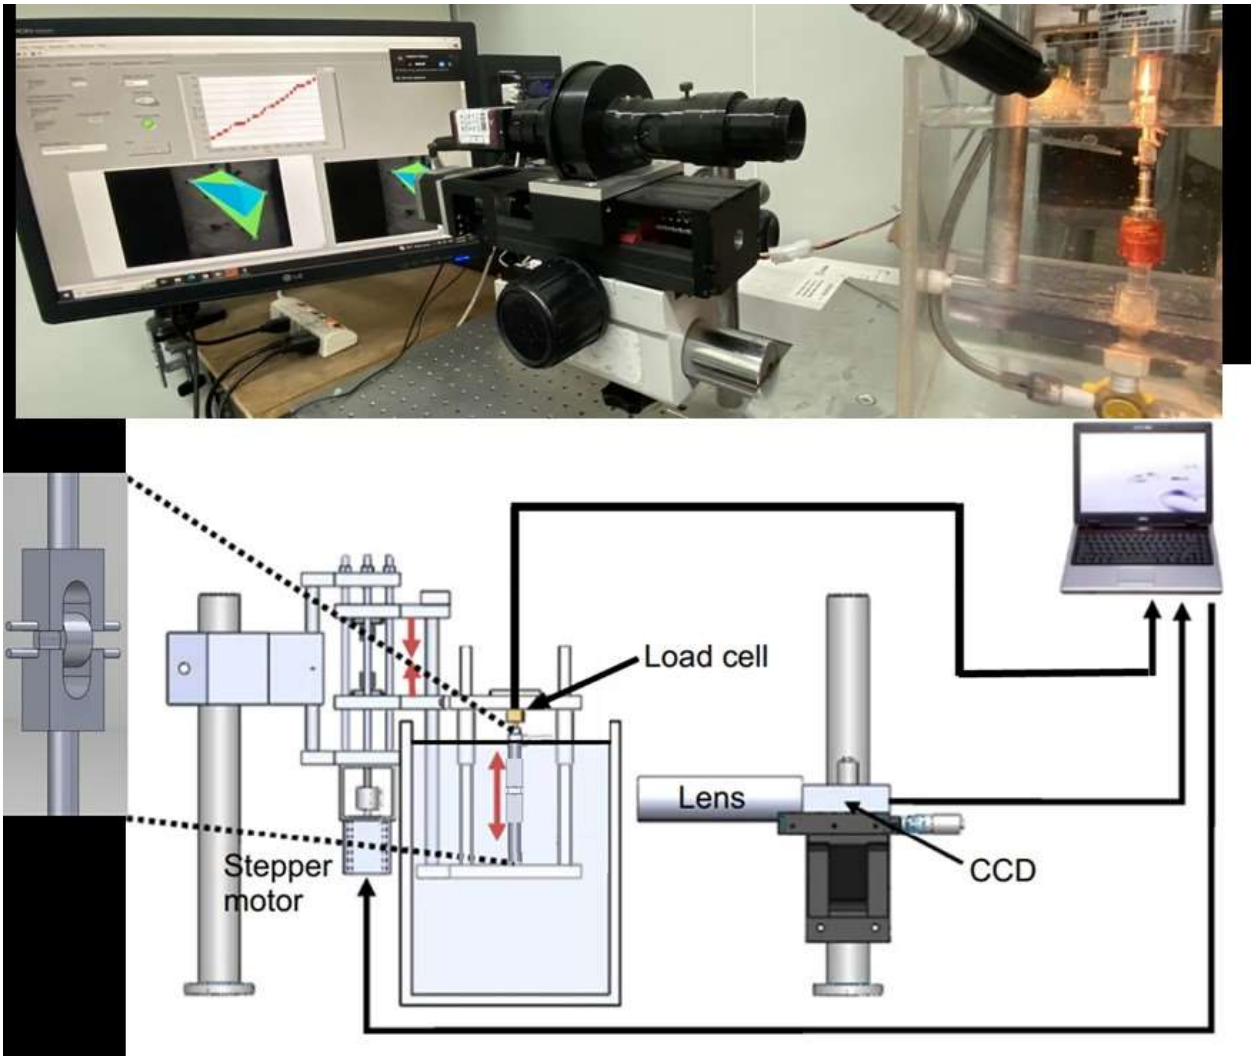
Introduction

Tissue-engineered vascular grafts (TEVGs) have gained increasing attention as alternatives to autologous conduits for vascular reconstruction. Decellularized blood vessels provide native extracellular matrix scaffolds with favorable mechanical properties and biocompatibility, yet efficient decellularization without compromising structural integrity remains challenging. Our previous work identified an abluminal watertight lining in human umbilical arteries; its removal altered vessel mechanics and markedly improved perfusion decellularization efficiency. Determining whether similar structures exist in other vascular beds is essential for optimizing decellularization strategies and producing high-quality scaffolds for TEVG development.

Methods

Porcine carotid arteries (PCAs) were used to investigate the presence and functional role of an abluminal lining. A highly viscous collagenase solution was applied to the external surface to selectively degrade this lining. Histological staining with three complementary methods assessed extracellular matrix preservation. Vessel-wall permeability was measured to quantify transmural flow. Mechanical behavior was evaluated using circumferential ring testing. A custom perfusion system was then used to assess decellularization efficiency using a 1% SDS solution for 48 hours followed by a 10% calf serum wash for 18 hours. Residual DNA content and histology were used to confirm decellularization effectiveness.

Results



Histology confirmed that medial extracellular matrix components were preserved after collagenase treatment. Permeability testing showed a substantial increase in transmural flow, supporting the existence and successful removal of an abluminal watertight lining. Ring testing demonstrated increased compliance after treatment, indicating that the lining contributes to the artery's passive mechanical response. Following perfusion decellularization, histological analyses showed extensive cell removal, and residual DNA decreased to approximately 100 ng/mg. Ring testing of decellularized arteries exhibited a

leftward shift in the stress–strain curve, suggesting the loss of compliant constituents during SDS treatment.

Discussion

Selective removal of the abluminal watertight lining significantly enhanced perfusion decellularization efficiency in PCAs without damaging medial extracellular matrix. This approach enabled preparation of fully decellularized vessels within three days. These findings highlight the biomechanical relevance of abluminal linings and support the potential of decellularized PCAs as scaffolds for tissue-engineered vascular grafts.

Prediction of Stent-Graft Placement After the EVAR Procedure: A High-Fidelity Computational Model

Eng Giulia De Campo[1], Dr Sara Barati[1,2], Dr. Anna Ramella[1,2], Dr. Francesco Migliavacca[1,3], Dr. Irene Fulgheri[3], Dr. Santi Trimarchi[3,4], Dr. Giulia Luraghi[1]

[1]Politecnico di Milano, Milan, Lombardy, Italy. [2]AllStent, Milan, Lombardy, Italy. [3]Foundation IRCCS Ca' Granda Ospedale Maggiore Policlinico,, Milan, Lombardy, Italy. [4]Department of Clinical Sciences and Community Health, University of Milan, Milan, Lombardy, Italy

Introduction

Endovascular aortic repair (EVAR) is a minimally invasive techniques commonly used to treat abdominal aortic aneurysm (AAA). The procedure consists in the deployment of a stent-graft in the pathological region of the aorta to exclude the aneurysm from the blood circulation. Variability in the pre-operative planning measurement, may results in inconsistent device positioning and sizing, leading to post operative complications [1]. In this context, computational models can provide information about stent-graft placement, varying device location and size. The aim of this work is to validate a finite element (FE) model of the EVAR procedure and to provide support to clinicians in the pre-operative planning phase.

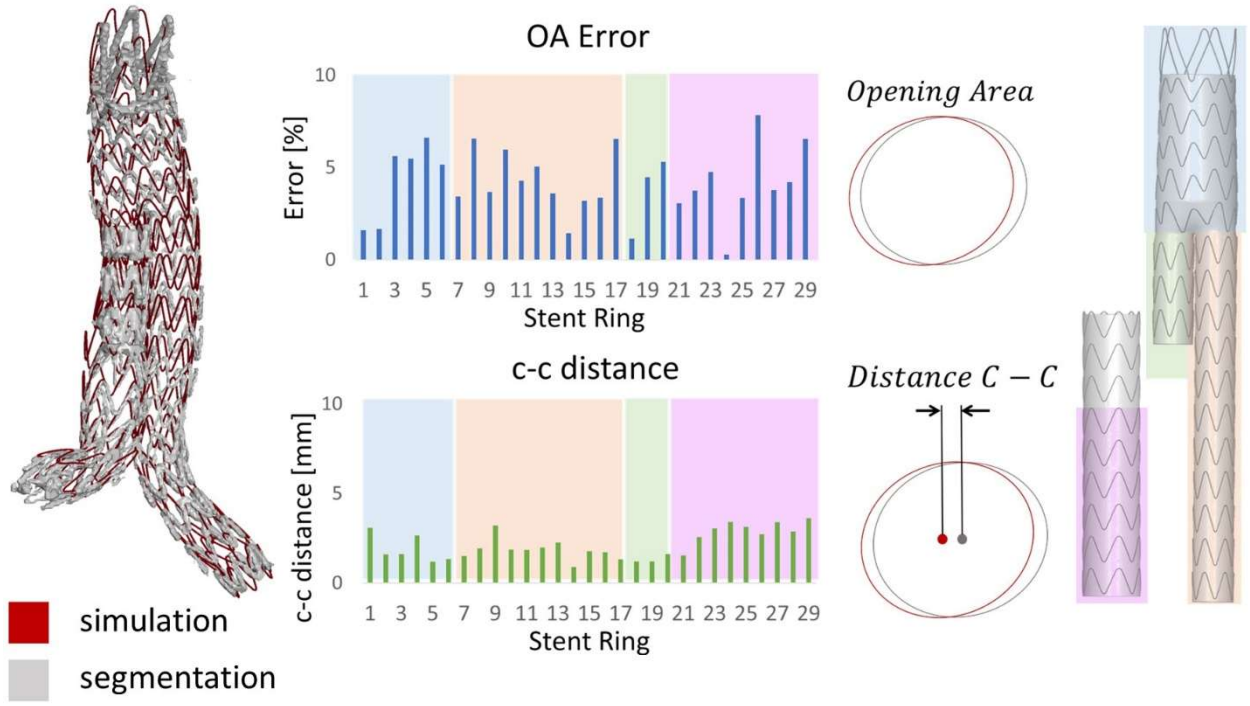
Methods

Stent-graft models are carefully designed with material properties tuned accordingly to the results of crimping tests. The device comprises either the main body and the limb component.

The FE model replicates the entire EVAR process, including device crimping, delivery, and gradual release in the aorta [2]. Those steps are replicated for the limb component which is introduced from the contralateral femoral artery.

A 3D-printed rigid anatomy is used to reproduce the EVAR procedure in-vitro. CT images of different stages of the stent-graft release are acquired to validate the simulation results, by comparing the opening area (OA) and the distance between the centers (c-c distance) of the simulated and segmented stent rings (Figure1). The same evaluation is performed on 3 patient-specific anatomies.

Results



The validation with the 3D-printed rigid model, resulted in a mean error in the OA between the simulated and segmented stent-graft of 4.2% and a mean c-c distance of 2.15mm (Figure1).

Preliminary results on a first patient specific anatomy are in agreement with the ones achieved on the rigid model, with a mean OA error of 4.47% and a mean c-c distance of 2.18mm.

Discussion

This work shows the importance and the usefulness of numerical simulation in predicting the outcome of EVAR implantation. The possibility of virtually testing different device sizes and landing zones can provide clinicians with valuable support during the pre-operative planning phase.

Clinician Requirements of a Home-Based Gait-Retraining System With Real-Time Feedback and Remote Monitoring

Ms Christy Oi-ying Chan Master's student[1,2], Dr. Jos Runhaar PhD[1], Dr. Selma Papegaaij PhD[3], Dr. Lennard Voogt PhD[4], Dr. Mariska Wesseling PhD[1], Dr. Martin Schepers PhD[3], Dr. Ignazio Aleo PhD[3], Ms Antoinette Torsij Master's student[5], Dr. ir. [3]Moveshelf Labs BV, Utrecht, Utrecht, Netherlands. [4]Rotterdam University of Applied Sciences, Rotterdam, South Holland, Netherlands. [5]Delft University of Technology, Delft, South Holland, Netherlands

Introduction

Altering foot progression angle (FPA) will affect the Knee Adduction Moment, and thereby knee-load. Consequently it may reduce pain, and slow down knee osteoarthritis progression. We recently developed a gait-retraining system with real-time feedback and remote monitoring to facilitate home-based gait-retraining programs. We interviewed physiotherapists to guide further development of our gait-retraining system.

Methods

This preliminary analysis is part of a larger feasibility study. Our system includes a single foot-mounted inertial measurement unit (IMU), a mobile app with a previously-validated algorithm to estimate FPA and provide real-time feedback, and a mock-up for a remote-monitoring dashboard (Figure). We recruited 10 physiotherapists who: have ≥2 years' experience, treat ≥2 knee-related cases per week, and have affinity for technology. We performed and recorded semi-structured interviews, during which we demonstrated the system, and inquired about opinions regarding usability and usefulness of the system, and what information clinicians desired to feel competent prescribing gait-retraining programs. So far, we have transcribed and thematically coded 5 interviews (Nvivo software).

Results

The first five participants were male physiotherapists located in North and South Holland. Regarding usability, clinicians preferred to see all summary statistics on a single screen/page to enhance interpretation. They confirmed the importance of showing FPA,

adherence to training, and patient-reported outcomes on the dashboard. Concerning usefulness, clinicians reported the system would help them to verify and monitor their patients' home programs, for example *"Is [my patient] on the right track?"*. They felt the system overall may motivate patients to adhere to treatment. Clinicians expressed a desire for the system to track additional parameters (e.g. spatiotemporal gait patterns) and different activities (e.g. stair climbing). Physiotherapists expressed that a system that could be operated fully outside of a lab would support patient care. Regarding decision support, clinicians expressed a lack of clinical practice guidelines or known literature to guide the design and monitoring of gait-retraining interventions.

Discussion

In this preliminary assessment, clinicians found our system to be supportive for monitoring home-based gait-retraining programs, though they sought broader functionality of the device and they lacked decision-making support. More sample diversity may enrich our dataset. Analyses are ongoing.

Traumatic Risk Assessment for Cerebral Exposure (TRACE): A Digital Platform for Real-Time Brain Health Monitoring in Sport

Ms Eleni Koumantou, Ms Emily Yik Kwan Chan, Mr Vahid Darvishi, Assoc. Prof. Mazdak Ghajari

Imperial College London, London, Greater London, United Kingdom

Introduction

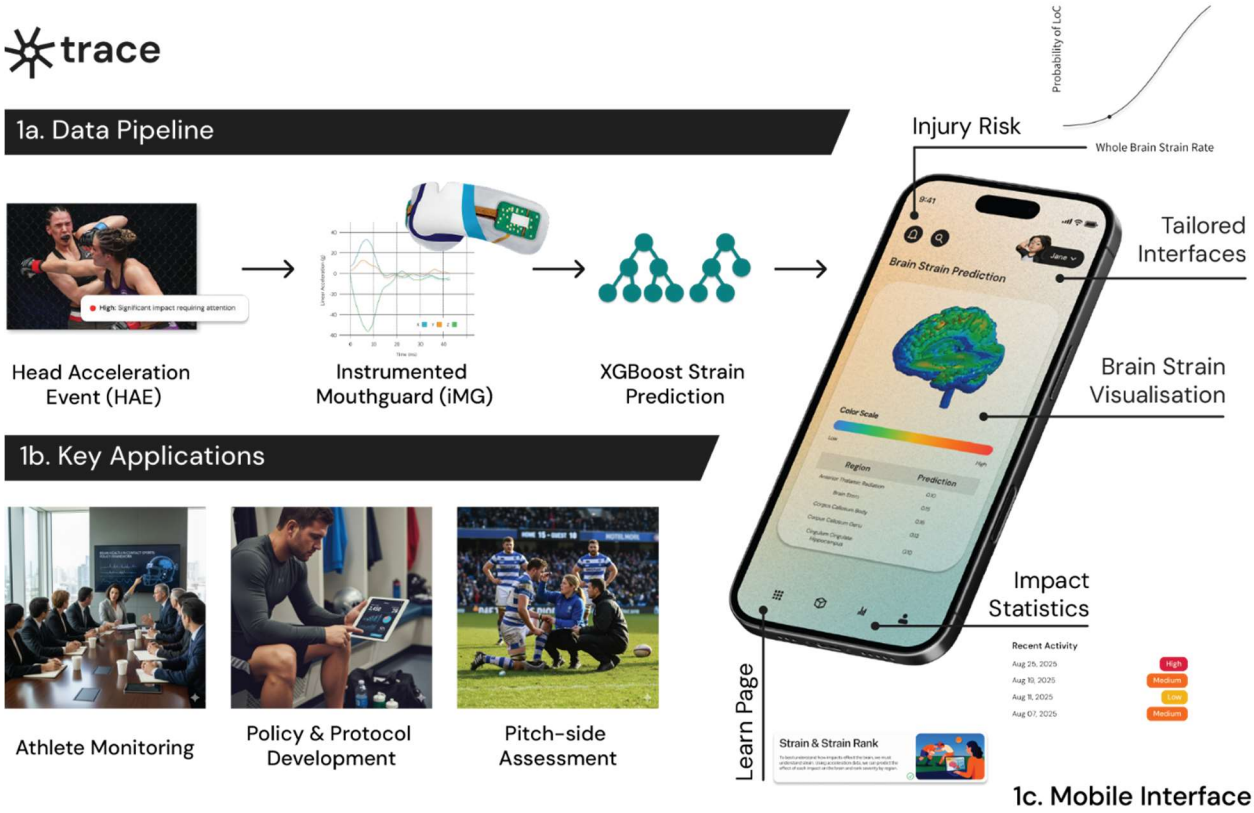
Head impacts pose brain health risks. The impact kinematics can be collected by instrumented mouthguards (iMGs) and translated to brain strain. This translation typically relies on finite element (FE) models that are time- and resource-consuming. Machine learning (ML) models on the contrary, provide real-time estimation of brain strain, yet they are inaccessible to non-experts. Therefore, we introduce TRACE, a user-ready digital platform that provides real-time estimates of brain deformation, enabling accessible, interpretable brain health monitoring.

Methods

Technical design. TRACE integrates a validated ML surrogate model that approximates FE brain strain predictions to quantify post-impact biomechanical response (Fig. 1a). The model is designed to be pitch-side available as it uses kinematic features that can be reliably streamed to pitch-side receivers from iMGs [1].

Usability test designs. Current version of TRACE has been developed to handle iMG-recorded impact kinematics and generate immediate brain strain visuals (Fig. 1c), after an iterative process to decide feature selection and UI design tailored to user groups. To test TRACE's usability, pilot testing has been designed in collaboration with our industry partner, an iMG manufacturer and head-impact surveillance provider. Evaluation criteria include technical validity, user interface and interaction (UI/UX) design.

Results



Technical validation. The ML model provides strain estimation under 0.1 seconds and has pitch-side availability enabled by its minimal requirement from iMG-collected kinematics.

UI/UX designs. TRACE provides brain strain estimation in interactive visuals and implements role- and sport-specific interfaces and features tailored for coaches, clinicians, and parents/guardians.

Discussion

This project is a translational initiative that aims to bridge the gap between on-field impact kinematics with biomechanical measures. TRACE will enable non-experts to make biomechanics-informed brain health decisions (Fig. 1b). This will ultimately benefit underrepresented groups like amateur and youth athletes who do not have excessive access to brain health experts, but also policy makers as they will gain insights from a wider range of populations often overlooked in studies. Future steps include: 1) conducting usability testing and interviews with athletes and coaches, 2) refining platform design based on user feedback, and 3) quantifying measurement uncertainty.

Presenting Gait Analysis Results to Older Adults Undergoing Joint Arthroplasty: A Qualitative Study and Patient-Centred Report Development

Mr. Gabriel Lonuzzo B. Eng, Mr. Imad Kashir, Alexandra Pop, Ms. Madeline Rao Shishis, Ms. Kassidy Appiah-Kubi, Ms. Maya Drozdov, Dr. Vincenzo Di Bacco, Dr. Matthew Ruder, Dr. Anthony Adili P.Eng, MD, FRCSC, Dr. Kim Madden, Dr. Dylan Kobsar

McMaster University, Hamilton, Ontario, Canada

Introduction

Motion capture provides objective biomechanical data that can inform clinical decisions surrounding joint arthroplasty. However, results are often communicated through technical figures and terminology that patients find difficult to interpret. Clear, accessible reporting is essential to support shared decision-making and engagement in perioperative treatment and rehabilitation. This study examined older adults' preferences for how gait analysis results should be communicated. Based on these findings, we developed a patient-centred gait report and software pipeline that translates complex biomechanical data into accessible formats.

Methods

Ten adults undergoing elective knee or hip arthroplasty participated in semi-structured interviews. Purposive sampling captured diverse demographics and surgical experiences. Interviews (~30 minutes) were recorded, transcribed, de-identified, and analyzed using thematic analysis. These insights informed the development of a prototype clinical gait report.

To automate report generation, custom Python software was developed to integrate clinical and biomechanical data, compute mobility metrics, and generate personalized reports featuring simplified diagrams, plain-language explanations, and colour-coded indicators. A clinician dashboard enables the selection of specific metrics and timepoints. The system was deployed in a longitudinal knee and hip arthroplasty cohort (n>200), and sample reports were shown to patients to collect feedback on clarity and perceived usefulness.

Results

Participants preferred results directly tied to daily activities, including walking speed, step length, joint angles, and stair performance. Comparative metrics (pre-/post-operative changes, bilateral symmetry, and age-matched benchmarks) were viewed as highly valuable for contextualizing progress. Tables were preferred for clarity, while graphs were

acceptable only when clearly labelled and had consistent colour-coding to improve interpretability. These findings informed a multimodal gait-reporting system that retrieves data from secure servers, computes personalized metrics, and presents results through simplified visuals. The software has generated 121 reports to date (Figure 1), with initial feedback indicating strong usability.

Discussion

This study demonstrates the importance of incorporating patient perspectives when communicating gait analysis results. Older adults prefer personalized, visually intuitive reports grounded in meaningful comparisons. By integrating automated data processing with user-centred design, the reporting tool improves the accessibility of biomechanical outputs and may enhance comprehension, engagement, and shared decision-making. Future work will continue to evaluate long-term usability, clinical integration, and effects on perioperative care.

St. Joseph's Healthcare Hamilton

Gait Report

McMaster University

Joint Angle Metrics (Details)

Peak Angle during Stance: Typical range: >10.0 | L: 20.1° | R: 17.8°

This angle represents how much your knee bends when your foot is on the ground. More bending = better shock absorption. Less = possible stiffness.

Peak Angle during Swing: Typical range: >50.0 | L: 54.2° | R: 61.3°

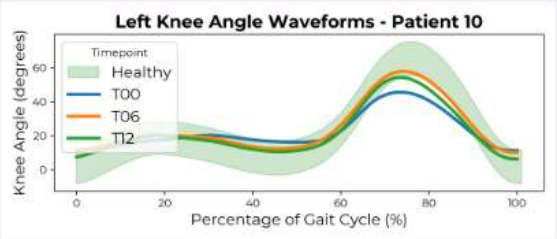
This angle represent how much your knee bends as your leg moves forward when you take a step. A larger angle means more flexibility.

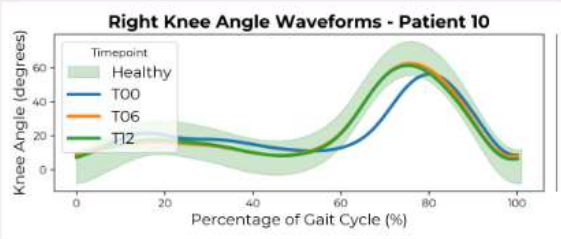
Range of Motion (ROM): Typical range: >5.00 | L: 12.7° | R: 10.5°

Your knee's range of motion (or excursion) represent how much your knee moves while supporting weight. More range of motion often means better joint function.

Outward (Varus) Thrust: Typical range: < 2.50 | L: 2.23° | R: 2.47°

When you place weight on your knee, it can move outward (like a bowed-leg). Less thrust can indicate better alignment and recovery.





Knee Alignment: Typical range: -5.00 - 5.00 | L: -4.17° | R: -6.08°

This indicates how aligned your leg is while walking. Ideally, your thigh and shin line up. Angling out or in can suggest alignment issues.

Knee Angle Waveforms:

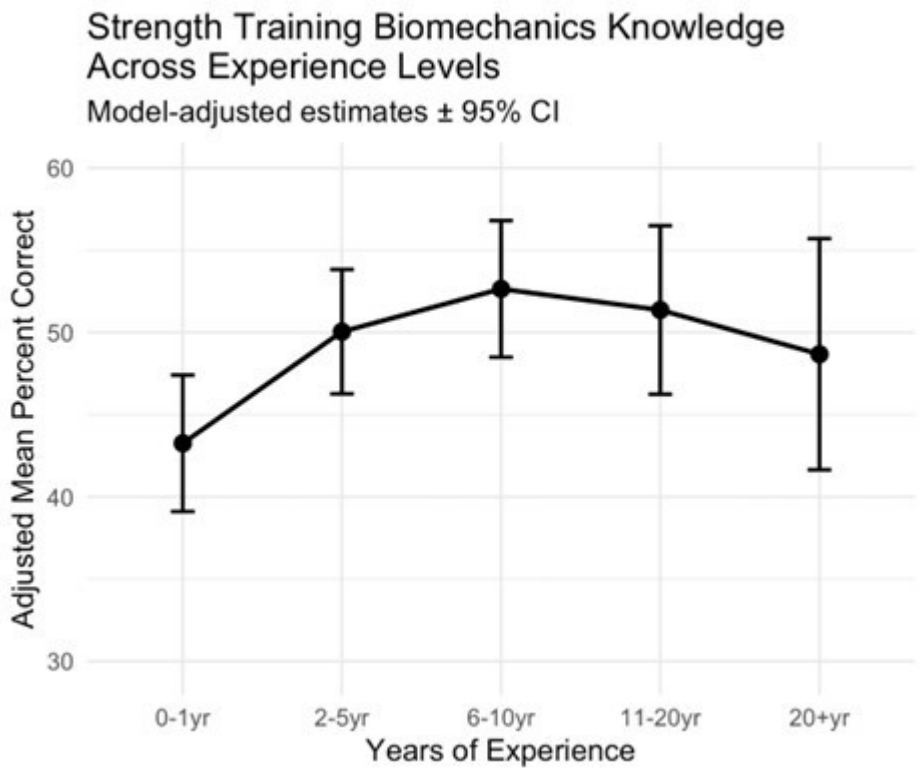
[10]Department of Kinesiology, University of Texas at San Antonio, San Antonio, Texas, United States. [11]Northland Analytics, Mountain, Wisconsin, United States

Introduction

Undergraduate and professional education in strength-training biomechanics requires integration of anatomical knowledge, force vectors, and movement principles into applied exercise contexts. Despite widespread training and credentialing, it remains unclear how well these principles are retained across career pathways and experience levels. This study evaluated overall strength training biomechanics knowledge among individuals engaged in strength training and examined whether professional role, years of experience, age, or gender predicted performance. We further compared observed performance to expected guessing accuracy to assess baseline knowledge levels.

Methods

Participants (N = 435) from diverse exercise-related backgrounds (academics, physical therapists, fitness professionals, sport coaches, students, and others) completed an online strength training biomechanics assessment focused on exercise technique, moments and moment arms, and joint loading concepts. Percent correct was calculated for each participant. Linear regression modeled performance as a function of occupation, years of experience evaluating exercise technique (0–1, 2–5, 6–10, 11–20, 20+ years), age, and gender. Estimated marginal means were used to characterize experience trends.



Results

Overall performance was low (M = 50.1% correct, 95% CI [48.8, 51.3]), only modestly exceeding expected guessing performance (29.47%), indicating limited mastery across the cohort. The regression model was significant ($F(11,416)=4.20$, $p<.001$) but explained limited variance (Adj. $R^2 = .08$), suggesting substantial unexplained heterogeneity. Years of experience emerged as the strongest predictor, with higher scores observed for 2–5 years (+6.8%), 6–10 years (+9.4%), and 11–20 years (+8.1%) of experience relative to 0–1 year, demonstrating a performance curve peaking at mid-career (see Figure 1). Professional occupation showed modest effects; fitness professionals scored lower than academics (−5.6%), while physical therapists, coaches, students, and others did not differ reliably. Age was not predictive. Female participants scored lower on average (−5.0%).

Discussion

Biomechanics knowledge in applied strength training was low overall and highly variable, with experience—rather than professional role—serving as the primary differentiator. The modest explanatory power of demographic predictors highlights the need for structured, accessible, and engaging instructional tools to bridge persistent learning gaps and promote equitable acquisition of biomechanics competence across training pathways.

Evaluating COACH: Time in Live Tackling Drills and Associated Head Acceleration Events in Youth Football

Mr. Giovanny A. Romero A. MS[1,2], Mr. William S. Carter[1,2], Dr. N. Stewart Pritchard PhD[1,2], Dr. Garret D. Bullock DPhil[1], Dr. Justin B. Moore PhD[1], Dr. Ty D. Holcomb PhD[1,2], Dr. Madison E. Marks PhD[1,2], Dr. Christopher M. Miles MD[1], Dr. Johna Register-Mihalik PhD[3], Dr. Joel D. Stitzel PhD[1,2], Dr. Kristie L. Foley PhD[1], Dr. Jillian E. Urban MPH, PhD[1,2]

[1]Wake Forest University School of Medicine, Winston-Salem, NC, United States. [2]Virginia Tech – Wake Forest University, Winston-Salem, NC, United States. [3]University of North Carolina at Chapel Hill, Chapel Hill, NC, United States

Introduction

Communities Aligned to Reduce Concussion and Head Impact Exposure (COACH) is an intervention to improve coaches' knowledge, skills, and attitudes for safer youth football practices. COACH aligns with National Federation of State High Schools (NFHS) guidelines, which recommend no more than 30 minutes of live tackling (full speed, to the ground) per practice. This study examines the relationship between minutes of live tackling and head acceleration events (HAEs) outcomes in youth tackle football players.

Methods

Athletes from seven youth football teams participated: three control (C) teams (12U_1C, n=18; 13U_1C, n=17; 13U_2C, n=14) and four intervention (I) teams (11U_1I, n=15; 12U_1I, n=14; 12U_2I, n=16; 13U_1I, n=21). Intervention teams coaches were trained in COACH guidelines before the season began. All athletes wore instrumented mouthguards to record HAEs. Trained staff collected biomechanical and video data in all practices and games to quantify live tackling time and verify HAEs. A linear mixed-effects model examined associations between HAEs, minutes of live tackling, intervention status (intervention vs control), and their interaction, with random effects for player and team.

Results

A total of 3,416 verified HAEs were recorded during live tackling across 146 practices. Control teams spent more time in live tackling (44.6±27.6 min) than intervention teams (18.6±26.1 min) and had more HAEs per minute (1.75±2.71 vs. 1.08±4.17). Across all practices, HAE rates increased by 0.04 events/min in control teams (SE = 0.004, 95% CI: 0.03–0.05) and 0.07 events/min in intervention teams (SE = 0.004, 95% CI: 0.06–0.08), with a slope difference of −0.03 events/min ($p < 0.0001$).

Discussion

Results show differences in HAEs between intervention and control teams during live tackling, with control teams sustaining more HAEs per practice and spending more time in live tackling. Control teams had higher mean HAEs and greater live-tackling minutes, whereas intervention teams showed a steeper increase in HAEs per minute, indicating greater head-impact burden per unit of live exposure. This pilot highlights how coaches implemented the COACH program in real-world settings and the need to balance live tackling time.

OA128-06

The Misuse of Biomechanical Evidence in Shaken Baby Cases

Professor Barbaram Pfeffer Billauer J.D. ,M.A., PhD

Elon University School of Law, Greensboro, NC, United States. University of Port, Porto, Portugal, Portugal. Institute of World Politics, Washington, DC, United States

Introduction

The diagnosis of *Shaken Baby Syndrome (SBS)* has recently come under legal attack. A small group of physcians and biomechanics professionals claim that biochemical evidence does support the diagnosis - which is caused by repeated shaking resulting in the brain banging against the skull (a *contre coup* lesion). using non-representative studies. In one recent case, the medical diagnosis was rejected by NJ's highest court based on these non-representative studies regarded as the consensus in the biomechanics community.

Methods

This research evaluates the biomechanical/medical evidence adduced in *State of New Jersey v. Darryl Neives and Michael Cafelli [4],* leading to the courts rejecting the SBS diagnosis entirely. The evidence submitted by the defendants' biomechanics expert relies on six articles, plus amici briefs by legal organizations supporting the defendants' rights. The studies relied on were evaluated for scientific reliability and validity and legal relevance. The studies are assessed for their relevance to human subjects (babies) typically diagnosed with the condition to determine whether the results and testimony based thereon are reliable, relevant, and valid to assess the issue.

Results

The studies relied on via expert testimony require a double extrapolation (from dolls or animals to adult humans and then to babies) which ethically cannot) be done). The tests do not assess the biological/physiological effects of *repeated* shaking in humans. They merely calculate the *external* force generated by a single shake in a dummy or an animal (where 33% of the test subjects actually sustained injuries consistent with SBS). Further the test conditions do not represent real life conditions and hence are invalid to determine

the effects of repeated shaking in a premature or vulnerable child. SBS involves internal injuries caused by forces generated by a cascade of physiological responses and hence are outside the purview of conclusions generated by testing external forces.

Discussion

This work demonstrates the misuse of biomechanics when the science is taken beyond its limits in a legal setting. Lawyers representing defendants are advocating these limited studies, while the child who has been severely damaged (or has died) is without redress.

Athletes With ACL Reconstruction Demonstrate Altered Movement Variability When Preparing to Respond to Perturbations: A Preliminary Analysis

Dr. Jamie Kronenberg PT, DPT, PhD, SCS[1], Dr. Michael Riley PhD[2], Dr. Laura Schmitt PT, MPT, PhD[3]

[1]High Point University, High Point, North Carolina, United States. [2]University of Cincinnati, Cincinnati, Ohio, United States. [3]Ohio State University, Columbus, Ohio, United States

Introduction

Athletes returning to sport following anterior cruciate ligament reconstruction (ACLR) must be prepared to respond to the dynamic nature of their sport. Complex, variable movement solutions are required to match specific situational contexts, such as responding to a perturbation in sport. The purpose of this study was to test the hypothesis that when preparing to respond to perturbations, athletes with ACLR would demonstrate altered movement variability, as characterized by recurrence quantification analysis (RQA), compared to uninjured athletes.

Methods

Twelve athletes with primary ACLR (6 female, age 21.1 ± 2.7 years) at the time of medical clearance for sports participation and 12 age-, sex- and activity-matched controls (CTRL) completed 3-dimensional motion analysis of walking on a self-paced treadmill. Each athlete completed baseline walking (BASE), walking before an anticipated gait perturbation (ANT; informed of perturbation prior to trial) and walking before an unanticipated gait perturbation (UNT; not informed prior to trial). Participants in the ACLR group received the perturbations in a random order and their matched-CTRL received the perturbation in the same order. Time periods of interest (POI) included the 10 seconds preceding the ANT and UNT perturbations. Movement variability was assessed using percent determinism (%DET) as calculated by RQA of involved limb (ACLR; non-dominant CTRL) sagittal plane knee kinematics during POI. A 2x2 mixed ANOVA tested group and anticipation effects.

Results

There was no significant difference in %DET between groups at BASE ($p=0.836$) and no significant group by anticipation interaction ($p=0.536$; $h^2=0.018$). There was no main effect of anticipation ($p=0.752$; $h^2=0.005$), but there was a main effect of group

($p=0.016$; $h^2=0.235$). Athletes with ACLR demonstrated significantly higher %DET compared to CTRL independent of anticipation (Table1).

Discussion

No significant interaction was found between group and anticipation, but athletes with ACLR showed higher %DET than CTRL when preparing for both perturbations. Higher %DET indicated greater gait predictability, indicating alterations in movement variability that may reflect differences in strategies used to prepare for a perturbation between groups. Future studies are warranted to further understand the impact of ACLR on movement variability and its potential impact on how athletes with ACLR prepare for and respond to perturbations.

Images (Optional)

Baseline			Anticipated	Unanticipated
ACLR	86.8 ± 3.2%	ACLR	89 ± 3.3%	89.9 ± 2.2%
CTRL	86.5 ± 4.7%	CTRL	87 ± 2.3%	87.7 ± 4.2%
Difference	p= 0.836	Group x Anticipation	p=0.536	
		Group	p=0.016	
		Anticipation	p=0.752	

Table 1. Average %DET ± standard deviation for each group. Larger values of %DET indicate increased predictability or repetitiveness.

OA129-02

Stretch-Shortening Cycle Mechanics and Leg Strength in Adolescent Male and Female Athletes Following ACL Injury

Mr. Landon Foley BSc., Dr. Nathan Boon-van Mossel DC, MSc., Dr. Kati Pasanen PhD, Dr. Karen Ballinger MD, Dr. Matthew Jordan PhD

University of Calgary, Calgary, Alberta, Canada

Introduction

Biomechanical testing is recommended to support athlete clearance for return to sport (RTS) following anterior cruciate ligament reconstruction (ACLR). Previous work has suggested that biomechanical outputs during stretch-shorten cycle tasks such as jumping may be useful at detecting lower limb deficits in adolescent athletes compared to traditional performance metrics (jump height) [1]. Additionally, there is a significant lack of literature examining stretch-shortening cycle mechanics and eccentric lower limb strength in adolescent athletes with ACLR. This study therefore aimed to investigate the lower limb stretch-shortening cycle and maximal strength characteristics in adolescent athletes following ACLR.

Methods

Adolescent athletes with ACLR (age: 14-17 years; n=21; females: n=11: mean post-op = 13 months +/- 7 months) performed maximal isokinetic concentric and eccentric contractions on a robotic leg press and maximal effort single leg vertical jumps on a force plate system. Paired t-tests were used to compare athlete performance between the ACLR and the contralateral limb. One-sample t-tests were used to compare athlete performance to established sex-based youth athlete benchmarks. Cohen's *d* was used to determine effect sizes. This study is currently ongoing.

Results

All athletes demonstrated significant deficits in stretch-shorten cycle performance between the ACLR limb and the contralateral limb ($p<0.001$, $d = 1.76$), and in stretch-shorten cycle braking phase strategy such as peak braking power ($p<0.001$, $d = 1.51$) and contact time ($p=0.02$, $d = 0.54$). Both male and female athletes presented significant deficits in stretch-shorten cycle performance and braking phase strategy relative to established youth athlete benchmarks. All athletes demonstrated significant deficits in both maximal concentric ($p<0.001$, $d = 0.87$) and maximal eccentric strength ($p<0.001$, $d = 1.00$) between the ACLR and the contralateral limb. Female athletes displayed greater deficits

in maximal concentric strength between limbs ($p<0.001$, $d = 1.79$) relative to male athletes ($p=0.159$, $d =0.49$).

Discussion

Adolescent athletes with ACLR demonstrate significant biomechanical deficits in both stretch-shorten cycle and maximal strength tasks, despite being at the time course of clinical RTS. Both biomechanical outputs and performance metrics may provide insight into deficits related to recovery from ACLR in this population.

Disentangling Movement Variability with Principal Component Analysis of Full-Waveform Motion Capture in Adolescent Athletes Post-ACL Reconstruction

Ms Mona Behrouzian BASc[1], Dr Tim Bhatnagar PhD, BEng, BSc, MASc[2,3], Dr Lise Leveille MD, PhD, MHSc, BSc[2,4,5], Dr Calvin Kuo PhD, PEng[1]

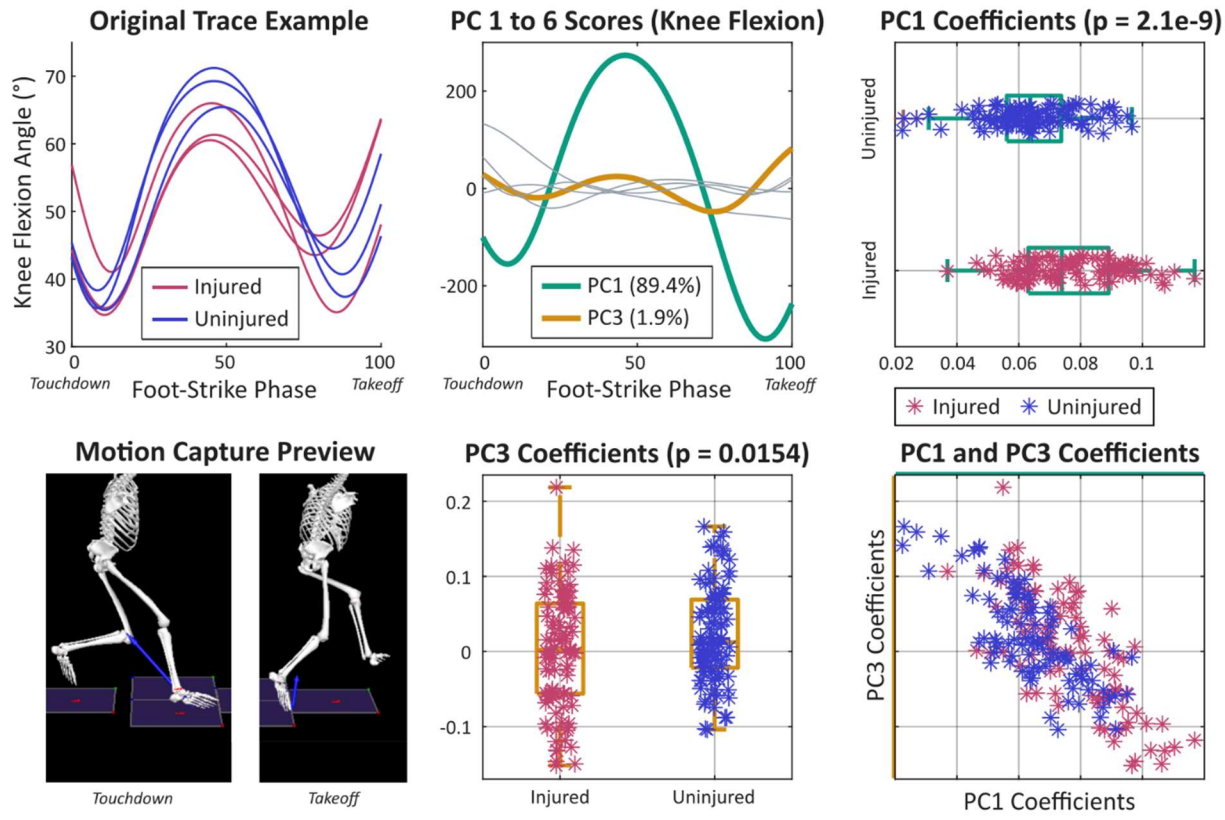
[5]Department of Orthopedics, University of British Columbia, Vancouver, BC, Canada

Introduction

Anterior Cruciate Ligament (ACL) tears are severe knee injuries, with re-injury rates up to 32% in adolescents. Return-to-sport (RTS) assessments for post-ACL reconstruction (ACLR) have been adopted by hospitals worldwide to screen for re-injury risk. However, no functional-testing RTS assessments have shown a significant association with reduced ACL re-injury rates in adolescents. Threshold-based pass-fail criteria with motion capture are common, but fail to consider the substantial movement variability exhibited by adolescents, caused by heterogeneity in size, sex, and age. To address this gap, the full waveforms of motion capture can be analyzed with Principal Component Analysis (PCA), which reduces multivariate datasets into a minimized set of key biomechanical parameters.

Methods

32 adolescent athletes (16.5±1.6 years, 23F) 9-12 months post-ACLR performed three 45-degree run-to-cut trials on each leg, while instrumented with motion capture (12-camera Qualisys system, 50-marker PRiSM set) to analyze full-body 3D joint kinematics (Visual3D) [1]. PCA was applied across the aggregated knee flexion angle of both legs during foot-strike. Extracted principal components (PCs) captured knee flexion movements that explained the greatest variability across the injured and uninjured legs and across athletes. PC coefficients (relative weight per knee flexion angle trace) of the injured and uninjured legs were compared with a t-test. This demonstrates whether a PC is differentially represented in the injured and uninjured legs.



Results

Two PCs (89.4%, 1.9% explained variance) showed significant differences (p=2.1e-9, 1.5e-2 respectively) between injured and uninjured legs. The former PC captures the variability in magnitude of knee flexion motion throughout foot-strike, while the second corresponds to stiffness in landing strategy, indicated by increased flexion during touchdown and takeoff.

Discussion

Using PCA in RTS screening can help to both disentangle movement variability and uncover the small adaptations (such as landing strategies) that are associated with injury. PCs from full-waveform analysis may be a stronger indicator of injury compared to traditional threshold-based criteria. This method can be expanded with additional joints to provide insights into inter-joint coordination and movement compensation. This enables future work exploring adolescents who exhibit abnormal movement patterns related to injury or other health conditions that affect movement.

In Vivo MR Elastography Reveals Cartilage Stiffness Changes Linked to Altered Gait Patterns Post-ACL Surgery

Dr. Emily Miller[1], Dr. Timothy Lowe[1], Dr. Hongtian Zhu[1], Dr. Stéphane Avril[2], Dr. Corey Neu[1]

[1]University of Colorado Boulder, Boulder, CO, United States. [2]Ecole des Mines de Saint-Etienne, Saint-Etienne, Auvergne-Rhône-Alpes, France

Introduction

Following ACL reconstruction, altered gait mechanics often persist despite surgical repair and may drive divergent cartilage remodeling patterns that initiate osteoarthritis [1]. However, the relationship between joint loading and early cartilage mechanical changes remains poorly characterized because conventional imaging cannot detect cartilage stiffness alterations before structural damage occurs. This study developed an MRI-based elastography method to quantify *in vivo* cartilage stiffness heterogeneity and examined how regional stiffness patterns relate to gait mechanics and patient outcomes in ACL reconstructed patients.

Methods

Twenty participants (mean age 24.9 years, BMI 23.5) underwent bilateral MRI scans and KOOS questionnaires approximately 12 months post-ACL reconstruction. Participants also completed gait analysis using markerless, smartphone-based motion capture, with musculoskeletal modeling estimating peak knee adduction moments and medial contact forces. DENSE MRI captured cartilage displacement during cyclic loading. An inverse elastography pipeline combining the virtual fields method [2] and adjoint optimization [3] generated stiffness maps with less than 6% reconstruction error in validation studies. Three stiffness heterogeneity metrics quantified mechanical organization: zonal stiffness contrast (depth-dependent gradient), zonal pattern irregularity (spatial consistency), and surface stiffness variability (regional differences).

Results

Significant gait-stiffness relationships emerged exclusively in the reconstructed limb, indicating local mechanoadaptation. In tibial cartilage, higher knee adduction moments strongly correlated with increased stiffness gradient and variance, suggesting overloading-driven stiffening. Conversely, femoral cartilage showed opposite patterns, where greater mechanical heterogeneity correlated with reduced knee adduction moments, consistent with underloading-induced softening. Lower KOOS physical function scores correlated

with increased tibial stiffness variance, while femoral patterns showed distinct regional associations. No gait-stiffness relationships appeared in the contralateral limb.

Discussion

This study presents the first *in vivo* cartilage elastography in humans, revealing that altered gait mechanics after ACL reconstruction correlate with spatially divergent cartilage remodeling. The contrasting pattern of femoral softening under reduced loading and tibial stiffening under elevated loading reflects loss of mechanical homeostasis that may drive early osteoarthritis progression. These findings support rehabilitation strategies targeting harmful loading patterns to restore mechanical balance and potentially slow cartilage degeneration.

Images (Optional)

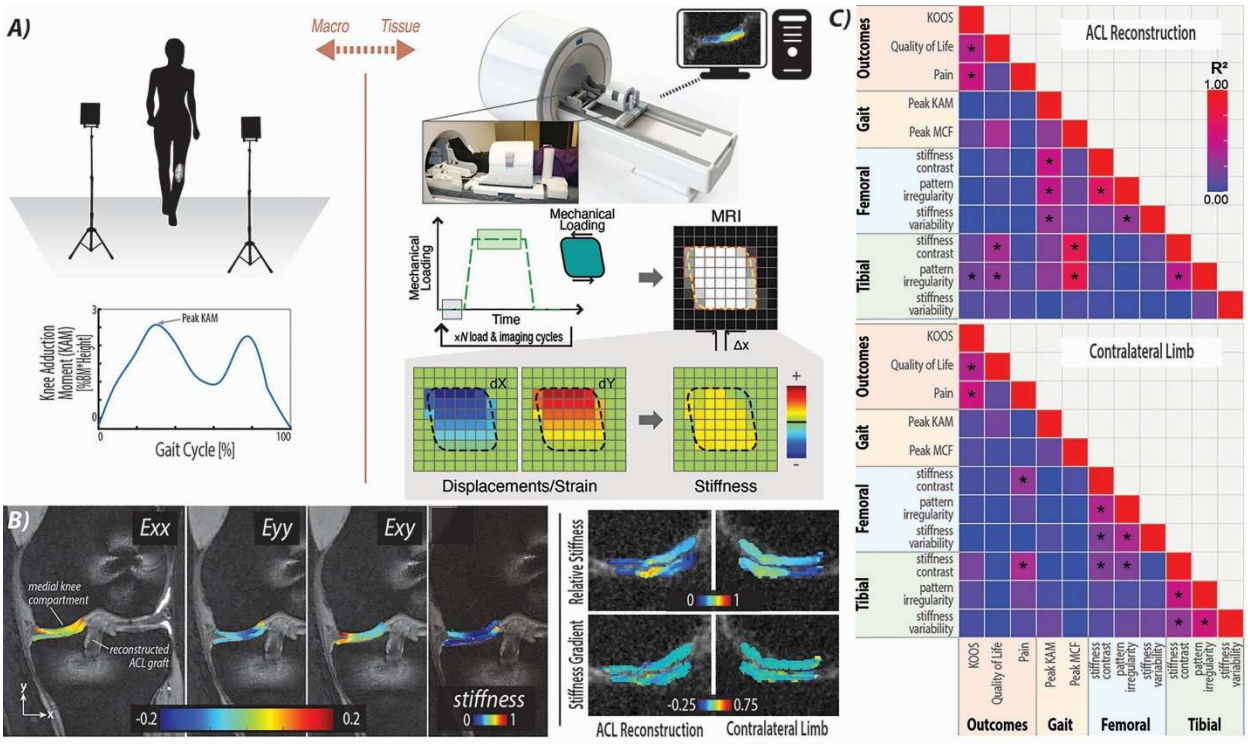

Figure 1. *In vivo* stiffness in articular cartilage was measured and related to human gait in the same patients post-ACL reconstruction. Markerless motion capture was compared to MRI-based measures of stiffness. *(A-B)* Noninvasive measurement of displacements/strain, and in combination with inverse modeling, enabled calculation of stiffness in tibiofemoral cartilage of ACL reconstructed and contralateral knees. *(C)* Correlations were found between stiffness and gait in both femoral and tibial cartilage.

Three-Year Bone Changes Following Acute ACL Injury: Bone Density and Microarchitecture Analysis Using HR-pQCT

Ms. Callie Stirling, Ms. Nina Pavlovic, Dr. Nathan Neeteson, Dr. Sarah Manske, Dr. Richard Walker, Dr. Steven Boyd

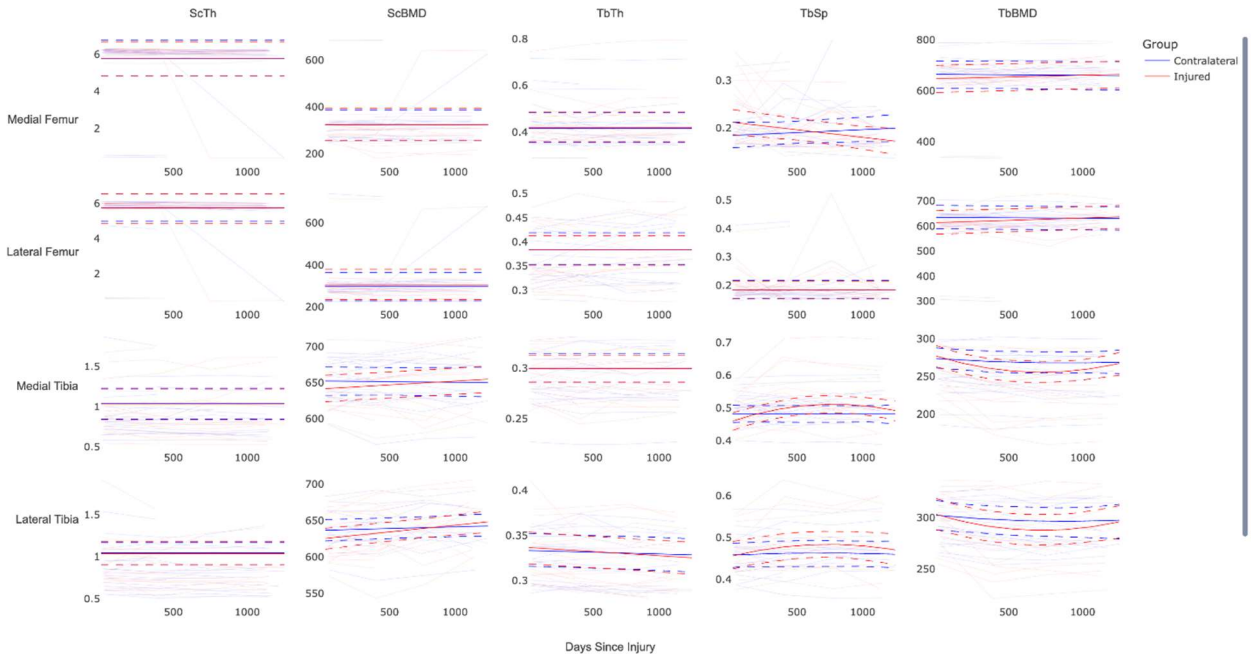
University of Calgary, Calgary, Alberta, Canada

Introduction

Anterior cruciate ligament (ACL) injuries frequently lead to post-traumatic osteoarthritis (PTOA). High-resolution peripheral quantitative computed tomography (HR-pQCT) allows precise assessment of bone density and microarchitecture, enabling tracking of periarticular bone changes over time. This study used HR-pQCT to quantify three-year bone changes, providing insight into processes contributing to PTOA.

Methods

This longitudinal prospective cohort study was approved by the Conjoint Health Research Ethics Board at the University of Calgary (REB19–1184). Baseline imaging was performed ~6 weeks post-injury with annual follow-ups. Participants either did not undergo ACL reconstruction (ACLR) or completed at least two visits before surgery; visits after ACLR were excluded. Bilateral HR-pQCT (XtremeCT II) imaging was performed at each visit and processed using automated methods developed in our lab. Weight-bearing compartments of the femur and tibia were analyzed at the subchondral plate and periarticular trabecular bone. Subchondral plate measures included bone mineral density (Sc.BMD; mg HA/cm^3) and thickness (Sc.Th; mm). Trabecular bone within 7.5 mm of the articular surface was assessed for BMD (Tb.BMD; mg HA/cm^3), thickness (Tb.Th; mm), and separation (Tb.Sp; mm). Longitudinal changes in HR-pQCT outcomes in injured and contralateral knees were modeled using mixed-effects models (R 4.2.2).



Results

Twenty participants (mean age 33.5 years, SD 10.2; 11 female) were included. Injured knees showed Tb.BMD losses in the medial and lateral tibia (−2.9% and −2.6%) and increases in the femur (+3.1% and +3.5%). Tb.Sp increased in the medial and lateral tibia (+6.2% and +4.1%) but decreased in the femur (−10.3% and −6.9%). Sc.BMD increased in the tibia (~+3%) and decreased slightly in the femur (~−1%). Contralateral knees showed minimal median changes (<1%). Injured knees exhibited larger, time-varying remodeling patterns (Figure 1).

Discussion

Early changes in subchondral and periarticular trabecular bone were observed following ACL injury. In the tibia, subchondral bone shifts toward a thinner trabecular network beneath a slightly denser plate, whereas femoral trabecular bone becomes denser and more compact under a less dense plate. This asymmetric, time-dependent remodeling aligns with early PTOA mechanisms, where alterations in local stiffness gradients and trabecular architecture of the joint can modify contact mechanics and may contribute to subsequent joint degeneration.

Analysis of Muscle Synergy Strategies During High-Risk Tasks in Patients Following ACL Reconstruction

Mr Ze Gong[1,2], Dr Di Ao[2], Dr Le Li[2], Dr Ming Zhang[1]

[1]The Hong Kong Polytechnic University, Hong Kong, Hong Kong, Hong Kong. [2]Northwestern Polytechnical University, Xi'an, Shaanxi, China

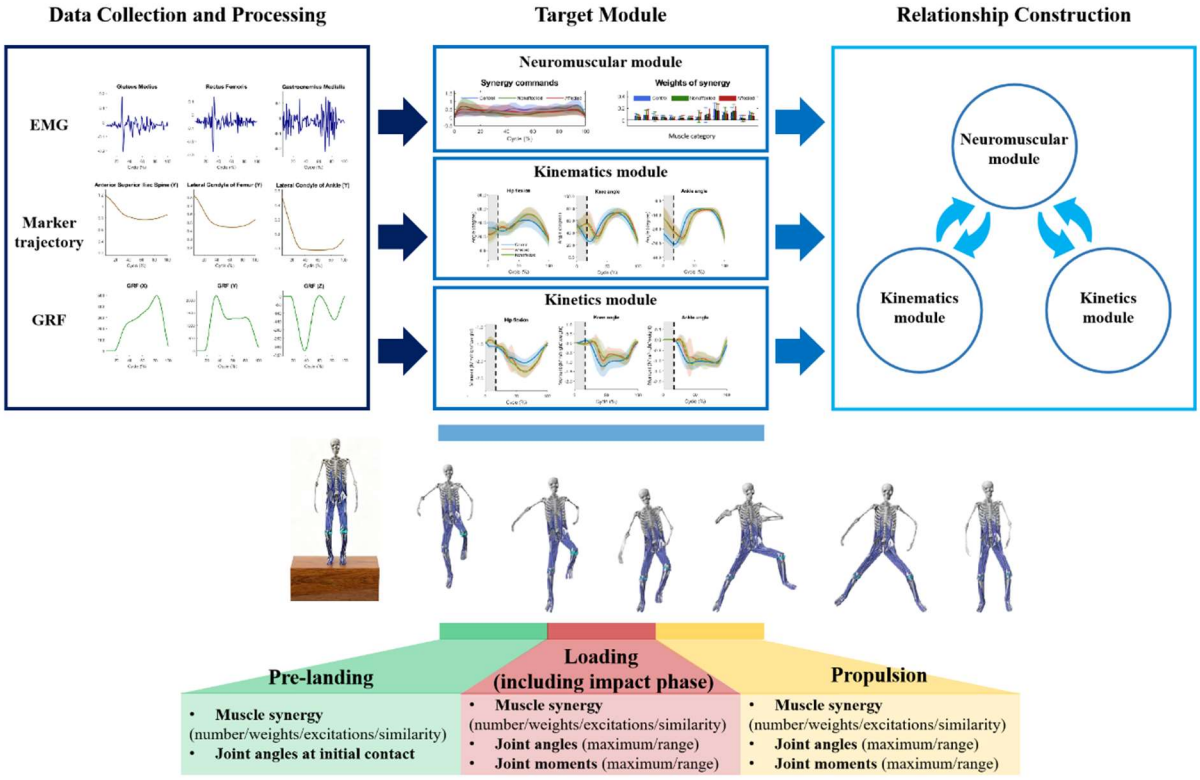
Introduction

Over 2 million annual anterior cruciate ligament (ACL) injuries lead to knee instability and osteoarthritis. ACL reconstruction (ACLR) restores structure, but only 50-60% return to pre-injury sports, with 6-time higher re-injury risk (driven by biomechanics)[1]. Muscle synergy—central nervous system's modular activation for stable movement—is critical for knee control in high-risk tasks, yet its role in ACL re-injury (e.g., if altered patterns raise risk) is understudied. This study explored ACLR patients' synergy strategies in single-leg tasks and biomechanical links, to define synergy's significance for re-injury prevention.

Methods

Thirty-three healthy subjects (17 males, 16 females) and 24 ACLR patients (14 males, 10 females) were enrolled, divided into Control (healthy dominant sides), Affected (ACLR patients' injured sides), and Nonaffected (ACLR patients' uninjured sides) groups. Data collection included electromyography, marker trajectory for kinematics, and ground reaction forces data during a single-leg landing and lateral jumping task. Non-negative Matrix Factorization decomposed EMG data to spatial and temporal components, with Variance Accounted For (VAF ≥95%) determining synergy number[2]. Temporal (CoA, FWHM, RMS) and spatial (vector weights) synergy characteristics were analyzed, alongside joint kinematics (angles) and kinetics (moments). Mixed-effects models compared parameters across groups, and Pearson correlation explored synergy-biomechanics relationships.

Results



During the impact phase (50ms post-initial contact), the Control group used more muscle synergies than ACLR groups, including an additional peroneus longus/gluteus medius-dominated synergy. Controls also had delayed knee extensor/flexor synergy activation, higher synergy activation RMS ($p<0.05$), and distinct biomechanics (greater hip flexion angles/moments) vs. ACLR subgroups; no FWHM differences existed. In the Affected limb,

synergy number correlated negatively with max hip/knee flexion angles and positively with max ankle plantar flexion.

Discussion

ACLR patients' altered synergy (fewer synergies, reduced activation, unspecialized patterns) links to adverse biomechanics: fewer synergies in the Affected limb associate with lower hip/knee flexion (poor shock absorption) and higher ankle plantarflexion (increased knee load)—key re-injury drivers. Controls' extra synergy boosts hip-ankle coordination for stability, confirming muscle synergy as a critical re-injury mediator and recovery biomarker.

Energetic Consequences of a Distal-to-Proximal Shift in Positive Joint Work During Gait are Opposite for Mobility Impaired vs Non-Mobility Impaired Older Adults

Dr. Jacob Thomas PhD[1], Ms. Zoe Smith MS[1], Dr. Brian Umberger PhD[2], Dr. Jane Kent PhD[1], Dr. Katherine Boyer PhD[1]

[1]University of Massachusetts-Amherst, Amherst, MA, United States. [2]University of Michigan, Ann Arbor, MI, United States

Introduction

Redistribution of positive joint work from ankle to hip during gait is a candidate mechanism for increased energetic cost of walking (CoW) in older age. Muscle weakness, which can differ by mobility status, may necessitate such redistribution [1]. We quantified groupwise differences in maximal isokinetic ankle extensor power (AEP_{Max}) and relationships between positive mechanical work distribution and both CoW and AEP_{Max}, to understand the energetic consequences of age-related positive mechanical work redistribution and the role of ankle extensor weakness in such redistribution.

Methods

Sixty-one participants; fourteen younger (6Female, 35.3±3.7yr, preferred walking speed (PWS):1.38±0.19m$\cdot s^{-1}$), nineteen older highly active (OHA) (8F, 73.3±2.8yr, PWS:1.49±0.21), fourteen non-mobility impaired older control (OC) (10F, 72.9±3.0yr, PWS:1.34±0.14), and fourteen older impaired (OI) (9F, 73.1±3.2yr, PWS:1.42±0.24); underwent overground gait analysis, isokinetic plantar flexion power testing (60 deg$\cdot s^{-1}$; dynamometry), and Short Physical Performance Battery (SPPB) measures before a seven-minute PWS treadmill walk with indirect calorimetry to quantify net CoW ($J \cdot kg^{-1} \cdot m^{-1}$). Stance-phase joint work was used to calculate redistribution ratio (RR; [$Work^{+}_{Ankle}$-$Work^{+}_{Hip}$]/[$Work^{+}_{Ankle}$+$Work^{+}_{Hip}$]). Physical activity was tracked for one week via accelerometry. Grouping was based on SPPB and physical activity. Statistical analyses included Pearson correlation coefficients and one-way ANOVA with Tukey's tests.

Results

AEP_{Max} was lowest for OI (0.71±0.17W/kg) and different (p<0.01) from younger (1.06±0.22W/kg), with no other groupwise differences. For OC, greater RR (greater hip relative to total work) was associated with greater CoW (r=0.50), while the opposite was observed for OI (r=-0.47, Figure 1). There were no associations between AEP_{Max} and RR for younger, older groups, or all older adults combined (p≥0.28).

Discussion

Opposite relationships between RR and CoW for OC and OI suggest group-specific energetic consequences of redistribution from ankle to hip during walking. AEP_{Max} was not related to RR in older adults, but may still have implications for age-related mobility loss, as AEP_{Max} was lowest for OI and different from younger. These results challenge popular hypotheses about mechanisms for, and energetic consequences of, age-related distal-to-proximal redistribution of mechanical work during walking.

Investigating the Potential to Reduce the Risk of Slips on Icy Surfaces With Gait training:*Preliminary Evidence of Gait Adaptation During Repeated Sessions of Walking on Ice*

Mr. Mohammadali Shahiri[1,2], Mr Pedram Karimi[1,2], Dr. Tilak Dutta[1,2]

[1]University of Toronto, Toronto, Ontorio, Canada. [2]KITE - Toronto Rehabilitation Institute – University Health Network, Toronto, Ontorio, Canada

Introduction

Falls are a major cause of injury-related hospitalizations in Canada, and winter conditions add to this risk due to reduced traction on icy surfaces. Existing prevention strategies, environmental control, slip-resistant footwear, and public awareness initiatives offer partial benefit but remain limited by cost, low adoption, and the lack of structured practice. Gait training has emerged as a promising complementary approach showing that individuals with winter-walking experience develop adaptive gait strategies that reduce slip likelihood. The objective of this study was to investigate whether repeated short-term ice-walking training can reduce slip risk.

Methods

The study took place in the WinterLab at KITE, University Health Network, using a custom ice walkway with embedded force plates. WinterLab is a self-contained laboratory mounted on a tilting platform (up to 15°). The ice surface was kept in a melting state (0°), and participants wore a safety harness. Three-dimensional kinematics were captured with an eight-camera Vicon system, along with video. Slip resistance was measured using the Maximum Achievable Angle test, which quantifies the steepest slope angle participants can safely walk up and down without slipping. Eight healthy young adults completed seven consecutive daily sessions (60 minutes each), consisting of level-walking trials, the Maximum Achievable Angle test, and force-plate walking. Participants wore curling sliders on both feet to increase task difficulty and matched their gait cadence to a metronome set to 40 bpm.

Results

Our preliminary results showed improvement in Maximum Achievable Angle across all participants. Most individuals began the study able to complete walking trials at slopes of

only 4°, but the majority achieved 8° after their fourth session. The ground reaction forces demonstrated declining anteroposterior shear forces at both level (0°) and at the maximum achieved slopes across participants.

Discussion

These findings suggest that repeated exposure to icy surfaces can facilitate gait adaptations that improve dynamic stability and reduce forces contributing to slip initiation. While preliminary and limited by sample size, findings indicate that experience-based gait training may serve as a useful slip-prevention strategy. Future work will include larger cohorts and detailed analysis of the biomechanical mechanisms underlying these adaptations.

What Is The *recovery Time* after a Perturbation?

PhD Student Ariane Lallès[1,2], Postdoc Romain Bechet[1], Professor Hélène Pillet[1], Professor Bruno Watier[2]

[1]Institut de Biomecanique Humaine Georges Charpak, Arts et Metiers Institute of Technology, EPF Engineering School, Universite Sorbonne Paris Nord, Paris, 75013, France. [2]LAAS-CNRS, Université de Toulouse, CNRS, UPS, Toulouse, 31400, France

Introduction

Balance control mechanisms can be assessed in the laboratory using several parameters, one of them, the distance between the body center of mass and minimal moment axis (**d**BCoM-MMA) has been shown to be sensitive to external perturbations [1]. Reaction to perturbation can be quantified by the perturbation recovery time (PRT). A recent method based on nonlinear dynamic system theory proposed a time-based analysis [2]. The goal of the study is to introduce the **d**BCoM-MMA as a balance feature in this method and to assess the time required to consistently return to steady-state gait.

Methods

38 healthy adults walked on a dual belt instrumented treadmill (1000 Hz, Treadmetrix®) with 50 markers tracked by 9 optoelectronic cameras (100 Hz, Vicon®). Participants walked at 1.2 m/s and experienced 8 slips and 8 trips at heel strike (target speeds: 2.04 and 0.36 m/s), with two intensities (±3 and ±10 m/s^2). 608 randomized perturbations were recorded. Following [2], we computed each participants' limit cycle and steady-state neighborhood from pre-perturbation data using anteroposterior (AP) and mediolateral components of **d**BCoM-MMA and AP and vertical BCoM acceleration. For each perturbation, we computed the current state's deviation from the limit cycle. A 1-second sliding window identified the earliest time at which 79.8% [2] of values remained below a threshold (80th percentile of pre-perturbation deviation). All other parameters followed [2].

Results

Participants returned faster to their steady-state gait after a slipping perturbation (Fig. 1). A significant number of trials resulted in PRT greater than 6 seconds. The contribution of the selected features, especially for BCoM acceleration components depends on the perturbation type.

Discussion

The results show average PRT consistent with the values reported in [2] for some waist-pull perturbations. The contribution of the acceleration of the BCoM appears as a predominant balance feature. For real-world instability assessment, BCoM acceleration is especially relevant and measurable by wearable sensors. Unlike discrete instability outcomes, PRT enables a continuous monitoring of multifactorial balance changes over time.

Images (Optional)

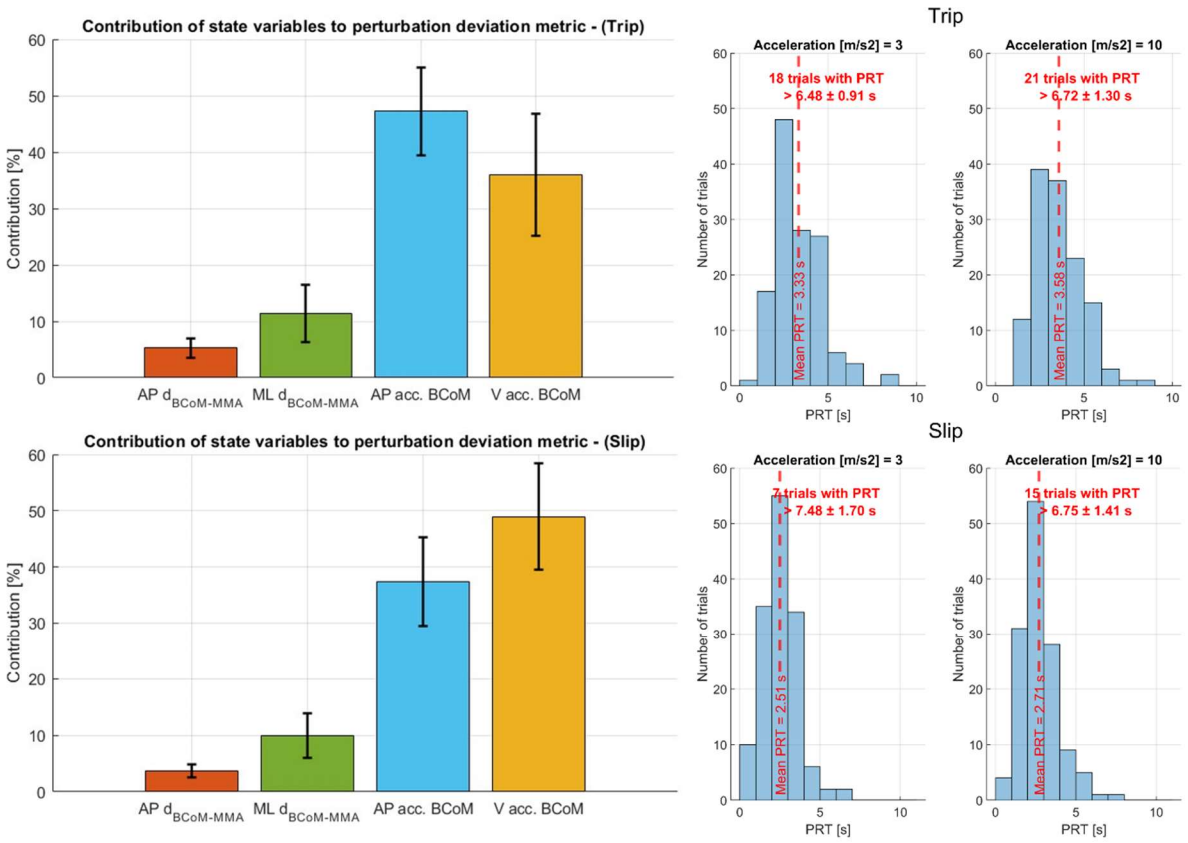

Figure 1: Contribution of selected features on the deviation metric for Trip and Slip perturbations. PRT is presented as a histogram for all recorded trials.

Timing of Trunk and Leg Reorientation During Turns Performed by Older Adults

Ms. Athena Efthymiou, Ms. Erin Kreis, Ms. Zahava Hirsch, Dr. Jun Liu PhD, Dr. Mitchell Tillman PhD, Dr. Antonia Zaferiou PhD

Stevens Institute of Technology, Hoboken, NJ, United States

Introduction

Falls are the leading cause of non-fatal and fatal injuries for older adults [1]. Turning maneuvers are closely associated with falls [2]. Many studies characterize gait patterns during turns [3] however, there are limited sources on balance states during a turn. This study compares the timing of maxima trunk and leg mediolateral lean angles during a walking turn, to better understand older adults' balance states during turns. From timing, we can learn if stepping or trunk lean initiates gait modifications during turns.

Methods

Ten healthy older adults (72.2 ± 6.03 years) completed 10-12 trials of straight-line gait, 90-degree leftward turns. The pelvis mediolateral axis and a vertical vector defined the frontal plane that allowed calculation of mediolateral trunk and leg lean angles. The leg angle used a vector from the right foot's center of mass to the hip joint center. Turn phase was defined based on [4]. Time of maxima in terms of percent time of the turn phase was also calculated. The time and percent time of maxima were compared using two-sided paired sample t-tests ($\alpha = 0.05$).

Results

During turns, the leg preceded the trunk in reaching its lean maximum (Fig.1A, $p=0.023$, Fig.1B, $p=0.009$).

Discussion

This study contributes further details regarding the cascade of gait modifications during turn initiation. Specifically, we found that older adults step outward such that the leg lean angle maximum precedes that of the trunk for most of the older adults in our cohort. Understanding the sequencing in turning provides more insight into balance control during turns. These findings help inform future fall-risk diagnoses and physical rehabilitation practices to reduce fall risk.

Gait Dynamics in Space and Time Reveal Distinct Impacts of Aging Across the Lifespan

Mr Seung Kyeom Kim[1], Dr Tyler Wiles[2], Dr Nick Stergiou[1,3], Dr Aaron Likens[1]

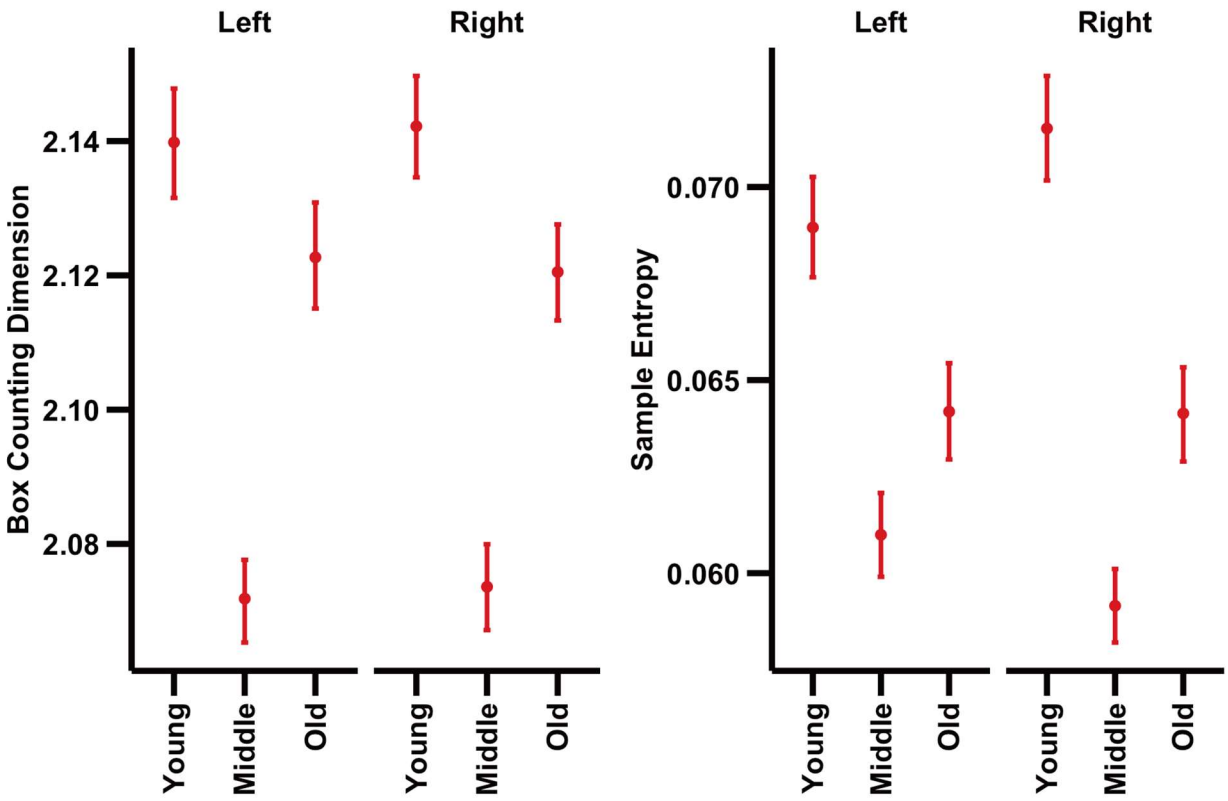
[1]University of Nebraska at Omaha, Omaha, NE, United States. [2]University of Florida, Gainesville, Florida, United States. [3]Aristotle University of Thessaloniki, Thessaloniki, Thessaloniki, Greece

Introduction

Human movement emerges from continuous interactions among multiple body components and the environment. Those interactions can be observed in a *state space*, a coordinate system that defines all possible states of a motor behavior. Within this space, stable movement trajectories form *attractors*, whose structures reflect how the system organizes and adapts. Movement variability analyses have focused on the attractor's temporal structure (how motion evolves over time) as well as spatial structure (how motion is distributed in space). We demonstrate a novel approach to the latter (i.e., spatial structure) by applying a multidimensional box counting dimension (BCD) on human gait kinematics and distinguish gait dynamics of adults across the lifespan.

Methods

126 adults (35 young(YA); 50 middle-aged(MA); 41 older(OA)) performed 4-minute overground walking trials. The spatial structure of gait was quantified using BCD of sagittal thigh kinematic; higher values indicate less constrained movement trajectories in space. Temporal structure of sagittal thigh kinematics was quantified using sample entropy (SampEn); higher values indicate more unpredictable movements over time. Metrics were computed for both thighs and *z*-scored. Multilevel modeling, a modern alternative to ANOVA, was used to examine age-related differences and limb effects.



Results

The multilevel model revealed moderate to large age effect on BCD (Figure 1). MAs exhibited lower BCD than young and OAs (D=0.418-0.585), indicating more spatially constrained coordination. Age and limb interactively modified SampEn. Post-hoc analysis within each thigh revealed moderate to large age differences for SampEn. YAs showed higher SampEn than MAs and OAs (D=0.386-0.653), indicating more temporally irregular, yet potentially more exploratory, movement patterns.

Discussion

MAs experienced more spatially constrained and more temporally predictable gait patterns than YAs. In contrast, OAs showed only increased predictability. Both results may be a byproduct of our sample; our OA were quite active and healthy, whereas MAs had the highest body mass index, on average, perhaps reflecting more sedentary lifestyles. Were the results to survive replication, one might speculate that spatial and temporal dimensions of gait have distinct mechanisms. Perhaps spatial changes in MAs compensate for changes in body mass, whereas temporal changes in timing dynamics reflect a more general pattern of aging.

When Age Isn't Enough: Testing Recruitment Validity and Functional Decline in Biomechanical Gait Data

Dr. Jason Franz, Dr. Eran Dayan, Dr. Michael Lewek

UNC Chapel Hill, Chapel Hill, NC, United States

Introduction

The field of biomechanics has long been central to enhancing understanding of age-related gait changes and to the development and evaluation of modifiable factors and therapeutic interventions. Much of our experimental work is based on a single fundamental premise – that our enrollment practices, to include our inclusion and exclusion criteria, are capable of capturing demographics that will lead to generalizable discoveries. One way to determine the efficacy of those practices is by testing measured in-lab data against the basic principle that physical function declines with advancing age. We use this retrospective analysis of previously-collected data across several domains of physical function to do just that. As an altogether alternative goal - one difficult to disentangle from our primary goal - we use the same analysis to inform the broader discussion of biological age versus chronological age in our biomechanical study of gait and instability.

Methods

Data from three studies with routine sample sizes (*i.e.*, n=16-29) were included that enrolled individuals ≥ 65 yrs who could walk without an assistive device, with normal or corrected to normal vision, who self-reported no neurological, musculoskeletal, cardiopulmonary diseases, self-reported no recent musculoskeletal injury, and with BMI ≤ 30 kg/m^2. Outcome measures spanned: (i) *functional performance* (i.e., timed up-and-go, dynamic gait index [DGI], 5x sit-to-stand, and comfortable walking speed), (ii) *balance* (i.e., anterior-posterior and mediolateral margins of stability and fear of falling), and (iii) *foot-ankle function* (i.e., plantar sensation and, during walking, foot-ankle leverage and ankle moment). Cross-sectional comparisons demonstrated that nearly every outcome was significantly worse for older vs. younger participants.

Results

Enrollment ages spanned 65-87 years. Only DGI score (r^2=0.19, p=0.017) correlated with chronological age; a weak trend approaching significance was observed for speed (r^2=0.13, p=0.055). No other outcome exceeded 10% variance explained by chronological age.

Discussion

Chronological age is a poor predictor of physical function among older adults enrolled in biomechanics studies using routine inclusion/exclusion criteria. Although differences between biological versus chronological age may be relevant, we are more convinced that our results reflect restrictive enrollment criteria that should be reconsidered to enhance the generalization and impact of our discoveries.

Images (Optional)

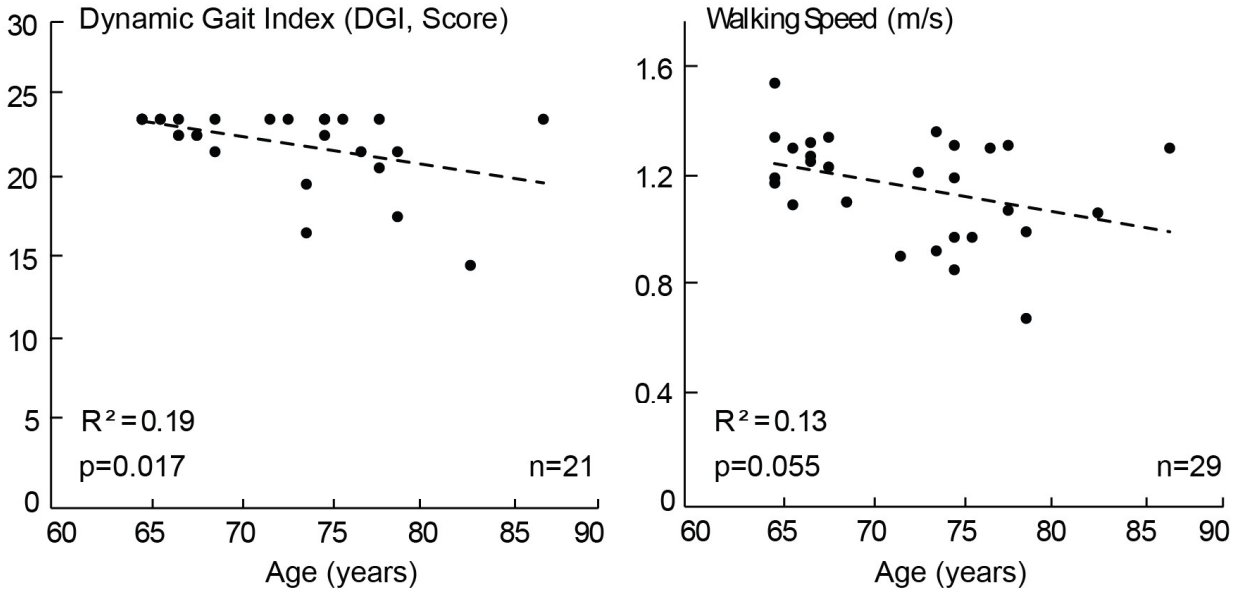

Figure 1. Scatter plots showing the distribution of DGI scores and walking speeds as a function of age. Only DGI score correlated with chronological age; a weak trend approaching significance was observed for speed. No other outcome exceeded 10% variance explained by chronological age.

Shoe Fit and Downhill Cycling Performance

Dr. Kathryn Harrison PhD, Dr. Daniel Feeney PhD, Ms. Bethany Kilpatrick, Ms. Milena Singletary, Mr. Adam Luftglass, Dr. Eric Honert PhD

BOA Technology, Denver, CO, United States

Introduction

Skill in navigating technical terrain is critical to performance in Downhill Mountain biking. This requires dynamically responding to obstacles to maintain balance while not losing speed. A rider's footwear may influence their proprioception and ability to respond to the terrain, as seen in trail running. Sample entropy has been used to evaluate aspects of footwear on athletes' adaptability to technical terrain; shoes with a wrapping upper designed to conform to the foot improved ability to navigate technical terrain[1]. This study explored whether a similar benefit exists in mountain biking.

Methods

Twenty-one expert downhill mountain bikers (10F/11M) completed three laps of a 5km black diamond downhill trail. The first lap was for familiarization. During the next two laps, riders completed the course in two different pairs of shoes: a clipless downhill shoe with standard lace and hook and loop closure, and the same base shoe with a wrapping closure activated by two dials. Data were collected from inertial measurement units mounted on the heel, the top tube of the bike frame, and the rider's sacrum. Sample entropy was calculated for each axis of the IMU acceleration signals throughout the trail. Sample entropy values were converted to subject specific z-scores and were compared between shoe conditions using Bayesian linear mixed effects models.

Results

In the wrap shoe, sample entropy of the foot was 4% greater in the vertical direction (97% posterior>0). On the bike, it was 2% greater in the mediolateral direction (88% posterior>0) and 1% greater in the anteroposterior direction (81% posterior>0). Sample entropy of the sacrum in the vertical direction tended to be 1% lower in the wrap shoe (74% posterior<0).

Discussion

The greater entropy of the foot and bike suggest that in the wrap shoe, riders were better able to adapt to changing terrain. This allowed them to maintain more consistent motion of

their torso, an indication of balance and skill. The improvements in the wrap shoe may be driven by more consistent contact of the riders foot with the shoe, similar to trail running[1].

SplitCranks: A New Technological Device for Leg-Independent Control of Bilateral Power Output in Cycling

PhD Marcos Kunzler, PhD Felipe Carpes

Applied Neuromechanics Research Group, Federal University of Pampa, Uruguaiana, RS, Brazil

PhD Marcos Kunzler

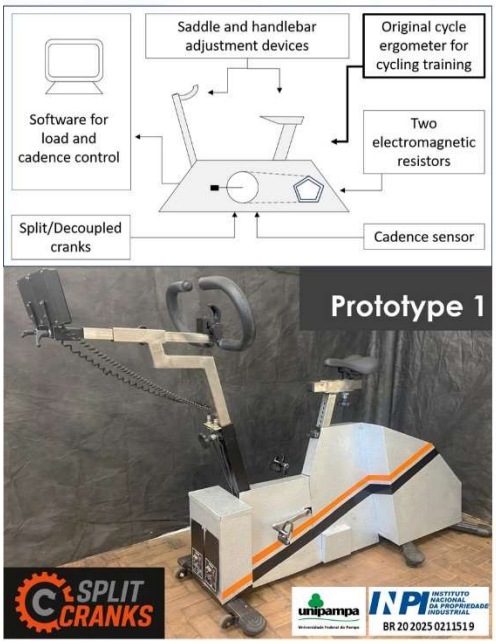
Introduction

Power output during cycling results from bilateral motion of both legs in a synchronous way using coupled cranks. Previous studies show that the use of decoupled cranks alters lower limb muscle activation and coordination, promoting balanced recruitment and reducing asymmetry [1, 2]. However, each leg may present different motion patters, and training and rehabilitation strategies may benefit of leg-independent movement control. Such insights come from split-belt treadmills in locomotion research and use of decoupled cranks by cycling athletes. To the date, to reproduce leg-independent movement control in cycling ergometers is not possible with commercial devices. In this study we describe the concept, construction, and pilot testing of SplitCranks, a new device now under patent registration.

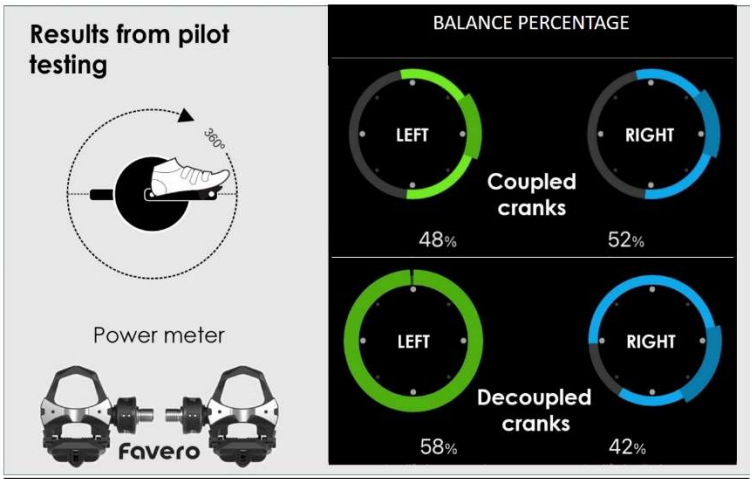
Methods

SplitCranks adapts the concept of split-belt treadmills to cycling by using two fully independent cranks, each connected to its own electromagnetic resistance unit and controlled by custom electronics and software (Figure 1). A prototype was built from a standard cycle ergometer, enabling leg-independent resistance, power, and cadence monitoring (Figure 1). A pilot test with a 42-year-old man recreational cyclist evaluated the system's feasibility. He completed two 5-minute sessions at 100 W - one with coupled cranks and one with decoupled cranks. Bilateral power and cadence were recorded with a Favero Assioma Duo powermeter. Left-right balance, energy distribution, and peak power phase were recorded.

Results



SplitCranks allowed individualization of mechanical load on each crank during pedaling. Using our prototype (Figure 2) we properly adjusted body positioning on the bike and



recorded unilateral power output and cadence during bilateral cycling. The pilot tests confirmed that participants comfortably adapted to the system while data are recorded. Results are in Figure 1.

Discussion

SplitCranks allows unilateral workload manipulation. Compared with traditional coupled cranks, the decoupled condition using SplitCranks seems to elicit more homogeneous power distribution along pedaling cycle and increased contribution from the non-preferred limb to power ouput, indicating strong potential for improving pedaling symmetry. Overall, SplitCranks provides a promising platform for performance optimization, technique refinement, rehabilitation, and research on motor control and biomechanics.

A Comparison of Cycling Positional Differences Between Tandem Stokers and Pilots Before and After Wind-Tunnel Optimisation

Mr Sean Husband PhD candidate[1], Prof Ciaran Simms Professor In, Mechanical, Manuf & Biomedical Eng[1,2,3], Mr Paul Carragher Physiotherapist[2], Mr Robert Coulthard-Wragg BSc, MSc[1]

[1]Trinity College Dublin, Dublin, Dublin, Ireland. [2]Sport Ireland Institute, Dublin, Dublin, Ireland. [3]Cycling Ireland, Dublin, Dublin, Ireland

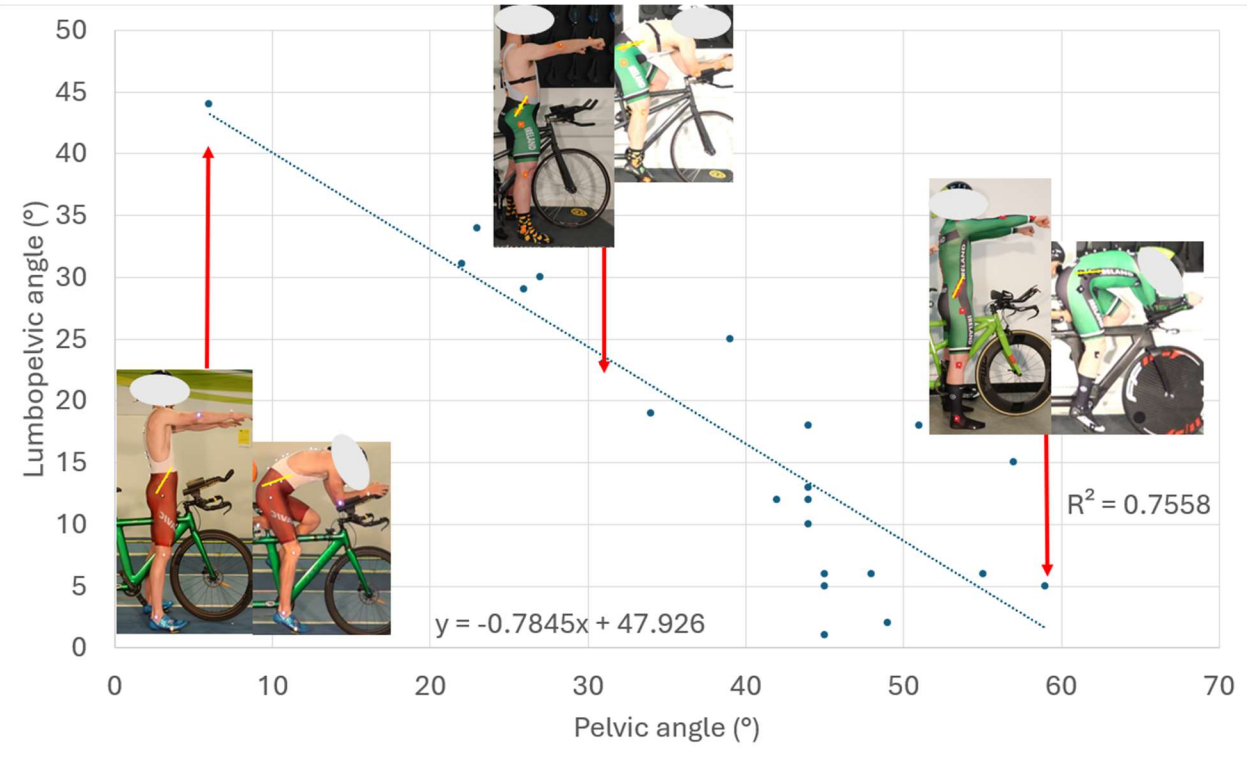
Introduction

Tandem cycling is a specialized category of cycling regulated by the UCI. Visually impaired athletes, referred to as stokers, compete alongside their guides, commonly known as pilots. The inclusion of an additional cyclist introduces complexity to cyclist positioning for aerodynamic optimisation, necessitating the simultaneous optimisation of both cyclist. Research on tandem cycling is limited, with Mannion et al. (2018) and Kopacz et al., (2014) being the only studies in this domain, examining various overall positions and aerodynamic properties, such as upright, crouched, time-trial, and frame-clench (where the stoker holds the frame instead of the handlebars). The present study sought to elucidate the whole-body kinematic differences between the stoker and pilot both before and after wind-tunnel optimisation, and at different cycling intensity levels

Methods

Twelve elite tandem cyclists participated in a study conducted in a wind-tunnel in the UK (comprising six tandems: three male pilots with three female pilots, and three male stokers with three female stokers). Each participant pairing had reflective markers placed on the anatomical sites of interest. A single side-view camera was positioned to record the sagittal plane of the cyclist and bicycle. A calibration image was captured with participants straddling the bicycle, arms in front of their shoulders to prevent occlusion of markers.

Trials were conducted successively across two cycling intensities for 3 minutes, with participants instructed to maintain their race positions throughout the trials. Cycling intensities were derived from physiological laboratory testing.



Results

Pilots (M = 77°, SD = 12.9) demonstrated significantly lower elbow flexion angles compared to stokers p= 0.023 (M = 117°, SD = 34.8). Higher lumbopelvic tilt angles were associated with lower pelvic tilt angles. -.89, p=<.001,95% CI [-.96,-.53]

Discussion

The most significant differences were identified in the elbow and ankle angles, with pilots demonstrating greater elbow flexion and stokers consistently exhibiting greater ankle plantar flexion. A strong inverse correlation was observed for lumbopelvic tilt and pelvic tilt in pilots, but not stokers.

Head Acceleration Event Burden in Competition Downhill Mountain Biking: Insights from the Whistler Crankworx Competition

Mr. Matthew G. Neill MSc[1,2], Dr. James Tooby PhD[3], Mr. Nicholas Devert BSc[1,2], Dr. Cameron Owen PhD[4,5], Ms. Ember Larson BSc.[1,2], Dr. Jonathan D. Smirl PhD[1,2], Dr. Carolyn A. Emery PT, PhD[1,2]

[4]Carnegie Applied Rugby Research (CARR) Centre, Leeds Beckett University, Leeds, West Yorkshire, United Kingdom. [5]England Performance Unit, Rugby Football League, Machester, North West England, United Kingdom

Introduction

There is growing interest in quantifying the cumulative head acceleration event (HAE) burden in downhill mountain biking (MTB). Recent studies have detected neural differences post-ride compared to pre-ride in MTB riders, though the contribution of repetitive HAE exposure to this difference is not well quantified. Thus, the purpose of this study was to evaluate the number of HAEs sustained per day of competition in elite competitive MTB athletes.

Methods

Participants, recruited pre- or mid-competition, were fit with an instrumented mouthguard (iMGs; Prevent Biometrics) with a 5g linear acceleration trigger threshold and instructed to wear the iMG while riding. iMGs were synced pre-ride, provided to each rider before competition or training, and recovered post-ride for syncing and charging. False positives were removed using Prevent Biometrics integrated filtering. Teeth proximity sensor data confirmed mouthguard use. Poisson regression was used to calculate the incidence rate of HAEs greater than 5g's, per-athlete per-day.

Results

Twenty-one athletes (18 male,3 female) wore the iMGs for a cumulative total of 51 days of MTB riding, recording 101 true positive impacts. Thus, an incidence rate of 1.98 HAEs per person day (95% CI: 1.61,2.41) was observed.

Discussion

A previous study using accelerometers adhered to the skin reported 1031 HAEs >10g in 16 MTB riders over two sessions [1]. Our data suggests that the rate of HAE accumulation is much lower, likely due to the improved coupling between the iMG and the skull. Accumulation of HAEs may not be a major target for injury prevention in MTB and acute traumatic injuries such as concussion may be more burdensome. Human kinematics are likely impacted by the suspension geometry of the mountain bikes. Thus, future work should evaluate if iMG filtering developed in team sport is suitable for delineating true positive from false positive impacts sustained during MTB.

Examining Muscular Fatigue Across Repeated Golf Swings and Its Relationship With Performance

Mr Stephen Boulanger Ph.D.(c)[1], Mr John Li[1], Mr Nishad Rajmalwar Ph.D.(c)[2], Mr John McPhee Ph.D.[2], Mr Clark Dickerson Ph.D.[2], Mrs Jaclyn Chopp-Hurley Ph.D.[1]

[1]York University, Toronto, Ontario, Canada. [2]University of Waterloo, Waterloo, Ontario, Canada

Introduction

The golf swing is a highly coordinated movement that requires high muscular demands which dictate performance. Over repeated swings, the risk of muscle fatigue increases thereby potentially compromising overall swing performance. The aims of this study were to assess muscle fatigue through repeated golf swings and determine whether these patterns are related to psychophysical measures (rate of perceived exertion; RPE), and performance measures (ball speed, club speed, carry distance).

Methods

Thirteen male golfers have been recruited for this study (Age: 25.7 ± 2.6 years, BMI: 26.7 ± 2.1 kg/cm^2, Registered Golf Handicap: 8.6 ± 5.6) with additional participants forthcoming. Delsys Avanti and Snap Lead surface electromyography (EMG) sensors were affixed to thirteen upper limb and trunk muscles, bilaterally (Figure 1). Muscle specific maximal (MVIC) and submaximal isometric voluntary contractions (SVIC) at 50% MVIC were performed prior to swing trials. Swing trials were performed in sets of twenty repetitions with EMG data collected during the first five swings of each set. After each set, RPE was recorded. Once participants reached an RPE of $\geq$ 9 or 200 swing repetitions, the protocol was completed. SVICs were then performed to assess post-trial muscular fatigue.

Results

One-way ANOVAs revealed no significant differences in EMG amplitude in trailing or leading arms between pre- and post-swing SVICs. Trailing latissimus dorsi (LD; $p = 0.23$), external oblique ($p = 0.14$), leading anterior deltoid (AD; $p = 0.26$), and LD ($p = 0.07$) were nearing significance for effects of fatigue. Mean power frequency as well performance-related and skill level-related results will be forthcoming for further analyses.

Discussion

It was anticipated that the muscles, which are responsible for powerful exertions of the golf swing, would fatigue over the course of our swing protocol. Specifically, the LD and AD were expected to fatigue as they are responsible for forceful exertions of the shoulders. We suspect that the non-significant results indicate potential load sharing and muscular compensation as the swing protocol progressed which enabled muscles to recover. Further analyses are being performed to potentially identify these trends, in addition to assessing muscular demands during the swing protocol.

Predictive Accuracy of Golf Clubhead Speed from Body-Derived Kinematic Variables

Dr. Bryndan Lindsey[1], Mr. Yuanshuo Tan[1], Mr. Xiujie Sun[1], Ms. Chunping Liang[1], Mr. Kezhe Zhu[1], Mr. Huiming Pan[1], Mr. Bo Xiao[2], Dr. Shenglong Le[2], Dr. Peter Shull[1]

[1]State Key Laboratory of Mechanical System and Vibration, School of Mechanical Engineering, Shanghai Jiao Tong University, Shanghai, Shanghai, China. [2]Department of Physical Education, Shanghai Jiao Tong University, Shanghai, Shanghai, China

Introduction

Wearable sensors have the potential to provide golfers with objective feedback on swing performance in real-time. Clubhead speed, in particular, is a critical determinant of driving performance resulting in increased carry distance and fewer strokes per round. Prior research has shown that body-derived kinematic variables, including pelvis–trunk separation (X-factor) and segmental rotational velocities, can discriminate skill level and predict ball speed. However, the ability to predict clubhead speed directly from these variables has not been established. Therefore, our purpose was to determine whether body-derived kinematics can accurately predict clubhead speed across golfers of varying proficiency.

Methods

Data were collected from 24 participants (male=17, age=25±0.7yrs, height=1.75±0.8m, mass=69±13kg) using a whole-body motion-capture system. A Random Forest regression model was developed to predict clubhead speed using kinematic and temporal variables previously associated with swing performance. Validation was performed using leave-one-subject-out (LOSO) cross-validation and performance was quantified using mean absolute error (MAE), root mean squared error (RMSE), and overall R^2. Variable importance was assessed using permutation-based increases in prediction error, and recursive feature elimination (RFE) identified a minimal predictor set on which model results are based.

Results

Model validation results demonstrated strong predictive performance (R^2 = 0.84) with an RMSE of 3.21 m/s and MAE of 2.5 m/s. Variable importance analysis showed that predictive performance was driven primarily by time from top of backswing to peak lead arm angular velocity as well as peak trunk rotational velocity prior to impact (Figure 1). Pre-impact peak X-factor and lead arm velocity also contributed to the prediction.

Discussion

These results demonstrate that body-derived kinematic and temporal metrics can meaningfully predict golf clubhead speed with a small set of motion-based variables. The four-variable model explained 84% of the variance in clubhead speed, with mean absolute error of 2.5 m/s indicating low prediction error relative to typical speed differences across golfers. Variable importance revealed that rotational power generated by the trunk prior to impact, together with timing of downswing lead-arm acceleration, were the strongest predictors of speed. Addition of acceleration-based and sequencing metrics may enhance biomechanical interpretation and predictive performance.

A Novel *Reduced Order Model*-Driven Paradigm for Real-Time Predictive Modeling of TAVR and Pre-Procedural Risk Assessment of Coronary Obstruction

Dr. Imran Shah PhD[1,2], Dr. Sri Krishna Sivakumar PhD[1], Dr. Vinod Thourani MD[3], Dr. Alessandro Veneziani PhD[2], Dr. Lakshmi Dasi PhD[1,2]

[1]Georgia Institute of Technology, Atlanta, Georgia, United States. [2]Emory University, Atlanta, Georgia, United States. [3]Piedmont Heart Institute, Atlanta, Georgia, United States

Introduction

Predictive computational modeling of coronary obstruction (CO) following transcatheter aortic valve replacement (TAVR) has become critical for pre-operative risk assessment and optimized deployment of the bioprosthetic valve. However, traditional physics-based modeling approaches require extensive computational resources to simulate the entirety of the TAVR deployment process (48-96 hours), thus limiting the exploration of various procedural factors such as deployment depth or valve type. In this study, we introduce a novel *reduced order modeling* (ROM)-driven *in-silico* paradigm for performing real-time TAVR deployment simulations, thus enabling rapid risk assessment of CO.

Methods

The ROM framework was constructed in a sequential offline-online decomposition via the Proper Orthogonal Decomposition approach to rapidly capture the structural deformation of the Evolut R valve. Interactions of the stent frame with the patient-specific native anatomy were captured via a novel surrogate contact model. The ROM-based TAVR deployment framework was applied to a cohort of patients with angiographically confirmed obstruction (n = 7), and the predictive metric DLC/d was measured for modeling the risk of CO (DLC – distance from leaflet cusp to coronary ostia, d – coronary diameter). Results from the ROM simulations were compared against traditional full order model (FOM) simulations of the deployment process, as well as post-operative CT data.

Results

Results for the ROM-based deployment simulation for a sample patient are shown in Fig. 1A. The ROM simulation required less than 20 minutes to complete, resulting in a 99% speed-up compared to the traditional FOM. The framework accurately modeled the deployment of the Evolut stent frame and its interactions with the surrounding anatomy, and strong agreements were seen between the simulation results and post-procedural

outcomes (Fig. 1B). DLC/d indices measured from the ROM-based deployment simulations were in excellent agreement with measurements obtained from traditional FOM simulations as well (Fig. 1C), with average predicted differences of 10% between the two measurements.

Discussion

The proposed ROM framework enables real-time predictive modeling of the TAVR deployment process as well as accurate mechanistic insight for post-operative risk assessment of CO via the DLC/d metric, all on local computational facilities commonly seen in the clinic (i.e., a simple laptop).

Relationship Between Mechanical Dispersion and T-Wave Inversion in Arrhythmic Mitral Valve Prolapse

Mr. Vahid Naeini[1], Mr. Emilio Mendiola[1], Dr. Dipan Shah[2], Dr. Reza Avazmohammadi[1]

[1]Texas A&M University, College Station, TX, United States. [2]Houston Methodist Hospital, Houston, TX, United States

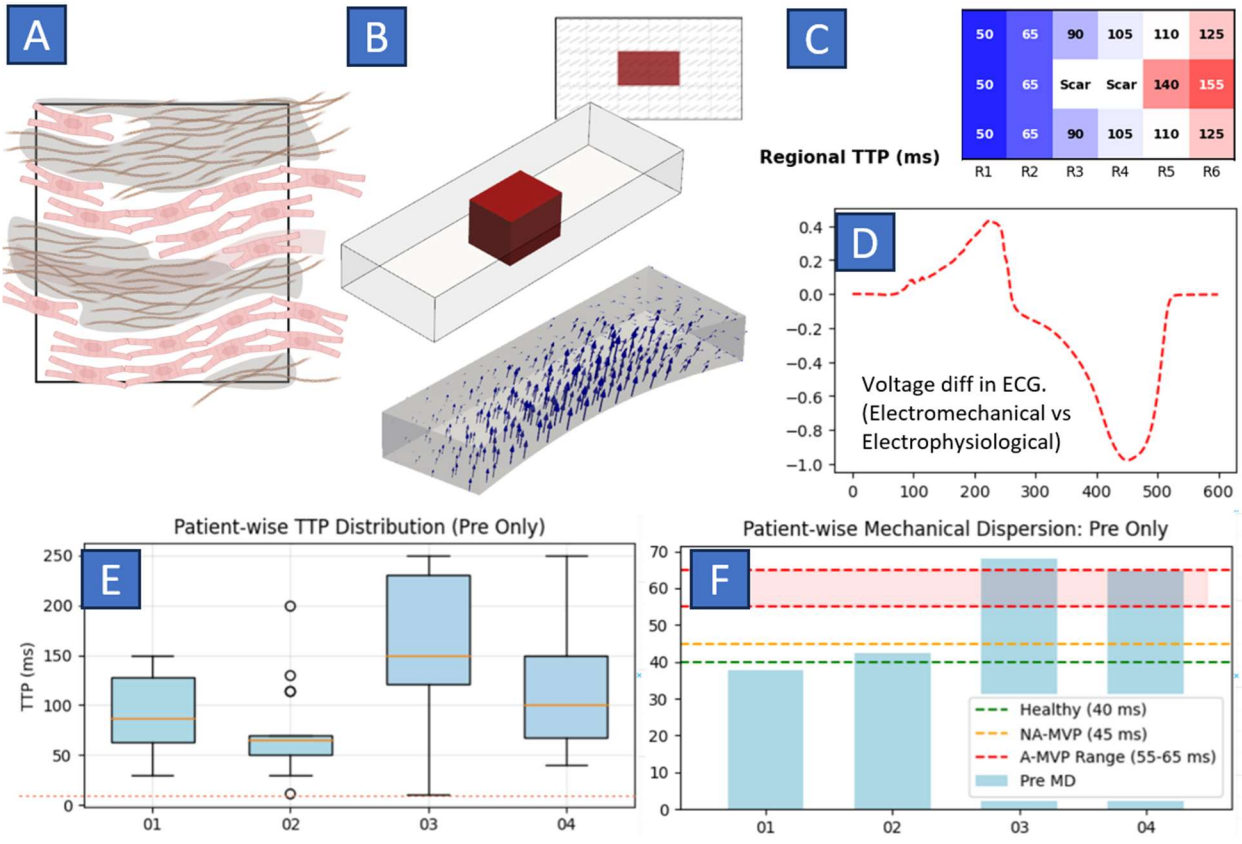
Introduction

Traditionally, mitral valve prolapse (MVP) has been defined by its primary symptom, regurgitation, yet the arrhythmic type (A-MVP) presents a risk of sudden cardiac death (SCD) that persists even after surgical interventions such as mitral valve repair. In this region, mechanical instability spatially co-localizes with electrical symptoms, specifically inferior-lead T-wave inversion. A major challenge in modeling this pathology is establishing a robust quantitative link between the disparate timescales of mechanical deformation and rapid electrical events.

Methods

A patient-specific coupled electromechanical (EM) framework was used to analyze cine-CMR data from 26 MVP patients (12 A-MVP, 14 non-arrhythmic). To test the mechanistic link, 3D in-silico slabs benchmarks were extracted from the inferobasal wall of each patient. These slabs preserved patient-specific anatomical features, including local fiber angles, wall thickness, and the relative location of fibrotic tissues observed in LGE. The slab mechanical dispersion (SMD) was defined as a functional metric representing local strain heterogeneity and linking local tissue mechanics to the whole-heart mechanical dispersion (MD) observed in CMR. Simulations were performed to compare models driven by fibrosis against fully electromechanically coupled models.

Results



A-MVP patients exhibited a higher-dispersion category than non-arrhythmic controls. In coupled slab models, a dispersion threshold > 50 ms predicted T-wave inversion with > 85% sensitivity. This categorical agreement was unique to the coupled framework, as uncoupled models failed to reproduce the inversion morphology regardless of substrate density.

Discussion

These findings suggest that mechanical dispersion, within a fully coupled framework, can serve as a functional surrogate for underlying electrophysiological behavior. Capturing

persistent strain heterogeneity provides a constraint that allows electrophysiological properties to be estimated directly from standard cine-CMR data.

An In-Silico Workflow to Virtually Perform Redo-TAVI using a Balloon-Expandable Device to Assess the Risk of Vascular Injury when Varying Balloon Expansion

Miss. Sheikh Umara Zoni[1], Mr. Luis Rene Mata Quinonez[2], Dr. Sanchita Bhat[2], Dr. Lakshmi Prasad Dasi[2], Dr. Shelly Singh-Gryzbon[1]

[1]The University of Cambridge, Cambridge, Cambridgeshire, United Kingdom. [2]Georgia Institute of Technology, Atlanta, Georgia, United States

Introduction

Expanding indications for transcatheter aortic valve implantation (TAVI) in lower-surgical risk cohorts raise concerns about transcatheter heart valve (THV) durability, as patients currently outlive their initial device. Once failed, redo-TAVI can be performed by implanting a second THV within the existing prosthesis. However, experience with redo-TAVI remains limited, and early clinical studies report complications arising from device-vessel interactions but lacks mechanistic insights. This study develops a computational platform for simulating redo-TAVI, and uses the platform to investigate the structural implications of inserting a balloon-expandable valve (BEV) within an existing BEV for varying deployment strategies.

Methods

A patient-specific aortic root was reconstructed from computed tomography (CT) images, while μCT was used to define a 23 mm BEV, including its frame and leaflets. Using ABAQUS, the BEV was crimped and positioned over a compliant balloon, then nominally deployed using fluid-cavity interactions. Redo-TAVI was subsequently simulated, with modified balloon inflation to represent **under-expansion** and **over-expansion strategies**. Tie constraints were applied between the prosthetic leaflets and stent frame, and between calcifications and aortic root. The root boundaries were fixed, with balloon ends constrained in-plane and rotationally. Hard-penalty contact was enforced with a friction coefficient of 0.26. Material models included hyperelastic (aorta and leaflets), elasto-plastic (frame and calcifications) and elastic (balloon).

Results

This work presents the first computational platform for simulating redo-TAVI, from valve crimping to deployment, inclusive of THV leaflets and stent frame. It was seen that under-expansion minimised aortic root deformation, although mid-valve “dog-boning” was

observed. Over-expansion caused increased root deformation and stent dilation, representing the highest mechanical risk of vascular injury (VI).

Discussion

During redo-TAVI, reduced annular area after the initial THV combined with increased stiffness from calcifications amplifies VI risk. Although under-expansion reduces global stress, it may compromise long-term valve performance. Furthermore, inadequate sealing can cause paravalvular leakage, and residual gaps from incomplete expansion may encourage thrombosis and restenosis, further narrowing the valve. Simulations highlight the need for precise expansion strategies in redo-TAVI to balance VI with valve durability. Self-expanding valves, which exert more adaptive radial forces, may mitigate these complications, with ongoing research evaluating this possibility.

OA132-05

Virtual Transcatheter Repair of Atrioventricular Valve Regurgitation Using an Open-Source Finite Element Simulation Framework

Dr. Seda Aslan

Children's Hospital of Philadelphia, Philadelphia, PA, United States

Introduction

Atrioventricular valve regurgitation is a major cause of morbidity in patients with heart disease. While surgical repair remains the standard of care, many patients are poor candidates for open-heart procedures, increasing the demand for transcatheter edge-to-edge repair (TEER) and transcatheter annuloplasty. Although these approaches have shown promising outcomes, their mechanical effects on leaflet stresses, coaptation, and device–tissue interactions remain insufficiently characterized. Image-derived models aid device sizing and anatomical feasibility but cannot predict functional performance or leaflet biomechanics. To address this need, we developed an open-source finite element framework to simulate TEER, band annuloplasty, suture annuloplasty, and combined strategies under physiologic loading.

Methods

A mitral valve from a 15-year-old patient was reconstructed using SlicerHeart and 3D Slicer and modified to generate P2 prolapse and annular dilation anatomies. Virtual repairs were performed in FEBio, including four MitraClip G4, a band annuloplasty (via annular circumference reduction), and a suture annuloplasty (via targeted annular displacement). Simulations incorporated a hyperelastic model, nonlinear chordae elements, leaflet contact, physiologic systolic pressure, and a compliant annulus condition. Functional (regurgitant orifice area, ROA; coaptation area, CA) and mechanical (leaflet stress and strain) metrics were quantified for each repair.

Results

TEER restored coaptation in prolapse but increased leaflet stresses, which varied with clip geometry; larger clips produced higher stresses. Staged leaflet capture increased CA but introduced greater mechanical loading, particularly in the dilated annulus model. Band annuloplasty achieved full coaptation at ~30% annular reduction and reduced leaflet stresses relative to TEER in dilation. Suture annuloplasty produced modest annular

reduction yet generated the largest CA in prolapse. Combined TEER + band annuloplasty yielded the best overall functional outcome in dilation (ROA = 0.06 cm^2; CA = 2.57 cm^2) with reduced stresses compared to TEER alone.

Discussion

This framework demonstrates how virtual repair can differentiate biomechanical and functional performance across transcatheter strategies. With further validation and expansion to diverse patient anatomies, such simulations may support personalized device selection and procedural planning.

Traumatic Brain Injury – Comparing Lateral and Sagittal Impacts with the CHIMERA Platform

Mr. Alexander Burden B.Eng, Dr. Wai Hang Cheng PhD, Mr. Luis Dias B.Eng, Dr. Jianjia Fan PhD, Dr. Mehwish Anwer PhD, Dr. Peter Cripton PhD, Dr. Cheryl Wellington PhD

UBC, Vancouver, BC, Canada

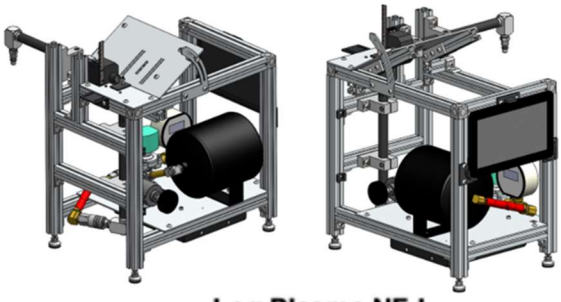
Introduction

Traumatic Brain Injury (TBI) is a heterogeneous injury in both its causes and outcomes. The direction of the initial head impact is a major source of variation, with previous studies showing that the rotational plane can have a substantial effect on brain injury severity. The Closed-Head Impact Model of Engineered Rotational Acceleration (CHIMERA) model of TBI has been used globally to produce human-like impact-acceleration injuries in a mouse model. The objective of this study is to characterize the differences between the well-established sagittal impact model with a lateral impact model of murine TBI.

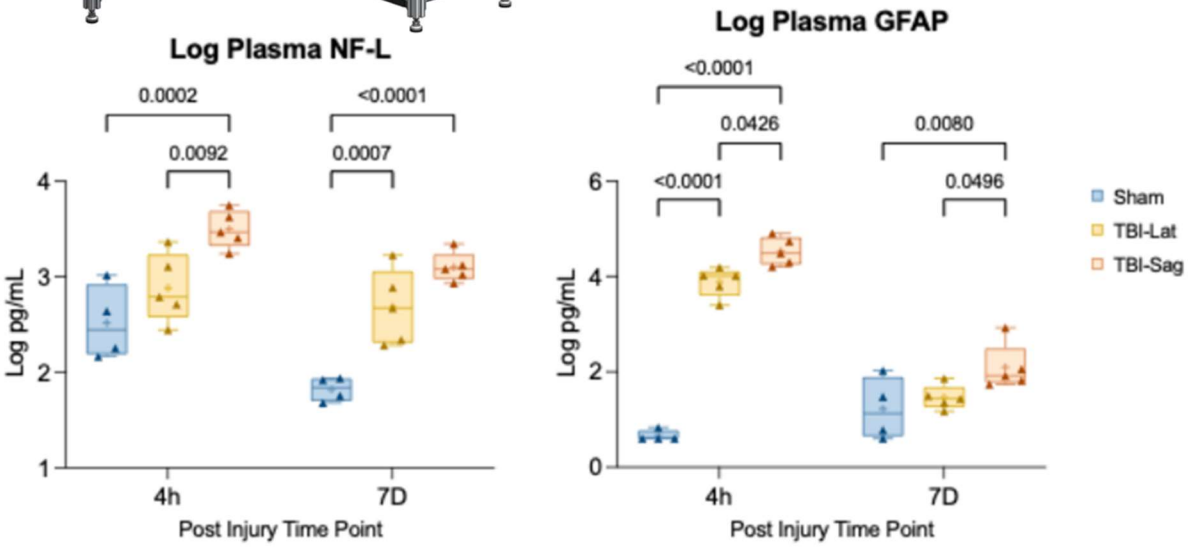
Methods

Firstly, trackers were implanted onto the skull of cadaver mice, which were then impacted with CHIMERA in either the sagittal or lateral direction, at a range of energies. Phantom v1212 high speed cameras captured head motion following impact at 19000 FPS. Linear and Angular Velocities were computed for each impact.

Subsequently, live experiments were conducted on 3-month-old C57BL/6 mice, separated into 3 groups, sham (n=5), lateral (n=5), and sagittal (n=7). All animals were anesthetized and provided with analgesics according to veterinarian approval. Animals in the lateral and sagittal groups then underwent a CHIMERA TBI at 2.7 joules and were allowed to recover. At 4 hours, saphenous blood was collected for plasma biomarker (GFAP/NF-L) analysis. At 1 week, animals were perfused and brains were collected for histology.



Results



Preliminary results from the cadaver experiments indicate that lateral hits resulted in trajectories with greater velocities. Furthermore, above 2 Joules, sagittal impacts do not cause an increase in velocity, suggesting more energy is absorbed by the skull. However, initial findings from the live animal study found the sagittal group exhibited increased mortality (28% vs 0%), LRR time (120 min vs 30 min) and significantly greater GFAP and NF-L at 4 ($p<0.0426$ and $p<0.0092$) hours post-injury. Preliminary histology shows differences in affected regions as well.

Discussion

Initial results suggest that lateral impacts result in a greater dissipation of energy into head motion, while sagittal impacts cause greater direct injury to the brain. Histology indicates that sagittal impacts affect the brain symmetrically, while lateral impacts are strongly biased to the injury site.

Factors Associated with Elevated Brain Strains in Youth American Football Players

Dr Enora Le Flao[1], Mr Chaokai Zhang[2], Dr Wei Zhao[2], Ms Samantha DeAngelo[1], Dr Adam Culiver[3], Mr Nick Shoaf[4], Mr Durshil Doshi[4], Dr Jingzhen Yang[5], Dr Sean Rose[5], Dr James Onate[1], Dr Zeynep Saygin[4], Dr Songbai Ji[2], Dr Jaclyn Caccese[1]

[1]The Ohio State University Wexner Medical Center, Columbus, OH, United States. [2]Worcester Polytechnic Institute, Worcester, MA, United States. [3]Indiana University Indianapolis, Indianapolis, IN, United States. [4]The Ohio State University, Columbus, OH, United States. [5]Nationwide Children's Hospital, Columbus, OH, United States

Introduction

American football players regularly sustain head acceleration events (HAEs). The resulting brain strain may lead to acute and long-term neurological impairments. It is essential to understand HAE exposure to design effective and targeted risk reduction strategies. The objective of this study was to identify factors affecting the magnitude of HAE-induced brain strains experienced by youth football players.

Methods

HAEs were collected from 75 American football players (8-12 years old, split into age-based teams) over two seasons using instrumented mouthguards during games and practices. True positive, high-quality HAEs with a peak linear acceleration and angular velocity over 10 g and 2 rad/s, respectively, were included for analysis. A subsequent analysis focused on video-verified game HAEs, using annotations of action (being tackled, tackling, blocking), mechanism (helmet-to-ground, helmet-to-opponent, body impact), and player position. The kinematics were used as input to a convolutional neural network based on the anisotropic Worcester Head Injury Model (WHIM) to estimate 95th percentiles of Maximal Principal Strains (MPS95). Generalized Linear Mixed Models (GLMMs) were used to assess various fixed effects on MPS95, using participant ID as random factor.

Results

A total of 2719 HAEs were included, with a median MPS95 of 6.70% [IQR: 4.75-9.47]. Games produced higher MPS95 than practices (Type III Wald χ^2 (1) = 8972.8, p <0.001; estimated means difference: +0.69%). Players in the intermediate team (5th graders) experienced higher MPS95 than those in the younger team (3/4th graders)(χ^2 (2) = 11.00, p = 0.004, +0.64%). MPS95 were similar across seasons (χ^2 (1) = 0.45, p = 0.50). Over the 403 video-verified HAEs, action, mechanism, and player position all showed a significant effect on MPS95 when tested separately. After removing collinear variables, a GLMM including

mechanism, player position, and team as fixed effects revealed a significant effect of the mechanism (χ^2 (2) = 6.38, p = 0.041). Specifically, helmet-to-ground predicted higher MPS95 than body impacts (+1.63%, p = 0.020).

Discussion

There were significant but subtle group differences in strain. Impact mechanism affected MPS95 after accounting for several factors. Helmet-to-ground impacts were a risk factor in this player cohort, and could be the focus of future risk reduction strategies.

Defining Axonal Injury Thresholds: A Multiscale Coupling of Tissue Deformation and Molecular Damage

Ms. Maryam Majdolhosseini, Dr. Alessandra Villa, Dr. Zhou Zhou, Dr. Svein Kleiven

KTH, Stockholm, Stockholm, Sweden

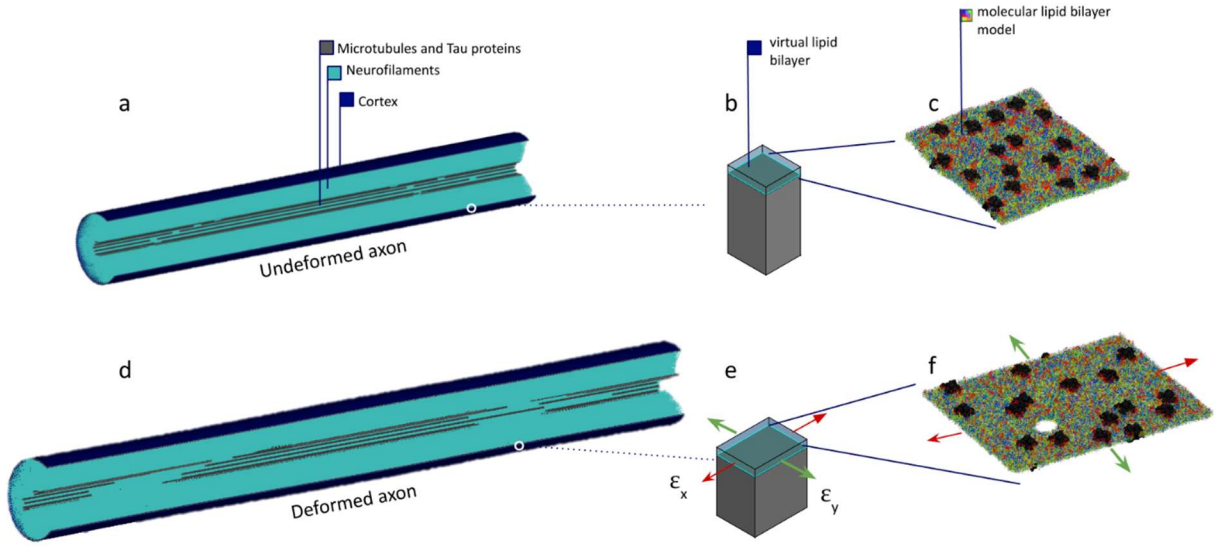
Introduction

Diffuse axonal injury (DAI) is a traumatic brain injury (TBI) characterised by the deformation of axons within white matter (WM). Although the exact mechanism remains elusive, membrane disruption is hypothesised to be the initial trigger of axonal injury. However, bridging the gap between macroscopic tissue strain and these molecular events remains a significant challenge. Building on this hypothesis, we developed a multiscale approach to determine axonal injury thresholds by directly coupling tissue-scale finite element (FE) models with molecular dynamics (MD) simulations.

Methods

The developed FE model represented brain WM, including an axon composed of microtubules, neurofilaments, and a cortex layer representing the axolemma, embedded within an extra-axonal matrix. Parallel MD systems modelled a human-axolemma lipid bilayer with a voltage-gated sodium channel (Nav1.1) embedded inside. The FE model was subjected to tension, compression, and shear and the local strains of the cortex were derived. The MD models underwent uniaxial tension to monitor the structural changes of the bilayer and protein. We assumed the local strain of the cortical elements in the FE model is equivalent to the strain applied to the MD axolemma, as shown in Figure 1. Consequently, injurious strains derived from MD simulations were coupled with axonal deformation results from FE models to identify macroscopic failure thresholds.

Results



MD simulations showed bilayer mechanoporation at 41% strain, while protein conformational changes occurred earlier, at 35% strain. This suggests that functional impairment of ion channels may precede structural rupture of the membrane. Therefore, protein disruption was defined as the injury threshold at the molecular level. Preliminary results of the FE simulations indicated that the load distribution to sub-cellular elements depends on the deformation mode. By mapping the 35% molecular threshold to the FE

model, we established macroscopic axonal injury thresholds of 15% in tension, 22% in compression, and 30% in shear.

Discussion

We implemented a multiscale method to investigate axonal injury thresholds by connecting cellular deformation with axolemma disruption. This approach establishes a mechanical foundation for defining physiologically relevant injury criteria, supporting the development of more effective diagnostic and protective strategies for TBI and DAI. Future work can examine the role of cytoskeletal variability.

Elevated Moderate-Severe and Bleeding Brain Injury Risk in Older Adults Despite Reduced Kinematic Exposure

Dr Claire Baker, Dr Mazdak Ghajari, Professor David Sharp

Imperial College London, London, Greater London, United Kingdom

Introduction

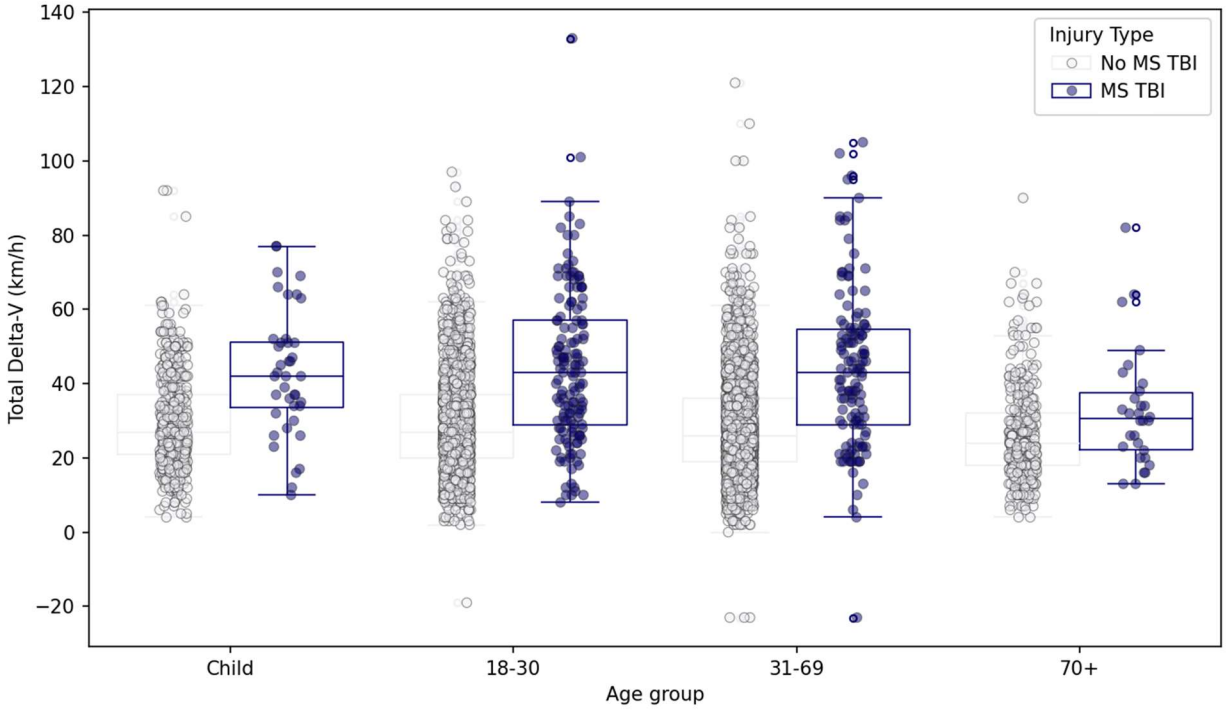
Road traffic collisions (RTC) are a leading cause of global morbidity and often cause traumatic brain injury (TBI) [1]. Age and collision kinematics separately influence TBI outcomes, but their interaction is unstudied. UK Co-operative Crash Injury Study (CCIS) and its successor the Road Accident In-depth Studies (RAIDS) data uniquely capture collision kinematics and clinical data. We previously showed delta-V (change-in-velocity) as a key TBI determinant. We examine age-kinematics influence on TBI prevalence/type [2].

Methods

25,079 subjects were investigated (18,624 from 2000-2010 CCIS, 6,455 from 2013-2024 RAIDS data, 20,336 (81%) had known ages). 3,975 vehicle occupants additionally had valid delta-V (CCIS: 3,345, RAIDS: 630). Mayo TBI was classified as previously described [2]. Injury rates were studied in four groups (18-30/31-69/70+yrs, plus children). TBI/age/delta-V interaction was analysed with Chi-squared and Mann-Whitney statistics.

Results

20,806 injured subjects (58.1%) included 1,613 fatalities. 2,872 TBI subjects included 1,488 (51.8%) moderate-severe, 782 (27.2%) mild, 602 (21.0%) symptomatic, 674 (23.5%) skull fracture, 790 intracranial bleeding (27.5%), 599 (20.9%) subarachnoid haemorrhage, 314 (10.9%) subdural haematoma and 93 (3.2%) axonal injury.



Moderate-severe TBI rate was higher in younger (18-30yrs, χ^2=48.8, p<0.00001) and older (70+yrs, χ^2=10.1, p=0.0014) adults compared to 31-69-year-olds, as was haemorrhage (SAH/SDH/non-specified intracranial bleeding) for both younger (4.0% vs 3.2%, χ^2=8.4, p=0.004) and older (4.6% vs 3.2%, χ^2=7.4, p=0.006) groups. Compared to 31-69yrs, skull fracture was not significantly higher in 70+yrs (p=0.06) but was in 18-30yrs (χ^2=35.6, p<0.00001).

Higher moderate-severe TBI rates in 70+ were not driven by higher RTC kinematics: in fact younger drivers experienced higher delta-V than those aged 70+yrs (31-69yrs versus 70+yrs: U_{MW}=501933.0, p=0.0008; 18-30yrs versus 31-69yrs: U_{MW}=2092839.0, p<0.0001). Occupants with moderate-severe TBI had higher delta-V than those who did not sustain moderate-severe TBI (children: 32.7km/h versus 29.8km/h, 18-30yrs: 44.1km/h versus 29.7km/h, 31-69yrs: 43.8km/h vs 28.3km/h, 70+yrs: 32.7km/h vs 26.2km/h).

Discussion

Older adults are more vulnerable to moderate-severe TBI/bleeding, despite being exposed to reduced RTC kinematics. This increased vulnerability has vehicle design and post-crash response implications. Further work will integrate biomechanically relevant variables (e.g. belt status).

Experimental and Computational Models for Grey-White Interface Damage in Traumatic Brain Injury

Mr Conal Sheridan, Dr Jamie Concannon

University of Galway, Galway, Connaught, Ireland

Introduction

The mechanism of brain damage in concussion is unknown, the unvalidated hypothesis being shear delamination at the grey-white matter interface [1]. Concussion-related damage is non-visible on medical imaging, though repeated concussions contribute to aggressive neurodegeneration [2]. Regional mechanical heterogeneity in the brain is often neglected [3], despite its relevance to strain propagation in impact. This study therefore mechanically characterises ovine brain tissues regionally and describes a novel constitutive formulation for their computational modelling.

Methods

Fresh ovine grey (GM) and white matter (WM) (n=880) from the regions described in Fig.1a were isolated in dissection for unconfined compression, tension and shear to 50%, and grey, white and interface samples were subject to tensile and shear fracture to assess the clinical hypothesis detailed above. A novel bilinear formulation was developed from existing principal-stretch based bilinear models, with anatomy and experimentally informed aligned fibres, using Green-Lagrange strain to control shear behaviour.

Results

GM and WM are asymmetric between compression, tension and shear, with strain-dependent stress varying minimally regionally within the cortical GM and corona radiata (CR) WM (Fig.1a), with deep brain GM and corpus callosum WM differing from the cortex and CR. Fractures occurred in the GM and WM as well as at their interface (Fig.1b), though the interface fracture initiation stress was at least 69% lower than bulk tissues. The proposed model matches existing bilinear model performance in compression and tension (Fig.1c), while reducing shear stress prediction error by up to 62% (Fig.1d).

Discussion

Insignificant variance within the cortex and CR supports their assumed homogeneity in literature [3]. Variability in fracture initiation and propagation locations call the clinical

hypothesis into scrutiny, along with the lower nucleation stress at the grey-white interface, suggesting further mechanical heterogeneity around this interface. Significant compression-tension-shear asymmetry in both tissues highlights the importance of fitting models to multi-mode experimental data, addressed by the proposed Green-Lagrange-based model. This heterogenous and highly asymmetric behaviour is informing the design of next generation headforms for impact damage assessment.

Ex Vivo Biomechanical Evaluation of Self-Expandable Metallic Stent Migration After Hepaticogastrostomy Using a Porcine Pullout Test Across the Liver Parenchyma and Gastric Wall

Prof. Hiroshi Yamada[1], Mr. Luyao Cheng[1], Prof. Yusuke Ishida[2], Prof. Takehiko Koga[2]

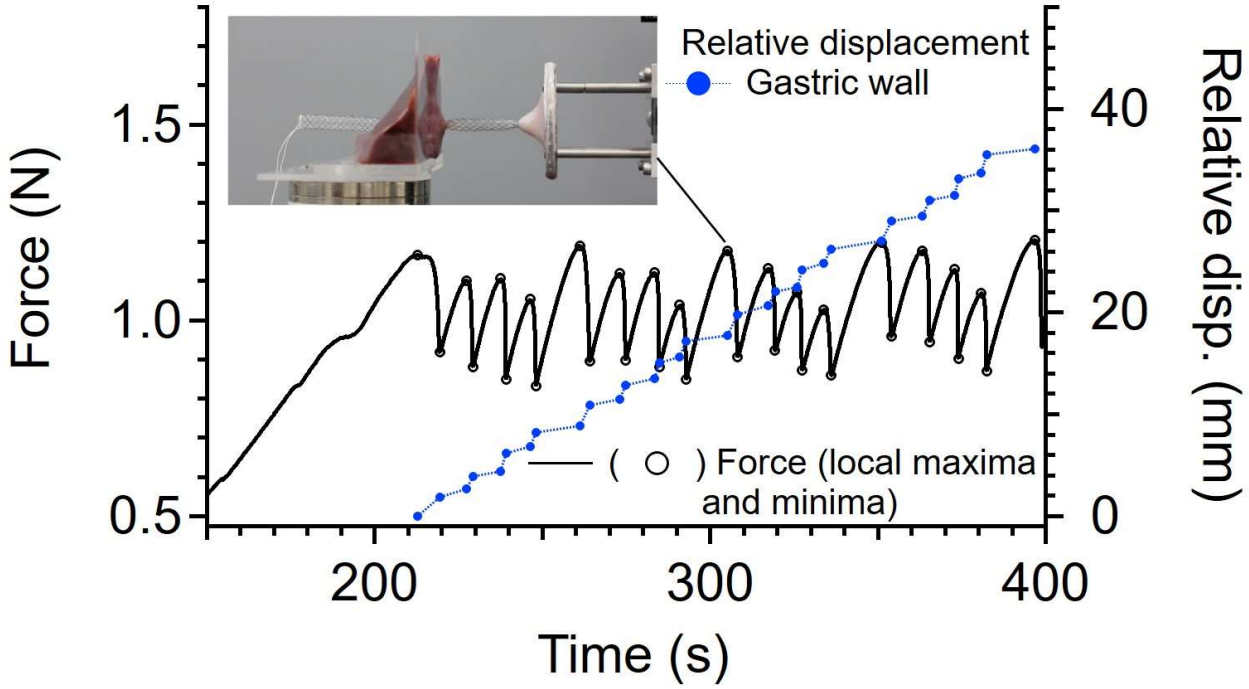
[1]Kyushu Institute of Technology, Kitakyushu, Fukuoka, Japan. [2]Fukuoka University, Fukuoka, Fukuoka, Japan

Introduction

Stent migration is a serious complication that can occur after endoscopic ultrasound–guided hepaticogastrostomy for biliary drainage. Although previous studies have evaluated stent mechanics using biomechanical models of the porcine gastric wall, migration involving both the gastric wall and liver parenchyma has not yet been investigated [1].

Methods

Displacement-controlled pullout tests were performed on a self-expandable metallic biliary stent (HANAROSTENT; Boston Scientific) along directions normal and oblique to the gastric wall surface. The lateral-to-normal velocity ratios were set to 0 for normal pullout and 0.25 for oblique pullout, while the pullout speed was maintained at 0.2 mm/s using two stepper motors. Three axial components of pullout force were measured with a force sensor, and stent motion was recorded on video. Relative displacement (slippage) between the stent and surrounding tissues, as well as axial stent elongation, were quantified by motion analysis of the videos.



Results

The figure shows the time history of axial pullout force during pullout in the normal direction. Relative displacement is also plotted at the local maxima and minima of the force. In the gastric wall, gradual stent slippage occurred at a mean velocity of 0.2 mm/s, with periodic acceleration and deceleration occurring inversely with the cyclic decreases and increases in pullout force. In contrast, liver-side slippage was absent or less than 11% of the total slippage across tests. Mean pullout forces were 1.1 N in the normal direction and slightly lower in the oblique direction.

Discussion

Compared with our previous liver-parenchyma-only pullout tests in the normal direction, the mean pullout force in the present model in the same direction was lower by 0.2 N. Overall, these results indicate that hepaticogastrostomy stent migration is governed predominantly by slippage at the gastric wall, with little contribution from the liver parenchyma, supporting clinical observations that migration occurs primarily on the gastric side.

Lung Parenchyma Characterization Following Ventilator-Induced Lung Injury: Biaxial Tensile Experiments and Inverse Finite Element Constitutive Modeling

PhD Candidate Matthew Shankel, Dr. Arif Badrou, Dr. Mona Eskandari

University of California-Riverside, Riverside, CA, United States

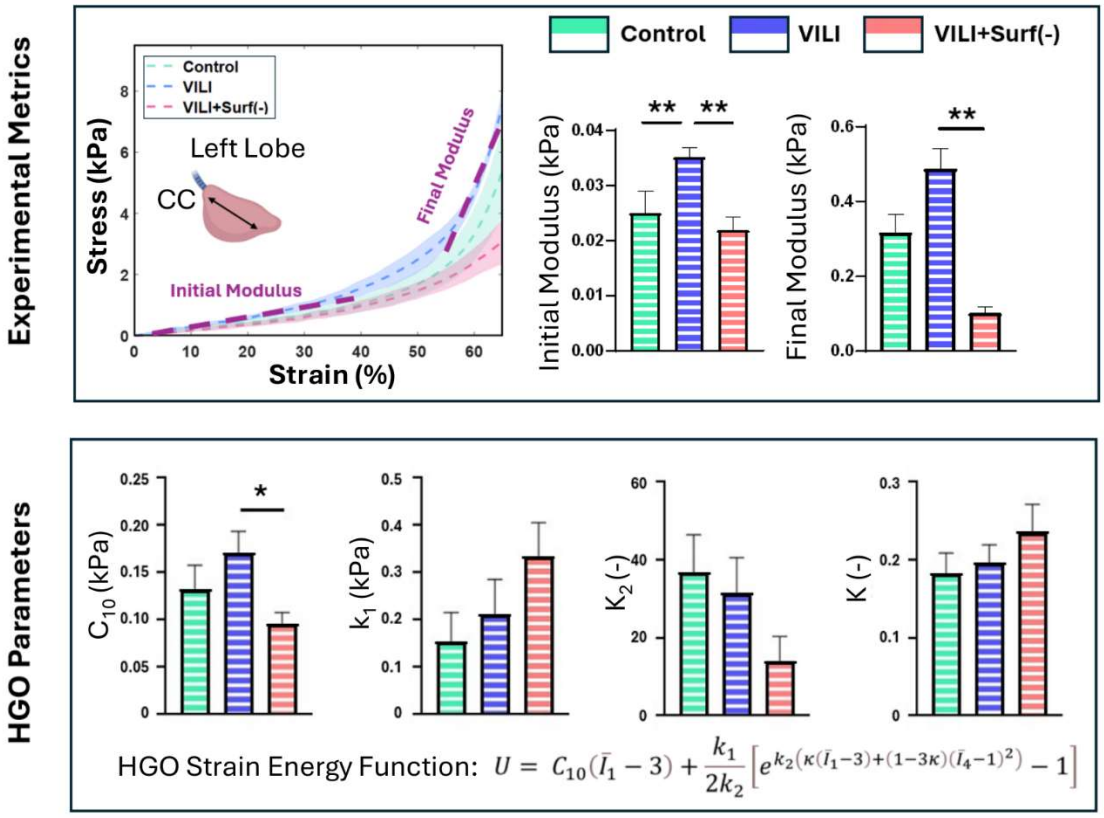
Introduction

Acute respiratory distress syndrome causes heterogeneous lung damage and surfactant disruption [1]. Essential mechanical ventilation can paradoxically damage the lung. Such ventilator-induced lung injury (VILI), exhibited as collagen reorganization, suggests matrix–fiber interactions influence parenchymal mechanics [1]. To investigate these mechanisms, we employ finite element analysis and constitutive modeling to characterize the biaxial tensile behavior of the parenchyma with and without surfactant present during injury.

Methods

Sixteen male Sprague–Dawley rats were euthanized under IACUC approval; six underwent saline wash to remove surfactant. Ventilation groups included control (15 cmH_2O driving pressure, 5 cmH_2O PEEP), VILI and VILI+Surf(–) (17 mL/kg tidal volume, 0 PEEP). Distal parenchyma was stretched biaxially at 1%/s to 65% strain, and First Piola–Kirchhoff stress was computed. Cranial-caudal data are shown due to matching trends across directions. Initial and final moduli were extracted using a bilinear fit. A finite element replica in Abaqus (21,594 quadratic membrane elements, quarter-symmetry, plane stress, incompressible) applied controlled displacements at rake holes [2]. Holzapfel-Gasser-Ogden (HGO) parameters (C_{10}, k_1, k_2, κ) were optimized with MATLAB's *lsqnonlin* using multiple randomized initial guesses. Shapiro–Wilk statistical testing used $p<0.05$.

Results



Maximum stress and modulus were greatest in VILI, while VILI+Surf(–) exhibited similar initial modulus but lower final modulus than control. HGO fits found C_{10} to be increased in VILI. k_1 and κ increased from control to VILI to VILI+Surf(–), whereas k_2 decreased across the same sequence.

Discussion

We find that VILI and VILI+Surf(–) distinctly alter parenchymal mechanics: VILI stiffens at high strain, whereas VILI+Surf(–) softens. HGO parameter shifts suggest altered matrix–fiber load sharing. Across groups, k_1 increased and k_2 decreased from control to VILI to VILI+Surf(–), indicating earlier fiber recruitment with reduced exponential stiffening as

injury increases, consistent with reported collagen elongation after VILI [1]. The high-strain softening in VILI+Surf(–) highlights that such tissue may fail when overstretched. These findings suggest injury-specific matrix–fiber interactions can advance models and ventilation strategies.

Effects of Brain Tissue Preparation on Regional Biomechanics in Tauopathy Mouse Model

Dr. Mohammad Tabatabaei, Dr. Lakiesha Williams

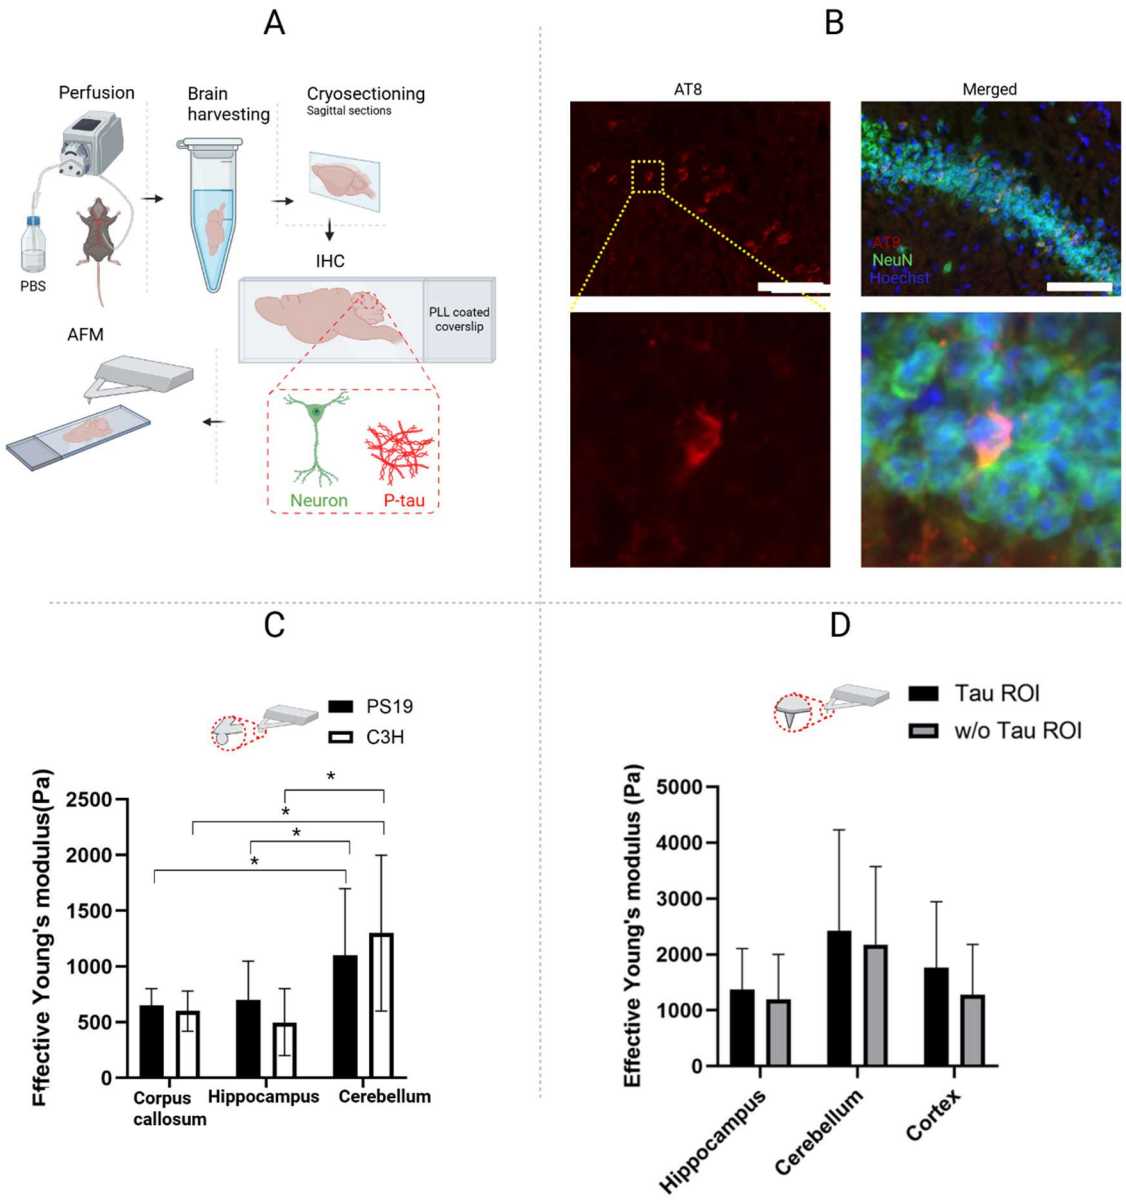
University of Florida, Gainesville, Florida, United States

Introduction

Brain mechanobiology plays a critical role in regulating neuronal function, glial activation, and neuroinflammatory signaling in neurodegenerative diseases such as Alzheimer's disease (AD) [1]. However, brain mechanical properties can be strongly influenced by tissue harvesting and preparation methods, potentially confounding interpretation of biomechanical changes [2]. Despite widespread use of atomic force microscopy (AFM) for brain biomechanics [3], the sensitivity of regional brain stiffness to tissue preparation workflows remains poorly defined. This study establishes a framework to assess how tissue processing influences regional biomechanical measurements in a tauopathy mouse model.

Methods

Sagittal brain sections (20 μm) were obtained from PS19 transgenic mice (n = 3, 9–13 months) and age-matched C3H wild-type controls (n = 3, 9–13 months) following PBS perfusion and snap freezing. Sections underwent immunohistochemical staining for phosphorylated tau (AT8), neuronal nuclei (NeuN), and nuclear labeling (Hoechst) without chemical fixatives (Figure 1A,B). AFM nanoindentation was performed using a quadratic pyramidal probe (0.1 N/m cantilever) to quantify Young's modulus across the hippocampus, cerebellum, and cortex.



Results

Global brain tissue stiffness did not differ significantly between PS19 and wild-type mice across major anatomical regions (Figure 1C). However, pronounced regional mechanical heterogeneity was observed within both groups. Subregions with higher neuronal density, particularly within the hippocampus, exhibited elevated local stiffness values (Figure 1D). Tau-positive regions in PS19 mice frequently overlapped with locally stiffer zones, despite preserved bulk mechanical properties. These findings indicate that regional brain biomechanics are highly sensitive to microstructural organization under the current tissue preparation workflow.

Discussion

These results demonstrate that regional brain biomechanics measured by AFM are strongly shaped by tissue preparation and local microarchitecture, independent of global tissue stiffness. Spatially resolved AFM measurements integrated with neurohistology provide a robust framework for evaluating preparation-dependent biomechanical variability in neurodegeneration. Ongoing studies are extending this approach to directly compare multiple tissue harvesting and sectioning methods, including vibratome-based preparation, to establish standardized biomechanical protocols for Alzheimer's disease research.

[6]Dutch Expert Centre for screening, Nijmegen, Gelderland, Netherlands

Introduction

Dynamic CT imaging enables three-dimensional evaluation of wrist motion and is increasingly used for diagnosing scapholunate (SL) ligament injuries. However, variability in protocols across institutions restricts comparability and hinders standardization. An important consideration is whether to adopt unilateral or bilateral scanning, as unilateral approaches often rely on external reference datasets for diagnosis. This study evaluates whether contralateral referencing in bilateral dynamic CT scanning supports SL injury diagnosis by assessing (1) the influence of scan protocol variation on outcome measures; (2) similarity between wrists of healthy individuals and contralateral healthy wrists of patients; (3) wrist motion symmetry in healthy individuals; and (4) contralateral referencing in patients with a unilateral SL injury.

Methods

This retrospective multicenter study combined data from three cohorts: (1) unilaterally scanned healthy volunteers (RUMC), (2) bilaterally scanned healthy volunteers (AUMC), and (3) patients with arthroscopically confirmed unilateral SL lesions (RUMC). Dynamic CT included one static scan and multiple frames during radial–ulnar deviation (RUD) and flexion-extension (FE). At RUMC, movements were performed freehand with forearm stabilization; at AUMC, motion was guided by a custom device. Scapholunate distance (SLD) was automatically measured at five points on the SL joint during both motions (Figure 1). For each parameter, means were calculated for wrist positions achieved by ≥70% of wrists.

Results

1. **Protocol differences**: Across five SLD measurements and two motions, differences between RUMC and AUMC were greatest during RUD, with mean absolute differences of 0.32 mm (dorsal, range 0.17-0.38 mm) and 0.37 mm (volar, range 0.22-0.45 mm).
2. **Healthy vs. contralateral wrists:** Mean differences ranged from 0.04-0.20 mm (max 0.32 mm), indicating similar motion patterns.
3. **Dominant vs. non-dominant**: Mean differences ranged from 0.03-0.16 mm (max 0.26 mm), showing symmetry within individuals.
4. **SL lesions:** Complete lesions showed mean differences of 0.78-1.25 mm (max 2.08 mm) compared to the healthy side; partial lesions had smaller, localized asymmetries (mean 0.09-0.21 mm, max 0.70 mm).

Discussion

Contralateral referencing in bilateral dynamic CT scanning is both possible and justified for diagnosing unilateral SL injuries. This approach avoids the need for reference datasets and should therefore be considered.

Images (Optional)

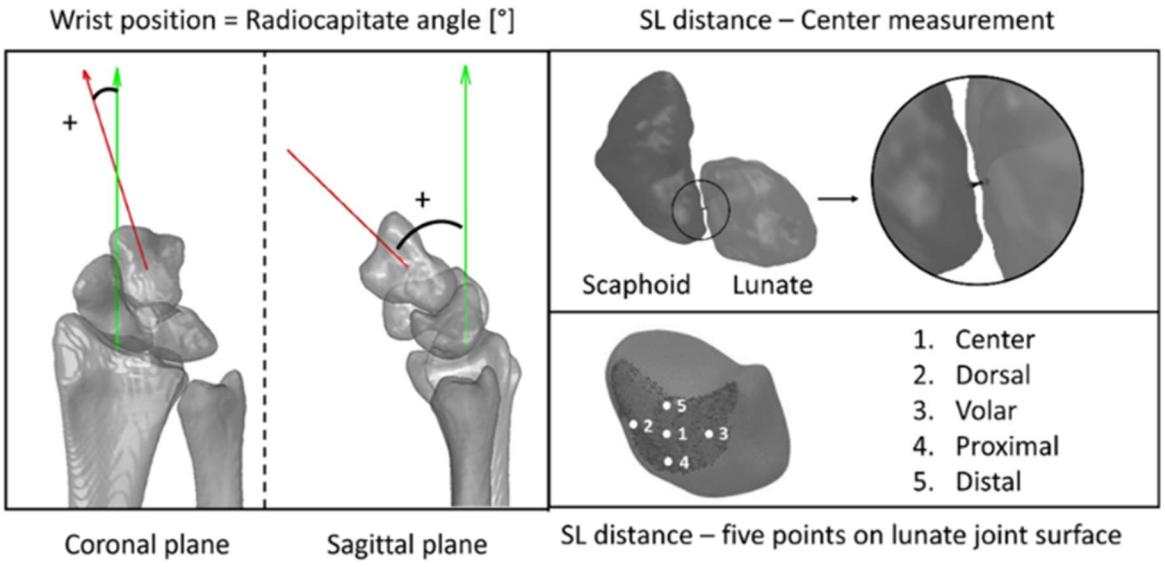

Figure 1: Visualizations of wrist position determination and automatic SLD measurements. The wrist position during RUD is defined as the angle between the radius axis and capitate axis in coronal plane. The wrist position during FE is defined as the angle between the radius axis and capitate axis in sagittal plane. The SLD is measured as the shortest Euclidean distance between the lunate and scaphoid joint surface at five pre-defined points.

Quantifying In-Vivo Lumbar Spine Kinematics Using Biplanar Videoradiography and MRI.

Miss Katherine Prentice[1], Miss Lauren Swain[1], Mrs Jenny Williams[1], Dr Michael Ward[2], Dr Emily Kelly[2], Professor Akbar Javadi[2], Professor Tim Holsgrove[2], Professor Jude Meakin[2], Professor Cathy Holt[1], Dr David Williams[1]

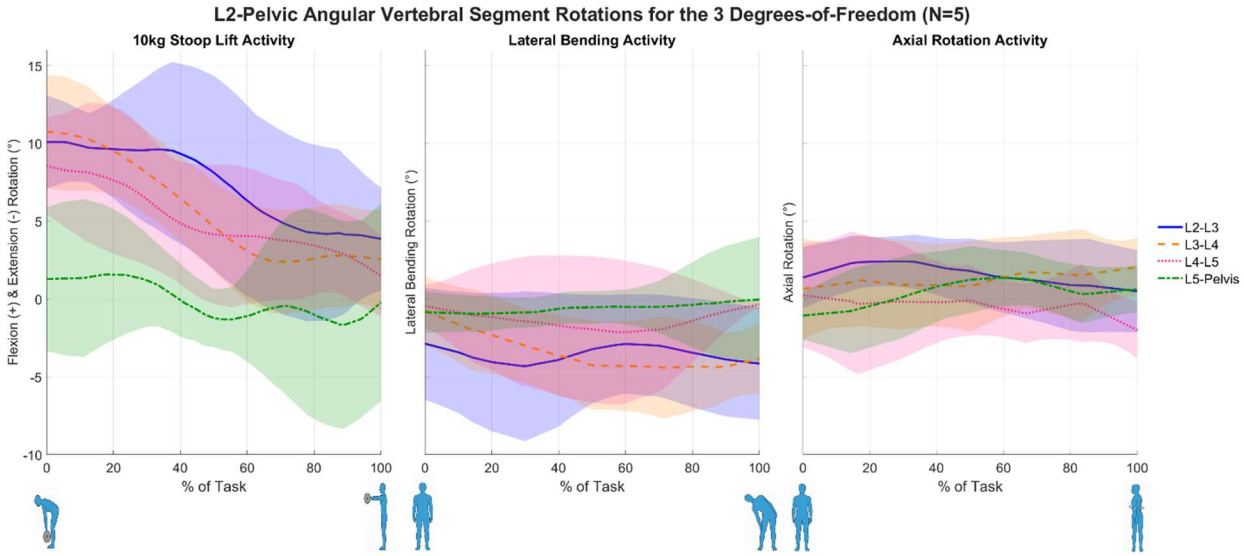
[1]Cardiff University, Cardiff, Wales, United Kingdom. [2]University of Exeter, Exeter, England, United Kingdom

Introduction

Spinal disorders are a major cause of disability, costing the UK healthcare system an estimated £3.2 [1] billion annually for back pain alone. Accurately measuring and assessing in-vivo spinal kinematics presents a significant challenge, both in improving treatments for spinal conditions and in providing a fundamental understanding of normal spinal motion. To address this, an in-vivo imaging pipeline combining Biplanar Videoradiography (BVR) and Magnetic Resonance Imaging (MRI) was developed to measure the direct movement of the vertebrae. This enables the capture of dynamic measurements of vertebral motion in the lumbar spine of healthy individuals during activities. The aim of this study is to quantify the inter-individual variability in spinal movement to establish a baseline of normal variations.

Methods

Subject-specific L2-Pelvic spinal kinematics was collected from five healthy-reporting participants. Participants underwent 3T MRI (T1-VIBE, Magnetom Prisma, Siemens) which was manually segmented into 3D bone models (Simpleware Scan IP, Synopsis). Anatomical coordinate systems were applied to each individual vertebra. BVR measurements (10Hz, 3.33ms, 85kVp, and 320mA) were obtained for three activities: stoop lift with a 10kg load, lateral bending, and axial rotation. Bone position and orientation for the lumbar vertebrae and pelvis were calculated by matching 3D bone models to BVR images (DSX Suite, C-motion, Inc.). Intervertebral kinematics were calculated (MATLAB, MathWorks, Inc.) based upon International Society of Biomechanics standards.



Results

As shown in Figure 1, flexion-extension angular RoM values were 6.2°, 8.2°, 7.1°, and 1.5° for levels L2-L3 through L5-Pelvis, respectively. Corresponding values for lateral bending and axial rotation were 1.3°, 3.1°, 0.1°, and 0.8° and 0.9°, 1.4°, 1.8°, and 1.7° respectively.

Discussion

Significant variability was observed between participants, as the contribution of each functional vertebral unit to overall lumbar spine motion differed for individual participants. This dataset establishes a comprehensive reference for healthy spinal kinematics, creating a baseline essential for identifying pathological deviations. These findings lay the groundwork for future clinical advancements in the diagnosis, treatment, and prevention of spinal disorders.

Comparison of Hip Contact Forces Across Skin Marker and Dual Fluoroscopy Informed Musculoskeletal Models in Femoroacetabular Impingement Syndrome and Asymptomatic Controls

Ms. Brooklyn Vargas BS, Mr. Seth Kussow BS, Mrs. Lindsay Schuring MS, Mr. Rich Lisonbee MS, Dr. Jared Zitnay PhD, Dr. Scott Uhlrich PhD, Dr. Andrew Anderson PhD

University of Utah, Salt Lake City, UT, United States

Introduction

Cam femoroacetabular impingement syndrome (FAIS) has been identified as a factor in the development of hip osteoarthritis, yet specific biomechanical mechanisms driving joint degeneration remain unclear. Comparing the biomechanics of FAIS to asymptomatic cam morphology (ACM) may help us better understand the pathophysiology of FAIS. While skin marker data (SM) is widely used for biomechanical analysis, dual fluoroscopy (DF) directly captures bone motion and avoids soft tissue artifact [1]. This study investigated: (1) differences in hip joint contact forces (HCFs) between FAIS and ACM using musculoskeletal modeling during level walking and (2) the impact of motion capture modality used for scaling and kinematics on HCF estimations.

Methods

Sixteen participants with FAIS (7M/9F) and thirteen controls with ACM having similar demographics (7M/6F) performed level walking at self-selected speeds on an instrumented treadmill in this IRB-approved study. A full-body skin marker set was used, while DF data were only available for landmarks of the pelvis and the side of interest. HCFs were estimated in OpenSim [2,3]. Three simulations were performed per participant: 1) SM scaling and kinematics, 2) DF-informed scaling and kinematics, and 3) DF-informed scaling with SM kinematics (DF-SM). HCFs were compared throughout gait using statistical parametric mapping ($p \leq 0.05$).

Results

For all simulated conditions, HCFs were not significantly different between FAIS and ACM groups. For both FAIS and ACM groups, each component of HCF was significantly increased using DF and DF-SM compared to SM (Figure 1). Minimal differences were found between DF and DF-SM conditions (Figure 1).

Discussion

Individuals with FAIS exhibited similar HCFs during walking compared with ACM, regardless of the motion capture modality used. Differences between the SM and DF results may be attributed to higher accuracy in model scaling, specifically improved scale factors and pelvic tilt, when using DF data. The similarity between DF and DF-SM simulations further suggests that more accurate model scaling may yield reliable results without requiring DF data for kinematics, significantly reducing the time and labor demands of DF.

Images (Optional)

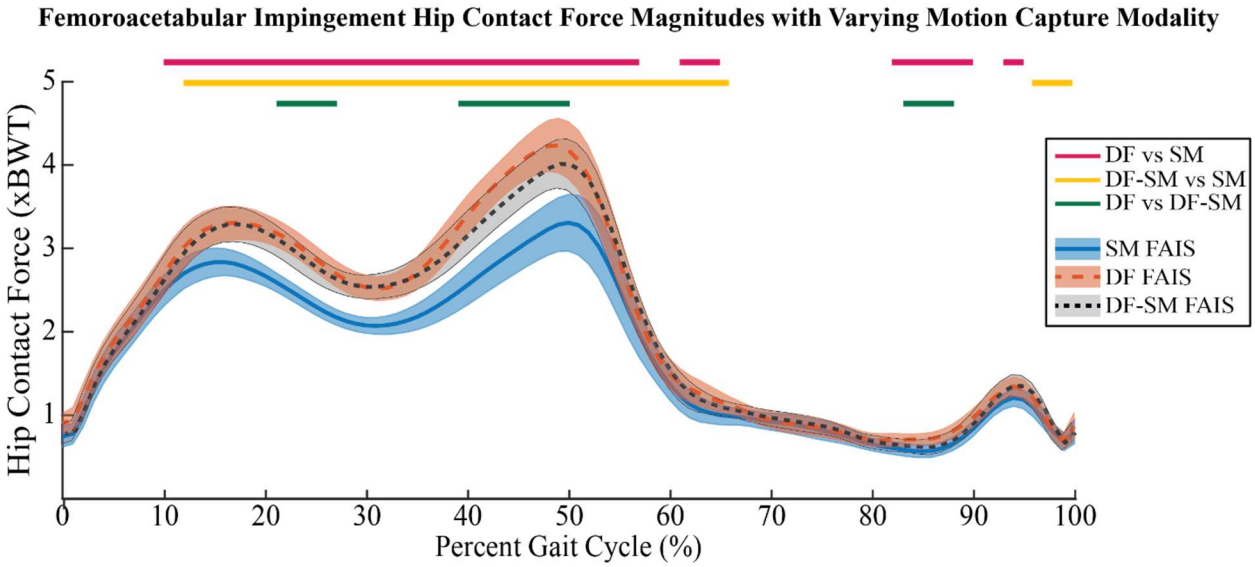

Figure 1: Hip joint contact force magnitudes during level walking in the femoroacetabular impingement syndrome (FAIS) cohort. Results were simulated under three condtions: (1) using skin marker (SM) data, (2) using dual fluoroscopy (DF) data, and (3) using DF data for scaling combined with SM data for kinematics (DF-SM). Differences detected by statistical parametric mapping ($p \leq 0.05$) are displayed above the figure.

Effect of Embedding Coupling-Curves-Based Knee Models Within Inverse Kinematics Compared to Bi-Plane Fluoroscopy-Driven Kinematics

Dr. Mehran Hatamzadeh[1], Mr. Kuan Hsien Wu[2], Dr. Tung-Wu Lu[2,3], Dr. Raphael Dumas[1]

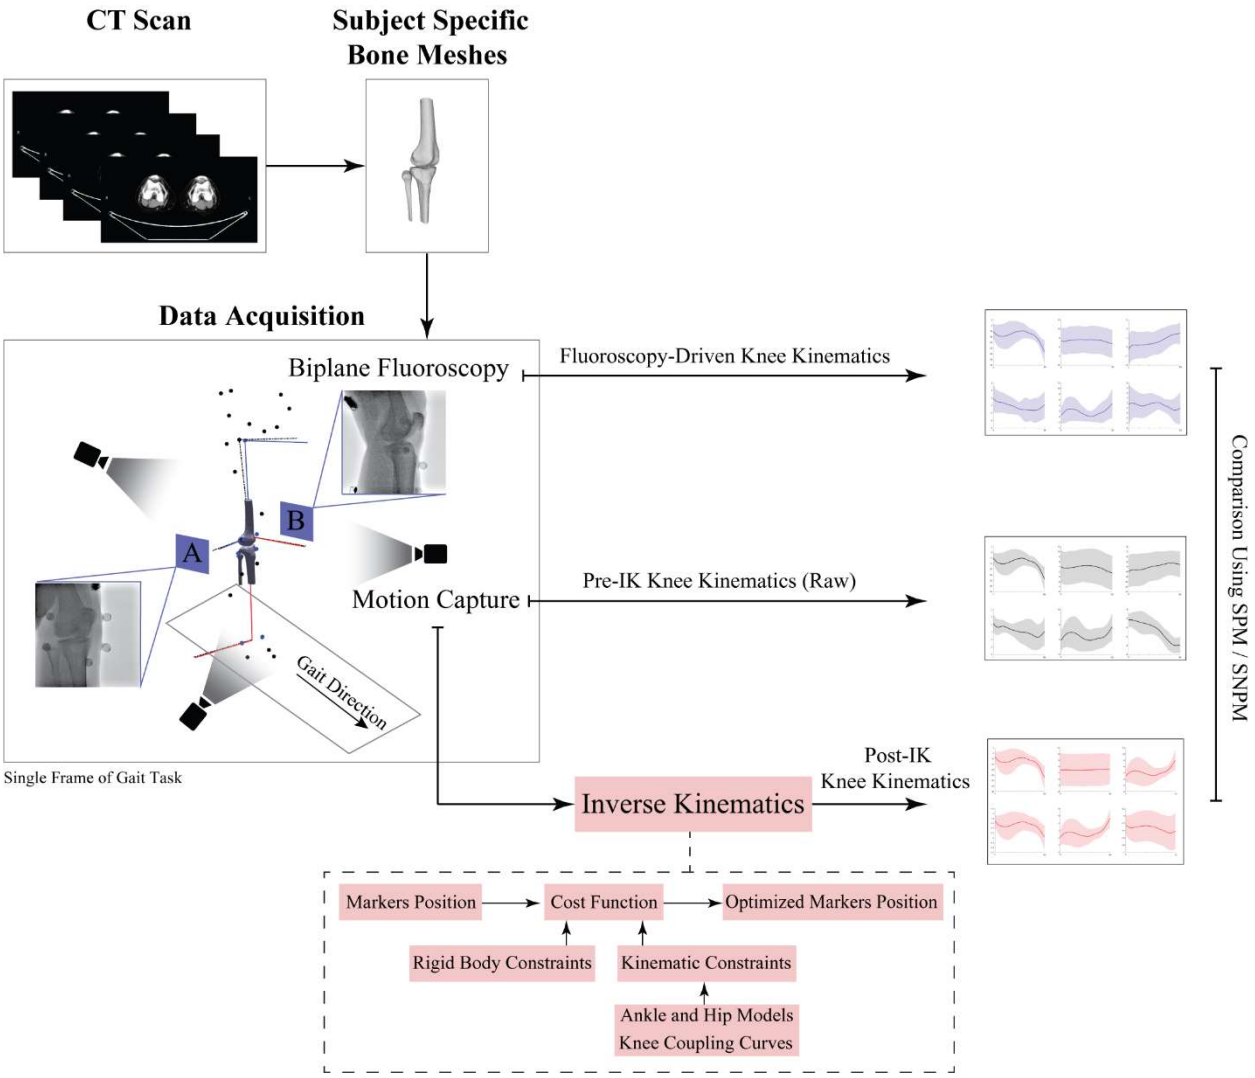
[1]Laboratory of Biomechanics and Shock Mechanics (LBMC), University Gustave Eiffel, University Claude Bernard Lyon 1, Lyon, Rhone, France. [2]Department of Biomedical Engineering, National Taiwan University, Taipei, Taiwan, Taiwan. [3]Department of Orthopedic Surgery, School of Medicine, National Taiwan University, Taipei, Taiwan, Taiwan

Introduction

Accurate knee motion analysis requires understanding tibiofemoral and patellofemoral joints' motion, each of which is described by 6 kinematic parameters that are coupled together due to knee ligamentous constraints and articular geometry. Consequently, researchers have developed simplified knee models that estimate its 6-DOF kinematics from fewer inputs, using either flexion alone (1-DOF) or flexion and internal rotation (2-DOF). However, their performance within a lower-limb inverse kinematics (IK) framework remains unclear. Therefore, this research assesses whether or not incorporating coupling-curve-based knee models into IK improves marker-based knee kinematics accuracy compared to the gold standard bi-plane fluoroscopy.

Methods

Eleven healthy participants underwent CT imaging to generate subject-specific bone meshes. They performed functional tasks in a bi-plane fluoroscopy system while skin markers were recorded simultaneously. Ground-truth 6-DOF tibiofemoral kinematics were obtained using fluoroscopy and bone meshes (Figure 1), while marker-based kinematics were computed before and after IK using hip (spherical) and ankle (universal) models, and five published coupling-curve-based knee models [1-5]. The ensemble kinematic curves' similarities were assessed using one-dimensional statistical parametric/nonparametric (SPM/SNPM) mapping.



Results

During gait task, none of the coupling-curve-based models improved knee kinematics accuracy. For all three rotations, analyses show that adding coupling-curve constraints to the IK procedure significantly degrades results. For the three translations, although RMSE values differed, SPM/SNPM found no significant differences between fluoroscopic kinematics and those from raw markers (RMSE 2.4–2.9 mm) or IK using Walker-Rajagopal [1,2] (RMSE 2–3.1 mm), Guan [3] (RMSE 2–4.2 mm), or Hume [4] coupling curves. In contrast, embedding Koo's [5] coupling curves in IK significantly degraded translation accuracy, with RMSEs of 5.06 mm (lateral–medial), 6.2 mm (anterior–posterior), and 5.8 mm (superior–inferior).

Discussion

Across walking trials, the coupling-curve–based knee models (e.g., Walker [1] models implemented in OpenSim by Rajagopal [2]) did not improve accuracy, indicating that alternative methods are needed for more reliable knee-kinematics computation in musculoskeletal modeling.

Biophysical Simulations Reveal the Impact of Tendon Stiffness on the Interplay Between Intrinsic Mechanics and Sensorimotor Feedback in Unsteady Movements

Dr. Hansol X. Ryu[1,2], Dr. Surabhi N. Simha[2,1], Prof. Gregory S. Sawicki[1], Prof. Lena H. Ting[2,1]

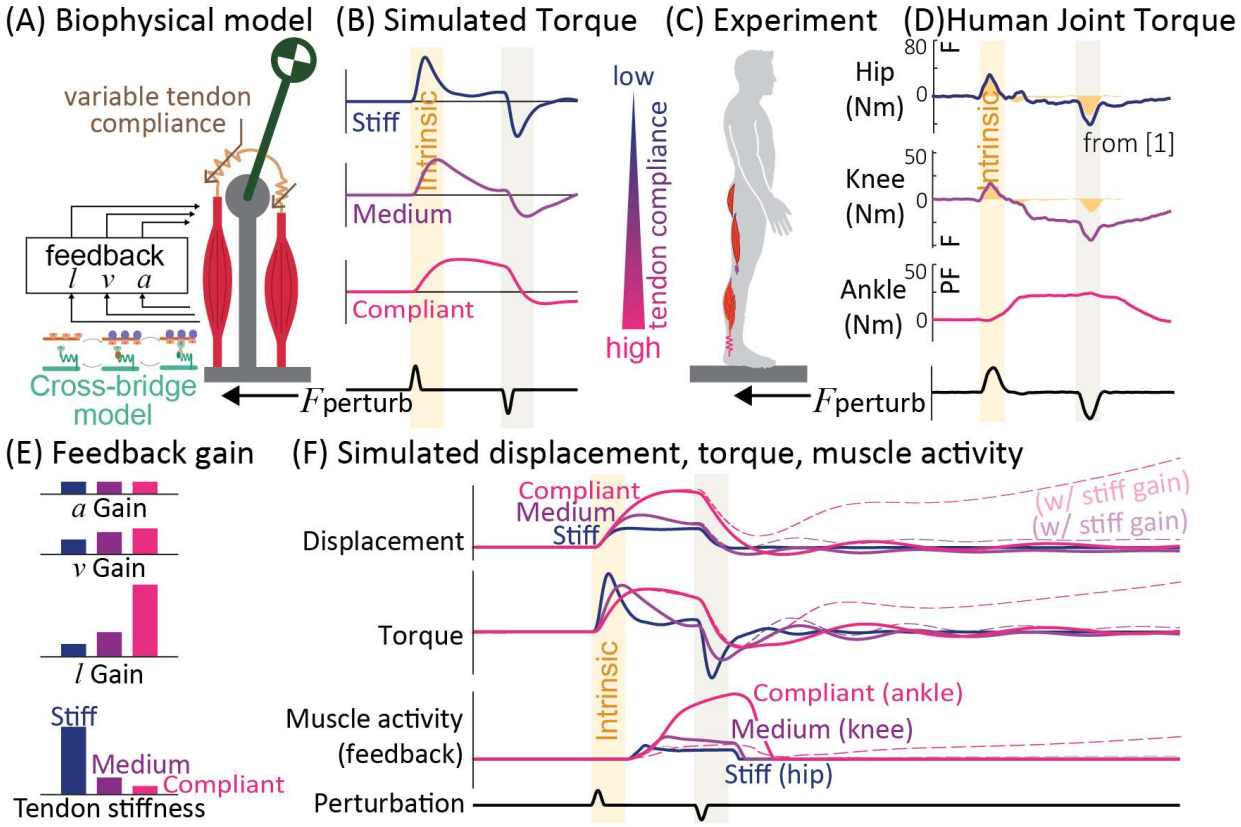
[1]Georgia Institute of Technology, Atlanta, GA, United States. [2]Emory University, Atlanta, GA, United States

Introduction

Control of unsteady movement depends on contributions from both instantaneous intrinsic mechanics of muscle-tendon unit and delayed sensorimotor feedback [1,2], with different ratio of contributions at different joints. Rapid muscle stretches due to perturbations are resisted by muscle short-range stiffness (SRS), a transient property arising from muscle cross-bridges. Joint torques in perturbed human balance rely primarily on intrinsic stiffness at the hip joint and sensorimotor feedback at the ankle [1,3]. Here we leverage a novel biophysical muscle model to systematically test the impact of tendon stiffness on the interplay between intrinsic and neural contributions to perturbation rejection. We hypothesized that tendon compliance reduces intrinsic stiffness contributions to unsteady movement control by absorbing the perturbation-induced displacement, thereby reducing the SRS contribution and increasing the reliance on feedback-driven activation.

Methods

We used a novel biophysical muscle model [4] that captures muscle SRS [5]—a property absent from standard Hill-type models [3]—in a closed-loop inverted pendulum simulation to study how muscle-tendon interactions influence control of unsteady movements. Muscle activation was modulated by feedback on simulated half-sarcomere length, velocity, and acceleration, with biologically realistic delays. Feedback gains were tuned to achieve stable steady-state after perturbation.



Results

Our model reproduced key trends seen in human standing balance [1]. Models with a stiff tendon (e.g. hip) had prominent and rapid increase in joint torque at perturbation onset, originating from instantaneous forces due to muscle SRS and low reliance on neural feedback. As tendon compliance increased (knee to ankle), the sharp rise in torque diminished, and more feedback-driven muscle activation (i.e. higher feedback gains) was required to stabilize the inverted pendulum.

Discussion

Our result shows that tendon compliance absorbs displacement from perturbations and reduces the SRS engagement in muscle fibers – shaping the balance between reliance on intrinsic mechanical responses and requirement for neural feedback to restore balance.

[4]Department of Civil and Mechanical Engineering, Technical University of Denmark (DTU), Kongens-Lyngby, Capital Region, Denmark

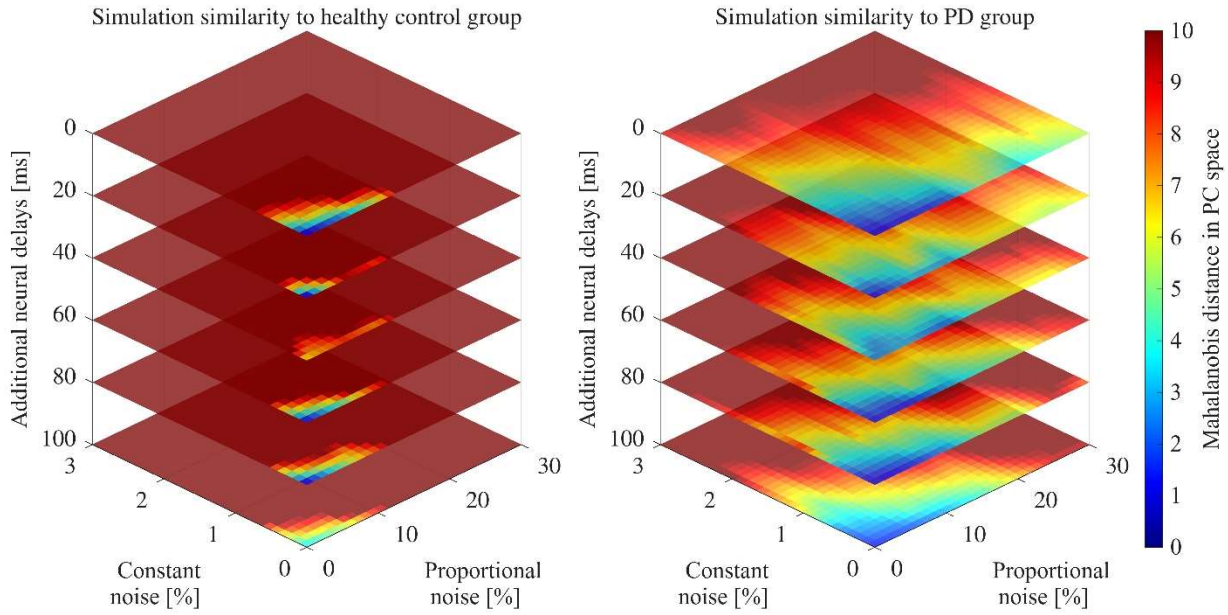
Introduction

Postural instability represents one cardinal symptom in Parkinson's disease (PD). However, underlying processes leading to these changes in postural control are still not fully understood. In this paper, we use predictive simulations to investigate the influence of internal sensorimotor parameters on postural control and to identify which parameter changes reproduce PD-like postural characteristics. Here, we focus specifically on alterations in motor noise and neural feedback delays as key internal parameters.

Methods

We used a previously published neuromusculoskeletal model [1] and forward dynamic simulations within the software framework SCONE [2]. The model consisted of 18 muscles and 6 degrees of freedom. Simulations were performed for quiet upright standing. We systematically increased motor signal noise and neural delays independently to assess their effects on postural control. Motor noise consisted of constant and signal-dependent Gaussian components. Additional neural delays were applied equally across all feedback pathways.

We used data from 31 PD patients and 31 age- and sex-matched healthy control participants (HCs) and applied a principal component analysis (PCA) to evaluate simulation results and to determine the simulations' agreement with experimental data. The PCA was based on kinematic outcomes, including joint angles, and sway-related center of pressure parameters. For analysis, we used the first 3 principal components, which explained over 70% of experimental data variance.



Results

Simulations showed that postural control behavior was close to HCs for small amounts of signal noise (Figure 1). Increasing motor noise and neural delays shifted simulations toward PD-like behavior, producing only minor differences in PCA projection distances compared with experimental PD data and increasingly separating them from HCs in PCA space at the same time.

Discussion

We found that simulations with small amounts of motor signal noise best describe postural control of HCs. Simulations with higher signal noise and additional neural delays showed reduced overlap to HCs but still considerably higher similarities to PD patterns. It has to be mentioned that especially variances of PD patients' sway parameters were significantly higher. Therefore, individual postural control performance is crucial for estimating personal internal parameters in future simulation work.

Emergence of Ankle-to-Hip Strategy Transition in Upright Posture via Reinforcement Learning with Biomechanical and Physiological Constraints

Dr. Seongwoong Hong Ph.D.[1], Professor Joo H. Kim Ph.D.[2], Professor Sukyung Park Ph.D.[3]

[1]KAIST InnoCORE AI Co-Research & Education for innovative Drug Institute, Korea Advanced Institute of Science and Technology (KAIST), Yuseong-gu, Daejeon, Korea, Republic of. [2]Department of Mechanical and Aerospace Engineering and Center for Urban Science and Progress, New York University, Brooklyn, New York, United States. [3]Department of Mechanical Engineering, Korea Advanced Institute of Science and Technology (KAIST), Yuseong-gu, Daejeon, Korea, Republic of

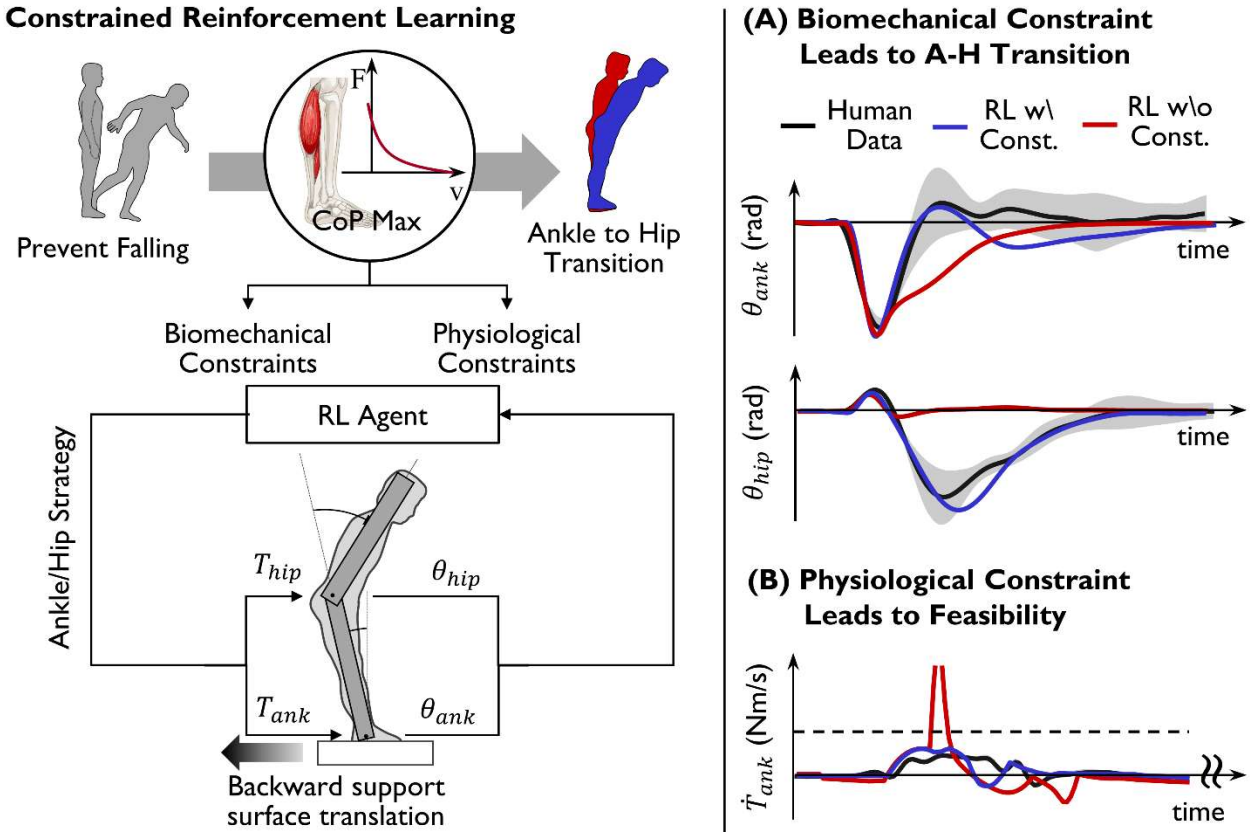
Introduction

Human balance control exhibits adaptability, such as the flexible transition between ankle and hip strategies in response to environmental perturbations. Understanding these mechanisms is critical given the fall risks associated with aging and neurological disorders. However, modeling this adaptability requires a framework that integrates environmental adaptation with biomechanical and physiological constraints. While Reinforcement Learning (RL) is promising for such nonlinear tasks, handling strict constraints remains challenging. Here, we propose a constraint-based RL framework that systematically incorporates these constraints, aiming to validate its ability to accurately reproduce and predict human balance control mechanisms.

Methods

We systematically applied biomechanical and physiological constraints using both hard and soft constraint approaches to examine their effects on learned control strategies within a PPO-based framework. The model was validated against human experimental data under backward perturbations.

Results



The model trained with the proposed RL framework successfully reproduced the gradual transition from ankle to hip strategy observed in humans as perturbation magnitude increased, across various initial conditions. This transition emerged only in models incorporating constraint for biomechanical ankle torque limits; unconstrained models consistently relied on ankle torque and failed to exhibit strategy transition. Furthermore, physiological torque rate constraints were essential for generating feasible torque profiles; without these constraints, joint torque rates reaching up to 20 times the physiological limits were observed. These findings indicate that biomechanical constraints act as drivers

of strategy selection in the reinforcement learning agent, whereas physiological constraints serve as execution conditions ensuring movement fidelity.

Discussion

These results demonstrate that the proposed RL model provides a valid computational approach for exploring interactions between constraints and motor control strategies. This framework can be extended to predict the effects of physical impairments, such as musculoskeletal disorders or neurological deficits, on postural stability. For instance, sensory transmission delays due to aging or neurological injury can be modeled as increased state observation latency, while muscle weakness can be represented as reduced joint torque limits, enabling predictions of how such constraint changes modify compensatory control strategies for postural maintenance. This approach is expected to contribute to understanding the stability-efficiency trade-off strategies humans adopt under various physical constraints.

Impact of Age-Related Changes in Muscle Function on Postural Control Strategies in Sit-to-Stand: A Musculoskeletal Simulation with Multi-Objective Optimization

Dr. Shoma Kudo[1,2], Prof. Akinori Nagano[3], Dr. Takuma Inai[1,2], Dr. Masahiro Fujimoto[1,2]

[3]College of Sport and Health Science, Ritsumeikan University, Kusatsu, Shiga, Japan

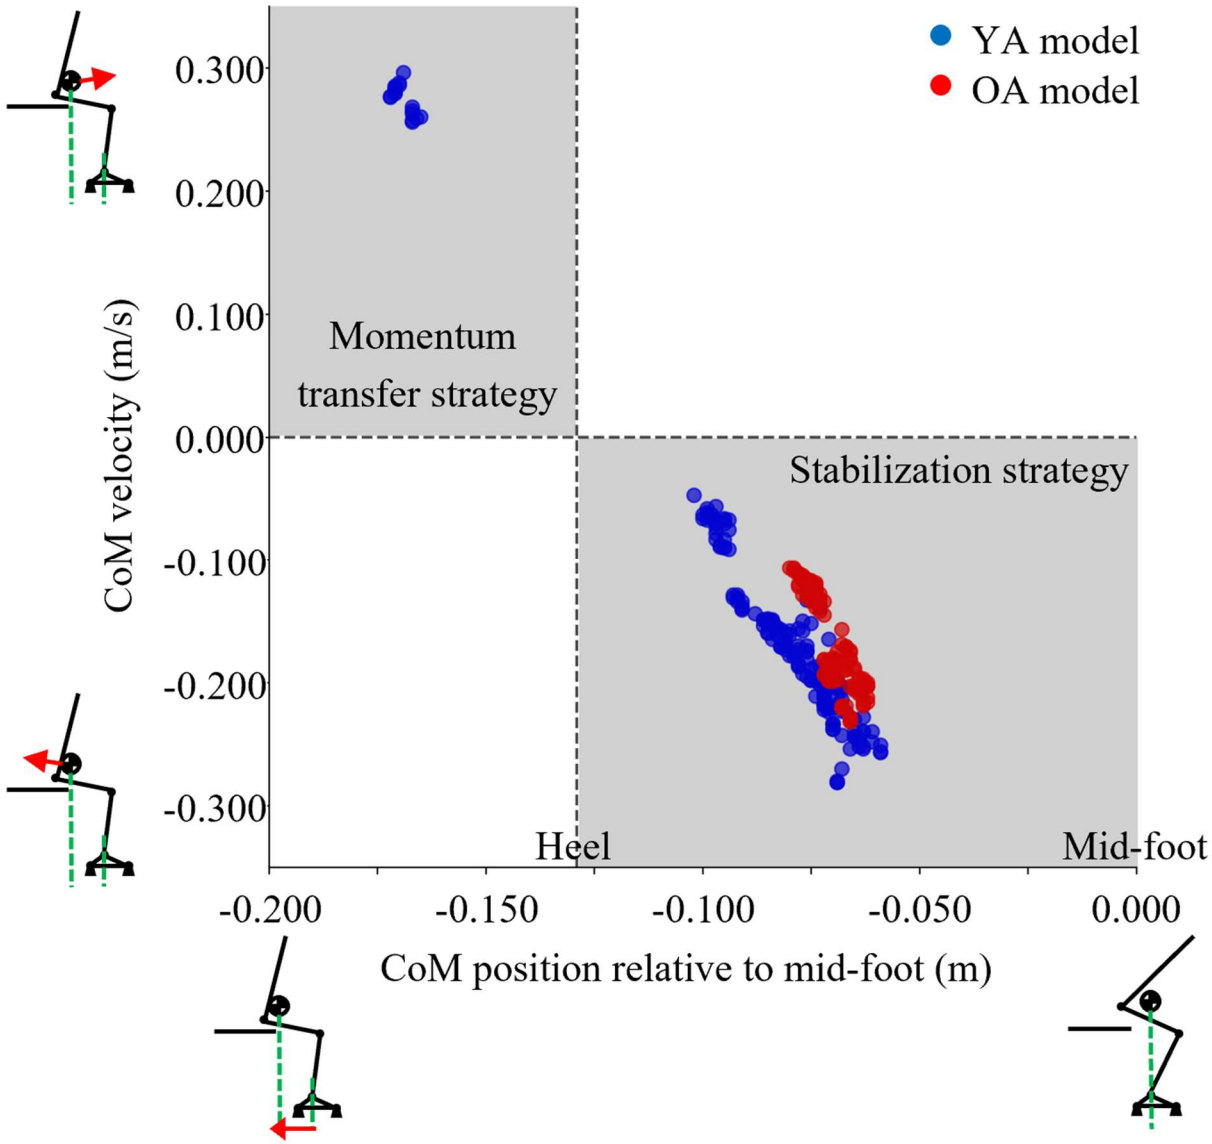
Introduction

Sit-to-stand (STS) is a fundamental activity that requires balancing multiple objectives (e.g., postural stability and muscular effort), and the prioritization of these objectives is considered to change with aging [1]. Older adults often adopt a conservative strategy to ensure stability, locating the center of mass (CoM) within the base of support (BoS) before seat-off—stabilization strategy. In contrast, younger adults tend to initiate STS while the CoM is located posterior to the BoS, utilizing greater horizontal momentum to bring the CoM inside the BoS at seat-off—momentum-transfer strategy. However, it remains unclear whether the difference in STS strategy arises from age-related changes in muscular function or from different prioritization of CoM control objectives. This study aimed to clarify the impact of changes in muscle function on STS strategy.

Methods

STS was simulated using two musculoskeletal models representing the muscle functions of young adults (YA) and older adults (OA) through an evolutionary multi-objective optimization [2]. The optimization was executed to find muscle activation patterns that achieve an upright posture from sitting while considering three objectives: (1) the distance of CoM from the BoS at seat-off, (2) CoM velocity at seat-off, and (3) the sum of muscle activation during STS. For each model, the distribution of successful solutions (i.e. Pareto front) and its range were evaluated.

Results



In the OA model, the CoM remained within the BoS at seat-off in all solutions, whereas the YA model located the CoM both inside and outside the BoS (Figure). For the YA model, the ranges of CoM position and CoM velocity were 0.059 to 0.172 m and −0.281 to 0.296 m/s.

For the OA model, the corresponding ranges were 0.062 to 0.080 m and −0.232 to −0.107 m/s.

Discussion

The OA model adopted only a stabilization strategy, showing narrower feasible ranges for CoM position and velocity, while the YA model demonstrated both stabilization and momentum-transfer strategies. These findings suggest that changes in muscle function limit CoM control during STS, forcing older adults to adopt strategies that prioritize stability at seat-off.

Direction-Specific Muscle Force Profile During Y-Balance Test

Mr. Dongho Ha[1], Mr. Taewoong Kong[1], Ms. Hyemin Han[1], Dr. Hoon Kim[1,2]

[1]Department of Software Convergence, Soonchunhyang University, Asan-si, Chungcheongnamdo, Korea, Republic of. [2]Department of Sports Medicine, Soonchunhyang University, Asan-si, Chungcheongnamdo, Korea, Republic of

Introduction

Y-Balance Test (YBT) is a test for assessing balance while reaching a foot in three directions to evaluate joint instability in a lower limb. Previous studies have commonly utilized electromyography to muscular coordination during YBT. However, electromyography only measures superficial muscle activation and cannot fully reflect muscle functions such as muscle force [1] which is important to understand neuromuscular function during balance. Therefore, the purpose of this study was to quantify lower-body muscle forces during YBT using musculoskeletal simulation.

Methods

Eight healthy people performed three trials for each direction of YBT with barefoot, while 3D position of reflective markers, ground reaction force, and muscle activations were collected. Then, joint angles, moments, and muscle forces were calculated using inverse kinematics, inverse dynamics, and static optimization in OpenSim, respectively. We quantified muscle forces from 12 lower-limb muscles while performing YBT in three directions (e.g., anterior (ANT), posterolateral (PL), posteromedial (PM)).

Results

Figure 1 summarizes peak normalized muscle forces (N/body weight) of 12 lower-limb muscles during YBT in three directions. Vastus lateralis (ANT: 4.2, PL: 3.7, and PM: 5.0) and soleus (ANT: 3.2, PL: 2.4, and PM: 3.1) exhibited consistently high forces across all directions. Gluteus maximus generated only small forces in ANT (0.7) but much larger forces in PL (2.7) and PM (2.6). Vastus lateralis, soleus, and vastus medialis generally exhibited greater forces in PM (5.0, 3.1, and 1.7) than PL (3.7, 2.4, and 1.2).

Discussion

In general, vastus lateralis and soleus were consistently serving as primary stabilizers. The marked contrast in gluteus maximus force (Anterior vs. Posterior) indicates a fundamental

shift from a knee- to hip-dominant strategy in posterior reaches. Moreover, PM exhibited a higher mechanical demand than the PL. This high demand resulted from complex rotational stress associated with crossing the body's midline, requiring greater force generation from the vasti and soleus. Therefore, clinicians should consider performance in each YBT direction as an index of direction-specific mechanical demands. Reduced reach in a given direction may indicate insufficient contribution of the primary stabilizing muscles and guide targeted strengthening.

Predictive Neuromuscular Simulations Indicate That Spinal Control Does Not Solely Explain Steady-State Human Walking

Dr. Mark Price, Dr. Nidhi Seethapathi

Massachusetts Institute of Technology, Cambridge, MA, United States

Introduction

Neural control of locomotion is thought to be hierarchical, with spinal reflexes governing the steady-state rhythm and supraspinal input governing volitional control. While spinal reflex-based simulations replicate rhythmic walking patterns, it remains unclear if they replicate other aspects of steady-state walking, like foot placement control [1]. We hypothesize that supraspinal control is required for human-like foot placement control during steady-state walking.

Methods

We simulated walking with a 3D neuromuscular model implementing two controllers: (i) a Reflex-Control (RC) model using a spinal reflex network [2] optimized via CMA-ES, and (ii) a Supraspinal-Control (SC) using full-body state information [3] trained via reinforcement learning. For both models, we added sensorimotor noise to simulate variability in the locomotor patterns. We analyzed the foot placement control signatures, specifically the R^2 values for predicting the next foot placement from past CoM states, contrasted with an autoregressive baseline predicting future foot placement from past swing foot states.

Results

The RC model reproduced normative human joint kinematics. However, it did not exhibit human-like CoM-to-foot placement predictions in the fore-aft direction (~60% model vs. ~30% human) and lateral foot placement was never better predicted by CoM states than an autoregressive baseline, unlike humans [4]. In contrast, the SC model, despite poor reproduction of normative joint kinematics, better reproduced human foot placement control signatures; its CoM-to-foot placement predictions were human-like in both lateral (~85% model vs. ~80% human) and fore-aft (~40% model vs. ~30% human) directions. Like humans, its lateral foot placement was better explained by CoM states than an autoregressive baseline.

Discussion

Overall, we conclude that conventionally optimized reflex control is insufficient for explaining steady-state human walking, particularly for foot placement control. The RC

model's superior replication of normative joint mechanics suggests the importance of spinal control in regulating the rhythmic pattern of walking, while the SC model's more human-like foot placement control suggests that supraspinal control is involved in stabilizing steady state locomotion.

Images (Optional)

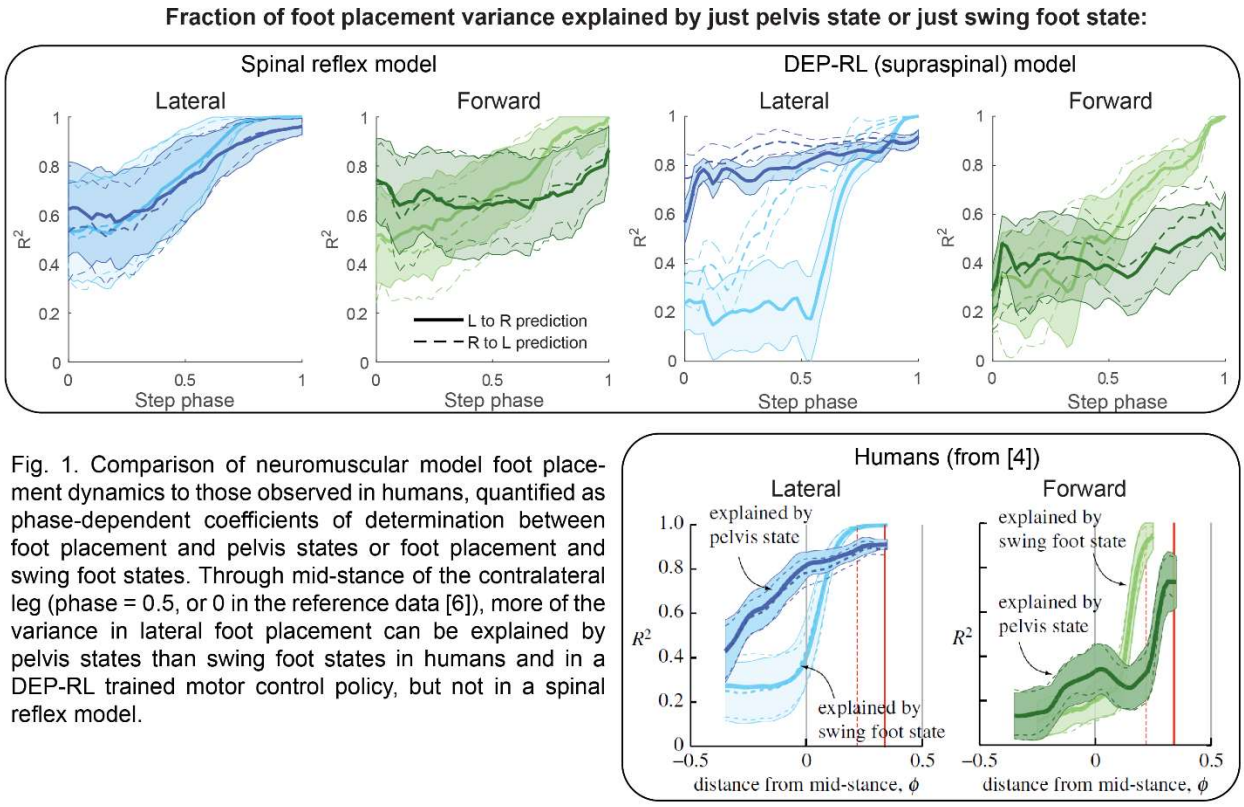

Fig. 1. Comparison of neuromuscular model foot placement dynamics to those observed in humans, quantified as phase-dependent coefficients of determination between foot placement and pelvis states or foot placement and swing foot states. Through mid-stance of the contralateral leg (phase = 0.5, or 0 in the reference data [6]), more of the variance in lateral foot placement can be explained by pelvis states than swing foot states in humans and in a DEP-RL trained motor control policy, but not in a spinal reflex model.

Dose- and Time-Dependent Effects of Intramuscular Botulinum Neurotoxin on Passive Mechanical Properties of Skeletal Muscle

Dr. Albino G. Schifino PhD, Mr. Timothy McGinley MS, Dr. Benjamin Binder-Markey DPT, PhD

Drexel University, Philadelphia, PA, United States

Introduction

Botulinum neurotoxin (BoNT) is used clinically to relieve hypertonic or overactive muscles following neurological injuries. However, clinicians have begun to question the efficacy of BoNT, and recent studies have shown paradoxical increases in passive mechanics of injected muscles. However, it is unknown how dose and time affect whole muscle passive mechanics. Thus, the purpose of our investigation was to assess the dose-response of BoNT on skeletal muscle in mice at 8-weeks and 12-weeks post-injection. We hypothesize that BoNT will result in a dose-dependent reduction of muscle mass and altered *ex vivo* passive mechanics.

Methods

60 C57Bl6 mice (30M, 30F) were injected with either 2 Units (U)/kg, 4 U/kg, or 6U/kg of BoNT into the gastrocnemius. All injections were performed on the left limb, leaving the right limb as a control. The lateral gastrocnemius muscles were dissected and tested bilaterally at 8-weeks and 12-weeks post-injection. Passive muscle mechanical testing was performed *ex vivo*, muscles were attached to a 5N force transducer and incrementally stretched by 5% muscle length, to a length of 130%. All data are reported as mean ± SEM. Muscle characteristics, and stress-strain relationships were analyzed via a Mixed-Effect Model with a priori $\alpha < 0.05$.

Results

Muscle mass ratios were significantly lower following BoNT, and demonstrate a dose- and time-dependency (Fig.1A). Maximal stress was greater in muscles-injected with 2U, 4U, and 6U, respectively, compared to the contralateral control at 8-weeks and 12-weeks. Stress-strain curves indicate BoNT-injected muscles exhibited significantly higher stresses than control muscles, with a dose-response (2U<4U<6U, $p< 0.05$) (Fig. 1B).

Discussion

Our data demonstrates a dose- and time-dependent response to BoNT injection. Reductions in muscle mass support acute dose-dependent atrophy. BoNT caused alterations in passive muscle mechanics, with a dose-dependent increase in passive stresses that remained elevated after 12-weeks indicating sustained remodeling post BoNT injection.

Images (Optional)

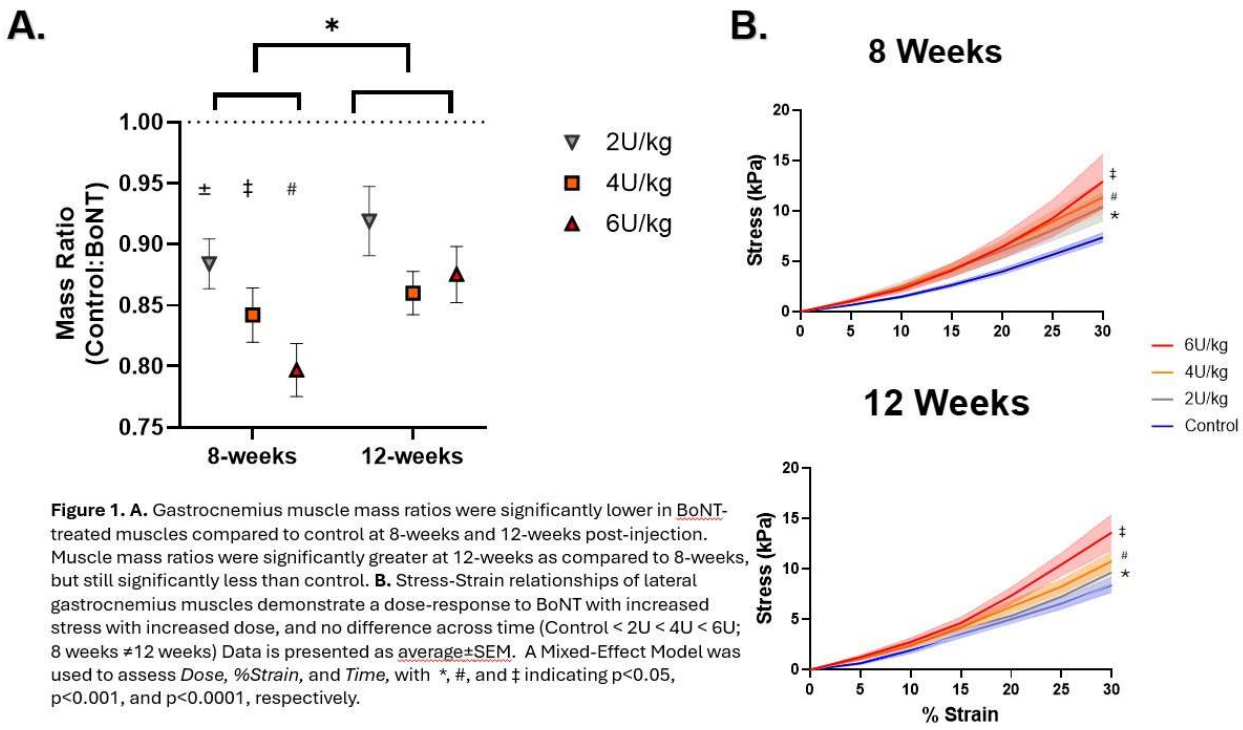

Figure 1. A. Gastrocnemius muscle mass ratios were significantly lower in BoNT-treated muscles compared to control at 8-weeks and 12-weeks post-injection. Muscle mass ratios were significantly greater at 12-weeks as compared to 8-weeks, but still significantly less than control. **B.** Stress-Strain relationships of lateral gastrocnemius muscles demonstrate a dose-response to BoNT with increased stress with increased dose, and no difference across time (Control < 2U < 4U < 6U; 8 weeks ≠12 weeks) Data is presented as average±SEM. A Mixed-Effect Model was used to assess *Dose*, *%Strain*, and *Time*, with *, #, and ‡ indicating $p<0.05$, $p<0.001$, and $p<0.0001$, respectively.

Explaining Sarcomere Length Non-Uniformities in Single Myofibrils

Mr. Chris Tiessen, Dr. Walter Herzog

University of Calgary, Calgary, Alberta, Canada

Introduction

Sarcomere length non-uniformity (SLNU) is an inherent property of mammalian striated muscle that remains unexplained. SLNU refers to variations in sarcomere length within a given muscle preparation and can be found at all levels of muscle, including whole muscle and individual myofibrils. SLNUs in myofibril preparations are of particular interest, because in an isolated myofibril, in-series sarcomeres experience identical tensile force and yet SLNU persists. This suggests there may be inherent differences between adjacent sarcomeres within the same myofibril. Moreover, recent work from our lab suggests SLNUs in myofibrils may be deterministic; some sarcomeres are always 'long', and others are always 'short.' Thus, we hypothesize that SLNUs may be explained by inherent variation in contractile and elastic protein content in adjacent sarcomeres within the same myofibril.

Methods

We developed a unique immunolabelling system for the giant elastic protein titin that enables relative densitometric quantification of titin content in adjacent sarcomeres without compromising contractile or elastic force production in individual myofibrils (Figure 1). Isolated rabbit psoas myofibrils (n=6) were mounted on our myofibril testing system where passive and contractile forces were measured using optical nano-levers, and titin content was quantified using immunolabel densitometry relative to sarcomere length non-uniformities during isometric contraction and passive extension. Sarcomere length non-uniformities and titin content were reported as a z-score, and correlations compared using a Pearson's correlation test. Additionally, we are currently in the process of performing Volumetric Focused-Ion-Beam coupled Scanning Electron Microscopy (FIB-SEM) on tested individual myofibrils which may be able to provide absolute quantification of sarcomeric protein content in adjacent sarcomeres.

Results

We found significant inverse correlations between sarcomeric protein content and sarcomere length in both passive ($p=0.0074$) and active ($p=0.0203$) states. This confirmed

our hypothesis, suggesting sarcomeric protein content varies between sarcomeres, predicting SLNUs. Results remain in progress for FIB-SEM of individual myofibrils.

Discussion

SNLUs were recognized as early as the 1960s and have been used to explain various muscle properties including history-dependent muscle properties and descending limb sarcomere instability. For the first time, we confirm variation in sarcomeric protein content occurs within individual myofibrils and may explain this inherent property of striated muscle.

OA137-04

Increasing Intramuscular Fluid Volume Increases Passive Tension in Mammalian Skeletal Muscle

Ms Samantha Falcone, Dr Richard Marsh, Mr Ofubofu Cairns, Dr Thomas Roberts

Brown University, Providence, RI, United States

Introduction

Experimental work in amphibian skeletal muscle [1] and modeling [2] have demonstrated that intramuscular fluid volume is an important determinant of passive force development during lengthening. This effect has been attributed to the interaction of intramuscular fluid and the collagenous extracellular matrix (ECM) that acts as a sleeve encapsulating muscle tissue [1]. However, this effect has not been investigated in mammalian skeletal muscle.

Methods

We exposed isolated mouse soleus and extensor digitorum longus (EDL) muscles to a graded series of hypotonic solutions to promote fluid uptake while measuring passive force development during lengthening, muscle mass, and 2D projected muscle area. We also separately investigated the effect of muscle tension on fluid uptake by comparing the masses of soleus muscles exposed to hypotonic solution and held at resting length to soleus muscles exposed to hypotonic solution and left slack.

Results

In 70%, 60%, 55%, and 50% hypotonic solutions, passive force in the soleus increased by 5.8±0.01%, 16.7±0.02%, 32.3±0.04%, and 64.8±0.06%, respectively. Passive forces in the EDL increased 8.5±0.03%, 64.3±0.19%, and 87.1±0.18% in 70%, 60%, and 55% hypotonic solutions, respectively. In both muscles, increases in passive force were accompanied by increases in mass and projected area. In our investigation of the effect of muscle tension on fluid uptake, we found that soleus muscles left slack and allowed to shorten when exposed to hypotonic solution gained much more mass than muscles held at resting length, suggesting that at resting length water uptake is limited by the buildup of hydrostatic pressure.

Discussion

These findings support the hypothesis that intramuscular fluid volume plays a key role in passive force development in mammalian skeletal muscle, consistent with previous

observations in amphibian muscle. The difference in fluid uptake and passive force development between the soleus and EDL muscles may reflect fiber-type differences in water permeability or in the ECM. Our data may be relevant for understanding *in vivo* alterations in human muscle properties resulting from exercise and passive stretching [3].

Impairments in Paraspinal Muscle Specific Force Production Following an Experimental Intervertebral Disc Injury in a Rodent Model

Dr Josh Briar PhD, Dr Alex Chan DVM, Ms Abbey Reid BSc, Ms Jana Michaud, Mr Adam Bui MSc, Ms Laura Blackburn BSc, Ms Courtney Phillips MSc, Dr Stephen Brown PhD

University of Guelph, Guelph, Ontario, Canada

Dr Josh Briar

Introduction

Paraspinal muscle dysfunction has been linked to chronic low back pain (LBP) [1], but the causative relationship between LBP and muscle dysfunction remains elusive. An experimentally induced intervertebral disc (IVD) injury animal model has been used to study corresponding structural and passive mechanical changes to the paraspinal muscles [2]. However, to date, there has been a lack of investigation into the influence of this experimental model of IVD injury on the active contractile properties of the paraspinal muscles.

Methods

31 male Sprague-Dawley rats were randomly divided into 4 groups: 15-week sham (n=8), 15-week IVD puncture (n=9), 10-week IVD puncture (n=7), 5-week IVD puncture (n=7). All rats underwent a retro-peritoneal incision and the L2-L3 and L4-L5 levels of the spine were identified. Animals in the puncture groups underwent an approximate 2mm penetration into each IVD of interest, while the sham group did not. Animals were sacrificed at different time points (5, 10 or 15 weeks) post-surgical intervention, and the contralateral multifidus and longissimus muscles were excised. Twenty fibres were isolated from each muscle and underwent active contractile testing in a pCa 4.5 solution for maximal activation. Each muscle's mean and coefficient of variation (CV) for specific force were calculated and compared between groups.

Results

A main effect of surgical group was observed for mean specific force ($F=5.284$, $df=3$, $p=0.003$, Fig 1); highlighting that it was significantly higher in the sham group than the week 5 ($p=0.018$), week 10 ($p<0.001$), and week 15 surgical groups ($p=0.002$). A main effect of

surgical group was observed for specific force CV ($F=3.77$, $df=4$, $p<0.01$); highlighting that the CV was significantly lower in the sham group than the 10-week injury group ($p=0.03$) and 15-week injury group ($p=0.04$).

Discussion

The current work highlights that following an induced IVD injury there is a significant reduction in force generating capacity of the surrounding paraspinal muscle fibres. Furthermore, the elevated specific force CV in the IVD injury groups reflects increased heterogeneity in force production capabilities of the paraspinal muscles, underscoring potential contractile impairments.

Curvature Regulate Cell Migration and Nuclear Dynamics

Mr. Chia-Chun Yeh, Dr. Pen-hsiu Grace Chao

National Taiwan University, Taipei, Taiwan, Taiwan

Introduction

Cells in vivo reside in complex topographies including cell-scale curvatures [1]. Recent work has identified “curvotaxis” where cells migrate in response to curvature cues [2, 3]. However, these systems often impose mixed curvature gradients, obscuring the effect of well-defined curvatures. Here, we aim to clarify the effects of curvature by confining individual cells in C-shaped microgrooves and characterize their behaviors.

Methods

Micromolded agarose walls [4] on fibronectin-coated coverslips impose curvature on mesenchymal stem cells in microgrooves. The patterns were 10 μm in width, with inner radii of 15 and 20 μm and a 270° arc span. For live-cell imaging, cells labeled with SpyDNA were seeded into the microgrooves. Time-lapse micrographs were acquired every 5 minutes for 12 hours in a stage top incubator. Nuclear shape and location were tracked and the shape changes were quantified by the dynamic nuclear aspect ratio index, which is the sum of frame-to-frame changes in nuclear aspect ratio (NAR).

Results

Cells conformed to the pattern with asymmetrical nuclear profile against the inner edge of the curve, potentially formed by the stress fibers above the nucleus (Fig. A). Live imaging found higher curvature increased cell migration speed and dynamic nuclear shape changes, which exhibit strong correlations (Fig. B & C).

Discussion

In this study, we found pattern curvature induced strong actin arcs that created asymmetric compression on the nucleus against the concave edge. Ongoing live imaging found the dynamic actin retrograde flow from the convex edge drove this nuclear movement (data not shown), which is confirmed by the dynamic nuclear shape changes. Liu et al has found inverse correlation between migration speed and curvature at a smaller scale (1/50-100 μm versus 1/15-20 μm in this study [3]). Potentially due to cell type and substrate differences, few actin fibers were observed in their system. Current studies are investigating a wider range of curvature as well as the role of actin structures on wavy cell migration.

Developing a Novel Genetically Encoded Molecular Tension Sensor

Dr. Takumi Saito

The University of Osaka, Toyonaka, Osaka, Japan

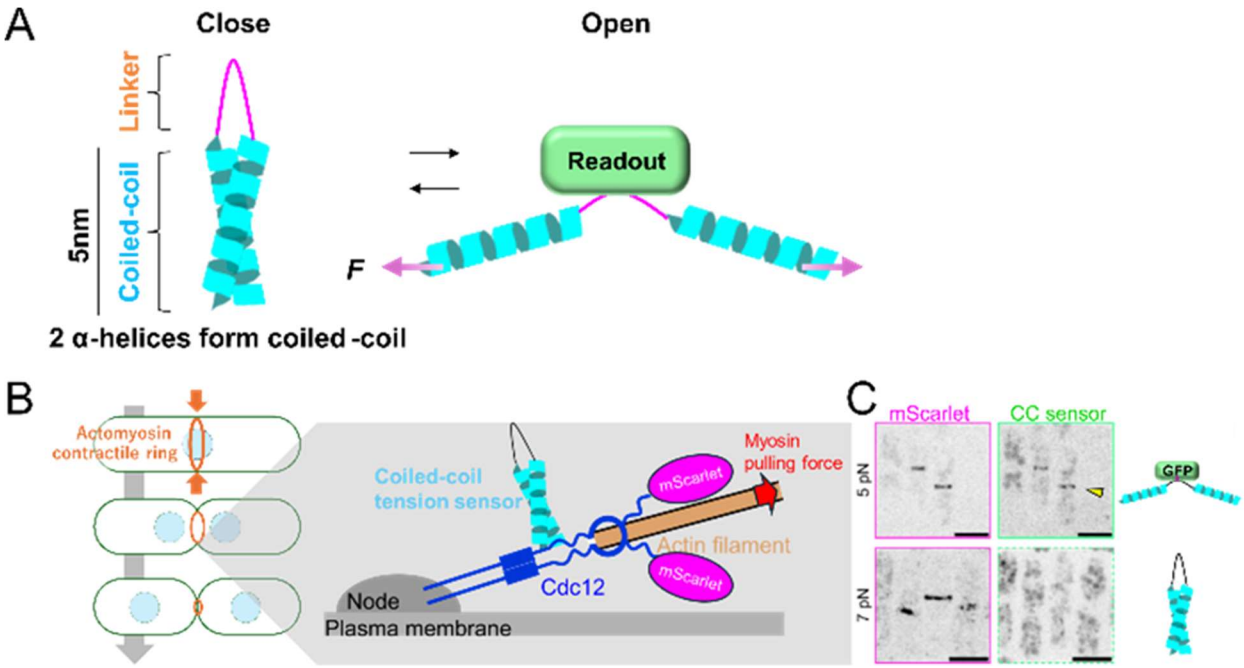
Introduction

Mechanical forces play a pivotal role in regulating cellular behavior through mechanotransduction. Although numerous molecules related to mechanotransduction have been characterized, and their signaling pathways have been identified, the mechanisms of how these molecules and molecular complexes transmit mechanical forces during cellular mechanotransduction, in living cells, are still unclear due to technical limitations. To overcome the limitations, we developed a compact and robust molecular tension sensor based on a coiled-coil structure, so-called “coiled-coil tension sensor” (1). The coiled-coil tension sensors open in all or none fashion when they are pulled by forces above a threshold pre-calibrated by optical tweezers (Fig. 1A).

Methods

To detect whether the CC sensors open or close, we used a split-GFP readout (1, 2). The CC tension sensors with the GFP11 linker were genetically inserted into several regions of formin Cdc12 by the CRISPR-Cas9 gap-repair system established by our group (4). As a representative case, the CC sensors were inserted between two formin homology domains (FH1 and FH2) (Fig. 1B).

Results



At the sensor insertion site, 5 pN sensors opened and exhibited fluorescence, whereas 7 pN sensors remained closed (Fig. 1C) (2). This result indicates that the forces between two FH domains are in the range of 5-7 pN. In addition to this insertion site, the CC sensors screened the force level along Cdc12, resulting in ~ 6 pN forces except in the dimerization domain.

Discussion

The coiled-coil force sensors revealed mechanisms of force transmission along formin Cdc12 during cytokinesis, as the representative results of force measurements on many other proteins (vinculin, spectrin, and endocytic proteins). Compared to FRET-based tension sensors, the CC tension sensors enable all-or-none binary force measurements

with a single fluorescent protein or luminescence, resulting in small, high S/N, and are capable of multiplex imaging. Thus, the CC sensors allow to quantify not only intramolecular force levels but also the fraction of molecules under tension, meaning that this approach offers a robust alternative for probing mechanotransduction at the molecular scale.

Tomographic Shearmetry of Dynamic Flows at Cell Surfaces Using Nanoprobes

Ms Arianna Giannetti[1], Mr Marcello Bonetti[2], Ms Joni Frederick[1], Ms Alessia Castagnino[1], Mr Thierry Gacoin[2], Mr Jongwook KIM[2], Mr Abdul Barakat[1]

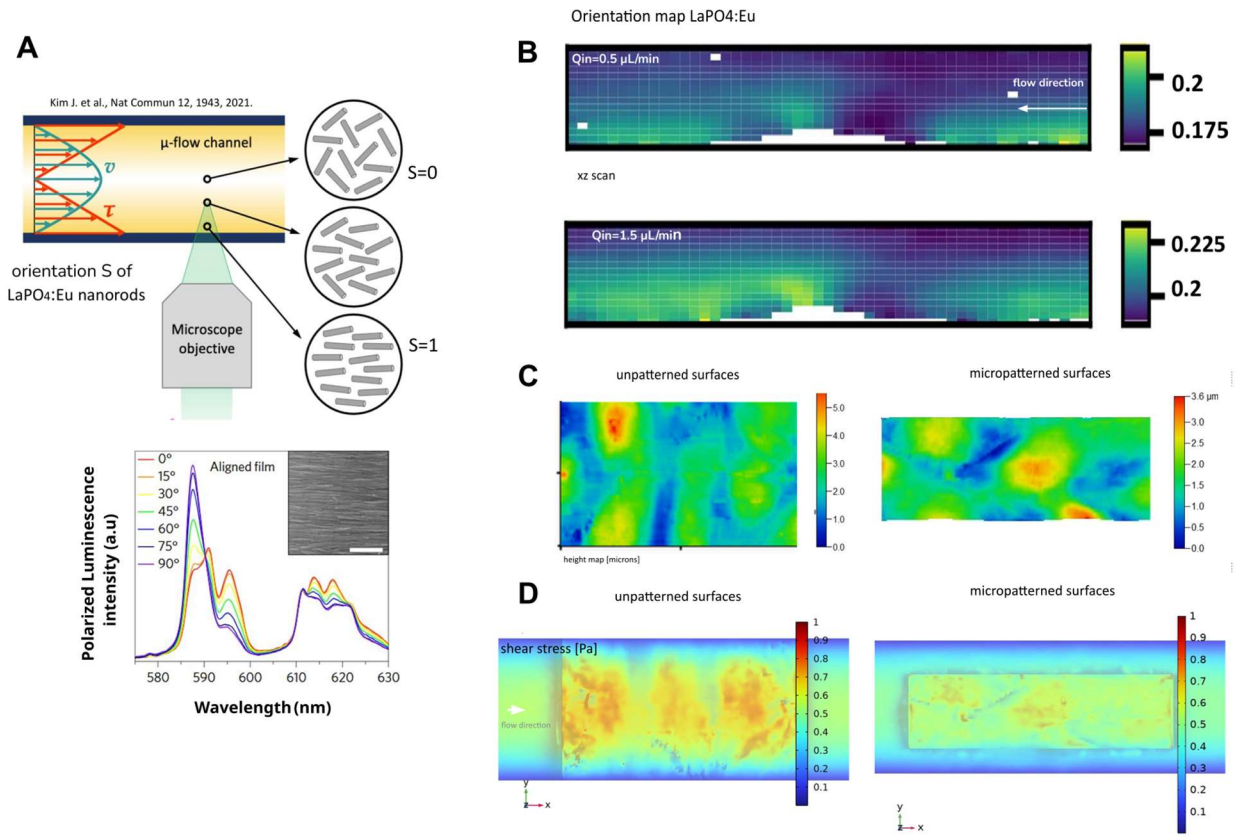
[1]LadHyX Ecole Polytechnique, Palaiseau, France, France. [2]PMC, Ecole Polytechnique, Palaiseau, France, France

Introduction

Mechanical forces due to fluid flow, particularly fluid dynamic shear stress, are known to play a crucial role in regulating a wide array of cellular functions. It is commonly assumed that adherent cells such as vascular endothelial cells (ECs) have no impact on the flow field. Computational simulations, however, suggest that EC topography can impact the local hydrodynamic environment, leading to significant shear stress gradients (Barbee,Am J Physiol,1995). Experimentally validating these computational predictions has remained elusive because conventional techniques such as particle image velocimetry (PIV) are very noisy due to inaccuracies in near-wall velocity measurement (Lafaurie,Biomed Microdev,2016).

Methods

Here $LaPO_4$:Eu nanorods serve as shear stress probes through their shear-induced alignment and polarized photoluminescence (Fig. 1A) (Kim,Nat Commun,2021). Spectroscopic analysis of their collective orientation enables tomographic mapping of the local shear stress on the surfaces of human umbilical vein ECs (HUVECs). In conjunction with nanorod-based shearmetry, atomic force microscopy (AFM) is used to characterize the 3D topography of ECs. To complement the nanorod-based shearmetry measurements, computational fluid dynamics (CFD) simulations are conducted on the AFM surfaces using COMSOL Multiphysics 5.6 to relate cellular topography to the local wall shear stress on the cellular surface.



Results

Preliminary results on spatial mapping of nanorod orientations on single isolated ECs indicate increased nanorod alignment with flow and a higher nanorod order parameter (S) at the apex of the cell compared to the surrounding cell-free regions (Fig. 1B). AFM measurements demonstrate that restricting EC spreading by culturing the cells on 15 μm-wide adhesive line patterns elicits cell elongation and significant height reduction (Fig. 1C). CFD simulations on ECs cultured on either unpatterned or patterned substrates reveals that surface undulations create cell-scale shear stress variations that are attenuated by cell height reduction on the line-patterned surfaces (Fig. 1D).

Discussion

The present results suggest that nanorod-based tomographic shearmetry can potentially enable experimental mapping of shear stress levels on EC surfaces. Future work will focus on such mapping and on comparing the measurements to CFD results. Additionally, efforts will aim to correlate local shear stress distributions with functional cellular responses such as intracellular calcium mobilization.

Magnetic Stiffening Cryogels With Hierarchical Alignment for Mechano-Modulation of Mesenchymal Stromal Cells

Dr Wen Chen

AO Research Institute Davos, Davos, Graubünden, Switzerland

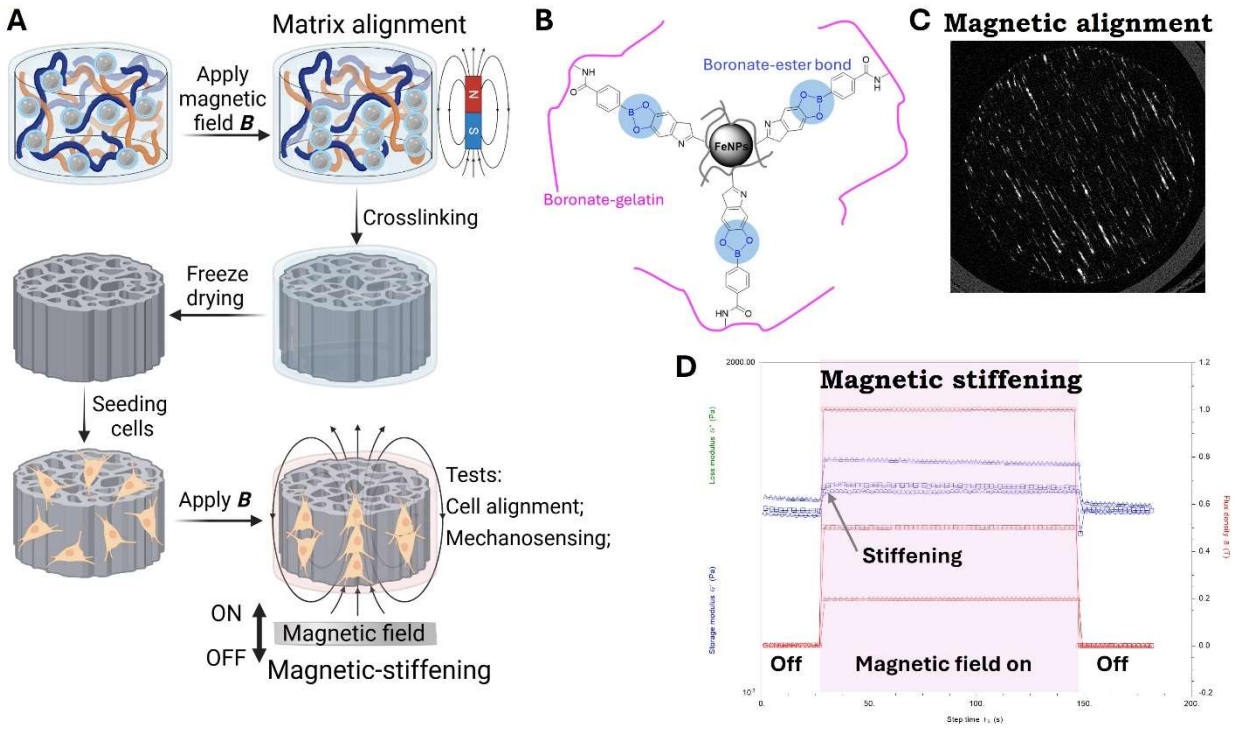
Introduction

Modulation of cells *in vitro* and/or *in vivo* plays an important role in tissue engineering and regenerative medicine. In our body, cells receive biophysical cues that mimic cellular microenvironment, including but are not limited to, topography, matrix stiffness and viscoelasticity, which can manipulate cell behaviors. [1] Furthermore, cells mechanically respond to their local microenvironment through dynamic interactions shaping biological functions. These dynamic behaviors are challenging to replicate in matrices for in vitro studies. This motivated us to develop 4D anisotropic *in vitro* models with tunable stiffness for regulating cell behavior, organization and mechanotransduction (**Figure 1A**).

Methods

Anisotropic cryogels were prepared by mixing boronate-functionalized gelatin with polydopamine-functionalized magnetic-responsive nanoparticles (**Figure 1B**) under magnetic field, followed by freeze-drying. The anisotropic structures were imaged by micro-CT. The mechanical properties of magnetic-stiffening were quantified by magneto-rheometer. The human mesenchymal stromal cells (hMSCs) at passage 5 were seeded on top of the anisotropic cryogels to study the effects of anisotropy and magnetic-stiffening properties on hMSCs organization and mechanotransduction under magnetic field.

Results



Anisotropic cryogels were prepared by aligning the magnetic nanoparticles in the hydrogel network, followed by freeze-drying. The anisotropic structures were imaged by using micro-CT (**Figure 1C**). Moreover, under magnetic field, the storage modulus *G'* of cryogels at a

concentration of 6 mg/mL magnetic nanoparticles and 30 mg/mL gelatin increased from 1600 Pa to 1700 Pa at a field intensity of 200 mT (**Figure 1D**).

Discussion

We developed anisotropic hydrogels with magnetic-stiffening properties. We are currently investigating the hMSCs behaviors in this 4D in vitro model. This approach will allow us to examine how anisotropy and magnetically tunable stiffness influence cell organization and mechanotransduction *in situ*. Insights gained from these studies will inform the design principles of scaffolds aimed at directing cell fate.

The Role of Focal Adhesion Kinase Signaling in Response to Dynamic Cyclic Loading Changes with Hierarchical Collagen Fiber Formation in Engineered Ligaments

Dr Akshay Bhatt PhD, Dr. Jennifer Puetzer PhD

Virginia Commonwealth University, Richmond, Virginia, United States

Introduction

Hierarchically organized collagen fibers provide strength to tendons and ligaments; yet regenerate poorly after injury.[1] Understanding how cells form these fibers is critical for enabling regeneration. Mechanical cues, including passive cellular contraction and dynamic external loads, drive fiber development, but how is largely unknown. Previously, we developed a static system that guides ACL fibroblasts to produce hierarchical fibers over 6 weeks [1] and have shown that dynamic cyclic stretch improves maturation.[2] Using our static system, we found focal adhesion kinase (FAK) signaling is critical during fibril formation, but not fiber or fascicle development. Here, we evaluate whether FAK's role changes with dynamic load.

Methods

Neonatal bovine ACL fibroblasts and collagen were mixed to form constructs at 20mg/ml collagen and 5×10^6cells/ml and clamped into a tensile-bioreactor (Fig.1A).[1,2] During fibril (0-2wks), fiber (2-4wks), or fascicle (4-6wks) formation, constructs were loaded with an established intermittent cyclic loading regime (Fig.1B)[2] and FAK was inhibited with 10μM PF-573228 (FAK-I). To compare FAK's role during dynamic-load vs. passive-static cues, one group had FAK-I for 3hrs during dynamic loading only(FAK-I 3hr), and another group had FAK-I for the full 2wks to block dynamic and static signals (FAK-I ET, Fig.1C). Post-culture, collagen organization, composition, and tensile properties were evaluated.[1,2]

Results

At 2wks, FAK-I ET disrupted fibril formation, while FAK-I 3hr still formed aligned-fibrils, indicating passive cellular contraction is critical to fibril formation. By 4 and 6wks, both FAK-I groups formed fibers and early-fascicles like controls, suggesting other mechanosensors drive later maturation (Fig.1D). FAK-I reduced DNA at each timepoint, while its effect on GAG, LOX activity, and collagen varied depending on organization (Fig.1E). Particularly, FAK-I during fiber and fascicle formation significantly increased collagen concentration with loading, suggesting an injurious response or a shift in mechanotransduction. Despite increased collagen concentration and organization at 4 and

6wks, FAK-I largely reduced elastic properties (Fig.1F), but had little effect on toe-region properties.

Discussion

Collectively, this suggests integrin-mediated adhesions are critical to sensing dynamic stretch, but this role decreases as hierarchical fibers develop. Other mechanosensors may have a more prominent role beyond the fibril level.

Cell Dynamics Driven by Substrate Elasticity-Topography Interplay for Microfluidic Applications

Prof. Hiromi Miyoshi PhD[1], Dr. Tomoko G. Oyama PhD[2], Dr. Kotaro Oyama PhD[2], Dr. Mitsumasa Taguchi PhD[2]

[1]Tokyo Metropolitan University, Hachioji, Tokyo, Japan. [2]National Institutes for Quantum Science and Technology (QST), Takasaki, Gunma, Japan

Introduction

Mechanical cues encoded in the cell-substrate interface critically regulate cell adhesion, migration, and fate decisions. We developed gelatin hydrogels that retain native adhesion motifs and span physiologically relevant stiffness ranges, and previously showed that substrate elasticity and topography influence cell morphology and actin organization [1]. Here, we focus on how the interplay between substrate elasticity and topography governs cancer cell motility signatures and lineage-associated signaling responses.

Methods

We examined fibroblast lines, breast cancer cell lines, and mesenchymal stem cells to evaluate adhesion and motility. Gelatin substrates were fabricated with stiffnesses of 10–350 kPa and topographies of micrometer-scale holes, pillars, or flat surfaces. Adhesion and migration were quantified by time-lapse label-free imaging and automated tracking [2]. Because ERK regulates proliferation–differentiation switches, ERK activity under distinct elasticity–topography conditions was evaluated using a FRET sensor [3].

Results

Cancer cells exhibited lower adhesion rates on stiffer substrates, in contrast to non-cancerous epithelial cells, which adhered more strongly as stiffness increased within the physiologically and pathologically relevant 5–200 kPa range. These opposing stiffness responses enabled discrimination of metastatic versus non-metastatic cells through label-free dynamic parameters. Mesenchymal stem cells exhibited stiffness- and topography-sensitive regulatory modes relevant to differentiation control. Specifically, pillar structures promoted more dynamic motility, with this effect being more pronounced on softer 50 kPa gels than on stiffer 320 kPa gels. Correlated with these changes in motility, elasticity–topography combinations also modulated ERK signaling in mesenchymal lineage cells: pillar structures induced dynamic temporal changes in ERK activity, whereas hole structures maintained ERK activity at low levels.

Discussion

Our results demonstrate that cell dynamics relevant to cancer identification and stem-cell lineage control arise from the interplay between substrate elasticity and topography, partly via migration control. It could reflect principles shared with soft-tissue and cardiovascular biomechanics. Gelatin gels spanning physiological–pathological stiffness ranges provide mechanically instructive environments suitable for microfluidic label-free diagnostic and culture applications.

Tunable Soft Robotic Pulmonary Artery Banding Device for the Management of Congenital Heart Disease

Dr. Yellappa Palagani[1,2,3], Dr. Luca Rosalia[4], Mr. Amit Sharir[1,3], Dr. Perry S. Choi[1,2], Dr. Yoshikazu Ono[1,3], Dr. Masafumi Shibata[1], Dr. Sayar Munshi[1,2,3], Dr. Alexander K. Reed[1,3], Prof. Mark A. Skylar-Scott[2,3,4], Prof. Michael R. Ma[1,2,3]

[1]Department of Cardiothoracic Surgery, Stanford University, Stanford, CA, United States. [2]Maternal & Child Health Research Institute, Stanford University, Stanford, CA, United States. [3]Cardiovascular Institute, Stanford University, Stanford, CA, United States. [4]Department of Bioengineering, Stanford University, Stanford, CA, United States

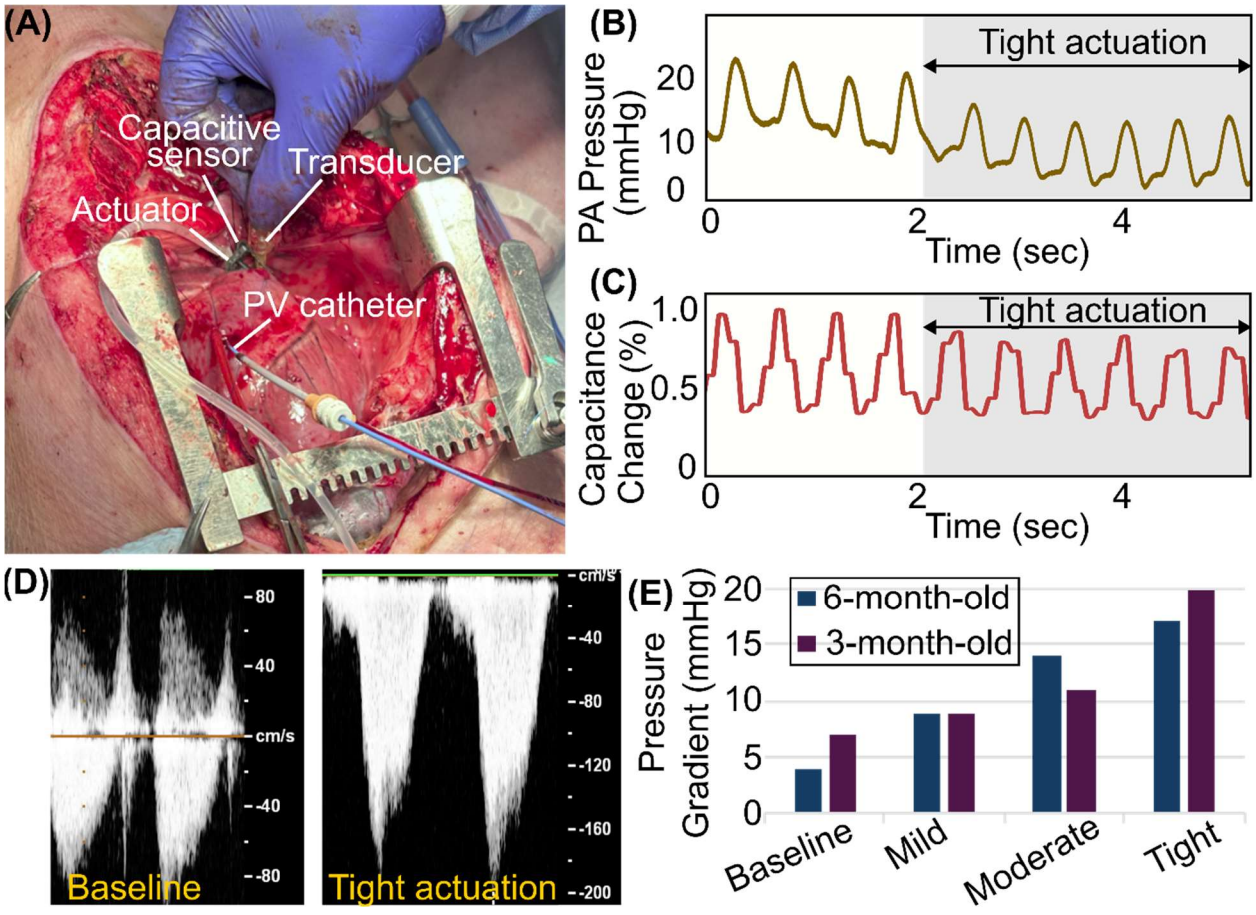
Introduction

Pulmonary artery banding (PAB) is a widely used surgical technique for treating neonates and infants with congenital heart disease to limit pulmonary over-circulation and retrain a deconditioned ventricle. However, the static nature of traditional PABs often necessitates additional surgeries for readjustment as patients grow, and rely on indirect measures to assess cardiac function. To address this gap, we present a tunable pulmonary artery band (tPAB) that allows remote adjustment and provides real-time, non-invasive hemodynamic monitoring.

Methods

The tPAB was developed with a 3D-printed soft robotic actuator and a capacitive sensor, customized to fit patient-specific anatomy. The actuator regulates the narrowing of the pulmonary artery (PA) through fluidic actuation, while a capacitive sensor continuously monitors the pulmonary hemodynamics. First, we characterized the actuation and sensing abilities of the band via *ex vivo* testing using a patient-specific pediatric cardiac simulator. *In vivo* experiments were then conducted in three- and six-month-old porcine models to evaluate tPAB effectiveness across various degrees of actuation. PA pressure changes measured by the tPAB were confirmed with Edward pressure transducer and apical epicardial echocardiography.

Results



In vivo pressure gradients increased with tPAB actuation. Pressure gradients measured 4, 9, 14, and 17mmHg in the 6-month-old porcine model and 7, 9, 11, and 20mmHg in the 3-month-old porcine model at baseline (0mL), mild (0.50mL), moderate (0.75mL) and tight

(1.0mL) actuation levels, respectively, as confirmed via continuous wave Doppler imaging. These findings demonstrate the significant impact of band actuation on arterial dynamics. Capacitive sensor readings from tPAB closely matched transducer measurements, showing decreased distal PA pressure during actuation. *Figure (A)* shows the tPAB procedure; *(B, C)* show distal PA pressure changes at baseline and tight actuation via transducer and capacitive sensor; and *(D, E)* show pressure gradients in porcine models.

Discussion

The results indicate that precise actuation of the tPAB enables accurate constriction of the PA, while band effectiveness and pulmonary pressure can be monitored non-invasively. By integrating remote adjustment with continuous hemodynamic monitoring, tPAB offers a novel approach to PA banding that aims to reduce the need for repeat surgeries and improve outcomes in congenital heart disease.

Understanding Extracorporeal Membrane Oxygenation and Impella Synergy Through a Patient-Specific Hybrid Mock Circulatory Loop

PhD Gasparotti Emanuele[1], PhD Emanuele Vignali[1], MD Dorela haxhiademi[2], Prof Simona Celi[1]

[1]BioCardioLab, Bioenegineering Unit, Fondazione Monasterio, Massa, Tuscany, Italy. [2]Anesthesiology and Intensive Care Unit, Fondazione Toscana Gabriele Monasterio, Massa, Tuscany, Italy

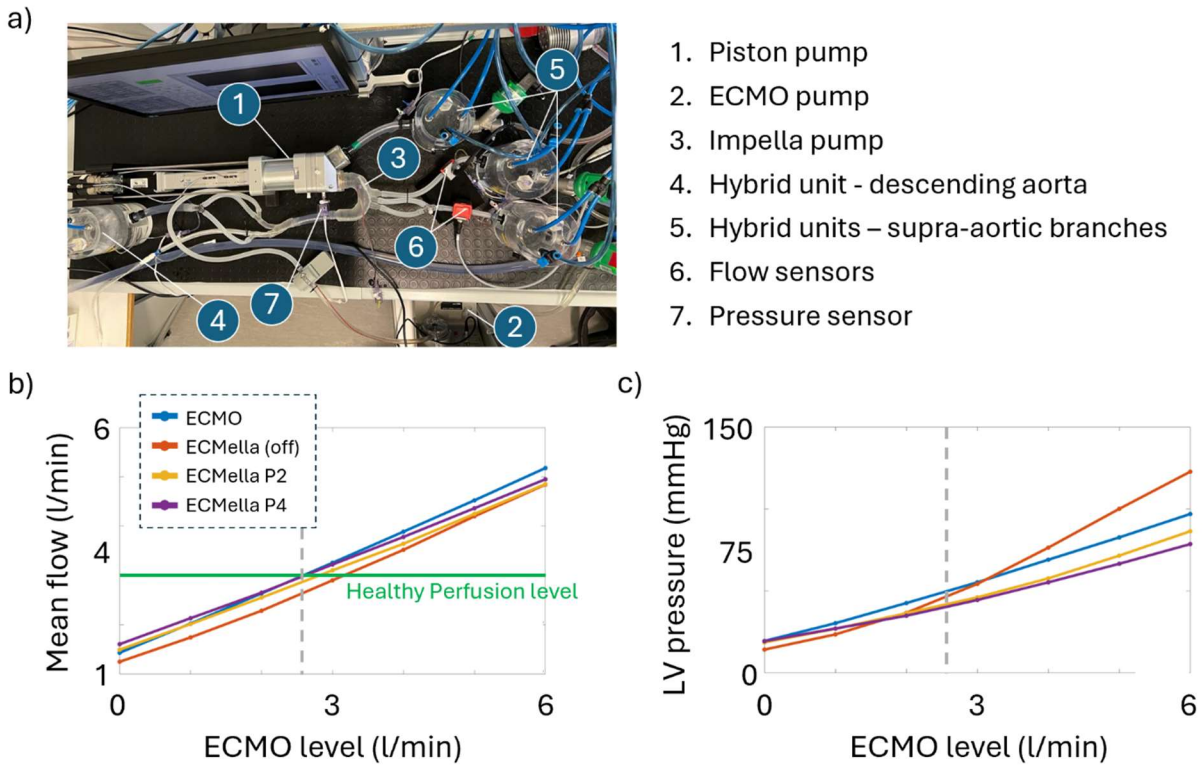
Introduction

Cardiogenic shock is a life-threatening condition marked by a severe reduction in cardiac output, often caused by myocardial or coronary dysfunction. The resulting hypoperfusion critically limits oxygen delivery to supra-aortic vessels, compromising cerebral circulation. Mechanical circulatory support devices such as ExtraCorporeal Membrane Oxygenation (ECMO) and the transvalvular Impella pump can temporarily restore systemic flow [1], yet their hemodynamic impact, including increased left ventricular loading, remains to be clarified. To investigate these mechanisms, this work presents in-vitro experiments designed to investigate the performance of ECMO, Impella, and their combined configuration (ECMella) under different shock conditions.

Methods

A hybrid-mock-circulatory-loop (hMCL) (Fig_a) was developed to reproduce physiological and pathological aortic hemodynamics [2]. A piston pump generated aortic flow profiles, while hybrid pressurized chambers implemented systemic boundary conditions. A patient-specific aortic phantom, including ascending aorta, supra-aortic branches, descending aorta, and iliac arteries, was manufactured from CT imaging. An ECMO pump delivered arterial return through the right iliac, and an Impella device was positioned across a biological aortic valve prosthesis. An experimental campaign (63 configurations) was performed by varying shock severity (30–70% stroke-volume reduction), ECMO flow (0–6 L/min), and Impella speed (Off, P2, P4). Hemodynamic metrics included supra-aortic flow restoration, afterload and left ventricular (LV) loading.

Results



ECMO alone restored supra-aortic healthy perfusion (Fig_b) in all shock conditions, but produced afterload elevation and increased LV pressure (Fig_c). Impella alone reduced LV pressures but was unable to restore physiological supra-aortic flow at any shock level. The ECMella configuration showed synergistic behavior: perfusion restoration occurred at

lower afterload than ECMO alone, and LV unloading depended on Impella speed. At P4, Impella compensated cannula-induced regurgitation and prevented LV overload even at high ECMO flows.

Discussion

The hMCL enabled controlled, reproducible assessment of ECMO-Impella interactions under cardiogenic shock. ECMO ensured perfusion recovery but increased ventricular loading, whereas Impella provided unloading without adequate systemic flow. ECMella offered the most balanced performance, restoring perfusion while mitigating afterload and LV pressure. The platform supports optimization of ECMella strategies and informs clinical decision-making in shock management.

A Data-Informed Growth and Remodeling Framework for Vein Graft Adaptation Following Coronary Artery Bypass Graft Surgery

Mr. Lazaros Papamanolis[1,2], Ms. Divya Adil[1,2], Dr. Ruizhi Wang PhD[3], Dr. Guoxiang Grayson Tong PhD[1,2], Dr. Elbert E. Heng MD[2,4], Dr. Jay Humphrey PhD[3], Dr. Alison Lesley Marsden PhD[1,2]

[1]Department of Bioengineering, Stanford University, Stanford, CA, United States. [2]Stanford Cardiovascular Institute, Stanford University, Stanford, CA, United States. [3]Department of Biomedical Engineering, Yale University, New Haven, CT, United States. [4]Department of Cardiothoracic Surgery, Stanford University, Stanford, CA, United States

Introduction

Coronary artery disease is a leading cause of mortality worldwide. Coronary artery bypass graft (CABG) surgery is the gold standard treatment for patients with diffuse, multi-vessel disease. However, saphenous vein grafts used in CABG occlude at high rates post-surgery, with the underlying immuno-mechanobiological mechanisms still unclear. In this work, we develop a modular growth and remodeling (G&R) computational framework based on longitudinal experimental rabbit data with the goal of characterizing the vein arterialization process and predicting tissue (mal)adaptations after CABG surgery.

Methods

Using a rabbit vein graft model of CABG surgery (carotid artery to jugular vein end-to-end anastomosis[1]), a total of 30 vein grafts were harvested over a period of 7 months following surgery. Biaxial mechanical testing was performed on excised grafts, followed by immuno-histological examination to quantify vessel mechanical properties, composition and inflammatory burden. Experimental data was used to inform and validate a novel G&R computational framework[2], which was developed in-house based on a modular solver architecture. G&R parameters were determined with the surrogate management framework, using training timepoints for model calibration and withholding validation timepoints for evaluating predictive performance (Fig. 1).

Results

Histological analysis revealed significant time-dependent structural remodeling of vein graft tissue, with substantial variability in collagen content over time. Mechanical testing data showed that vein grafts generally exhibit greater stiffness compared to control veins, with noticeable variability across samples. Simulated inner radius, thickness, and vessel composition (elastin, smooth muscle cells and collagen) showed good agreement with

experimental data, highlighting the model's ability to appropriately capture the main mechanobiological processes that drive growth and remodeling of venous tissue.

Discussion

These findings constitute a significant step in mechanobiologically characterizing vein graft failure after CABG surgery. Calibrated using longitudinal experimental data, the proposed modular G&R framework has the potential to accelerate identification of novel CABG treatment strategies. Future work will focus on utilizing the framework's predictive capabilities to optimize a medical device for mitigating vein graft failure.

Using a Values Self-Assessment to Encourage Engagement in an Undergraduate Exercise Science Biomechanics Class

Dr. Ashlyn Jendro, Ms. Stephanie Cotariu, Dr. Kaitlin Gallagher

University of Arkansas, Fayetteville, AR, United States

Introduction

While instructors provide examples of the relevance of biomechanics to a student's degree and future career, students may still not engage if the examples are not personal to them. The purpose of this study was to evaluate how a values self-assessment can generate student engagement with course material.

Methods

Students in a third-year Exercise Science biomechanics course (n=138) completed a values self-assessment. During Week 1, students listed three values, explained how each matters, and described how each might intersect with the class. Students were given a list of values to get started; however, they could list anything meaningful to them. During Week 11, students revisited their reflections, writing about how the value has intersected with the course, and added a new value they did not initially list or think would apply to biomechanics. During the last week of the course, students read an information form stating that the instructors wanted to evaluate the values self-assessment. Tabulating values can be evaluated without students' informed consent; however, their open-ended responses cannot be used as research data without student consent. We will know who consented on December 16th, after grades are submitted. For this abstract, the de-identified value lists were downloaded, cleaned for spelling errors, and grouped into themes.

Results

The attached table lists the top five values, which account for two-thirds of responses. During Week 1, the top two values were "Family & Friends" and "Religion/Spirituality/Faith." By Week 11, students' top two values added were 'Athletics/Exercise/Health', and 'Learning & Gaining Knowledge."

Discussion

While Exercise Science students are assumed to value athletics, exercise, and health, they bring diverse values for instructors to relate to. In a different Exercise Science class taught by one of the authors and with the same assignment[1], students discussed passing on

knowledge to family/friends, direct experience with how the content affects their family/friends, ethics/morality related to their spiritual values, and finding creative solutions. Our final presentation will include direct quotes as evidence of the detailed responses regarding the intersection of their values with the course.

Images (Optional)

Table. Top 5 values shared by students during the Week 1 and Week 11 self-assessments. In Week 1, each student listed three values. In Week 11, students added one more value.

Week 1 (n=396)	Percent	Added Value Week 11 (n=131)	Percent
Family & Friends	29.6%	Athletics/Exercise/General Health	19.9%
Religion/Spirituality/Faith	13.4%	Learning & Gaining Knowledge	18.3%
Learning & Gaining Knowledge	9.6%	Being Creative/Artistic	11.5%
Independence	6.6%	Scientific Reasoning	9.2%
Athletics/Exercise/General Health	6.3%	Belonging to a Group	8.4%

Faculty Engaged Graduate Recruitment Effort from Primarily Undergraduate Institutions

Dr. Liang Zhu

University of Maryland Baltimore County, Baltimore, Maryland, United States

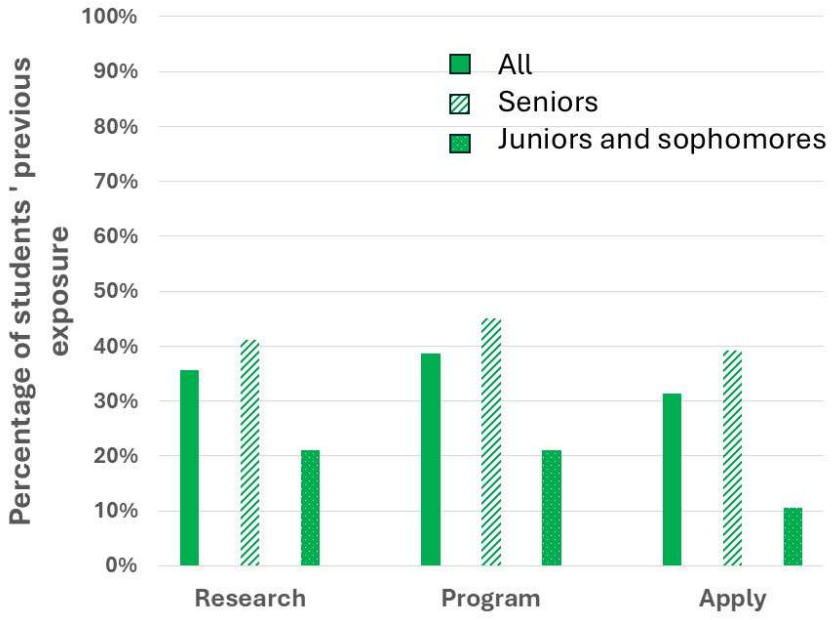
Introduction

Recent restrictions on international applications for US graduate programs have shifted our focus to domestic applicants. Unfortunately, the current practice of graduate recruitment is often passive, with minimal involvement of research faculty in STEM departments. The objectives of this study were to evaluate whether engaging research faculty in primarily undergraduate institution recruitment activities inspired students' interests in applying for graduate school in engineering.

Methods

In this study, a research faculty member visited 3 primarily undergraduate institutions to give a seminar to students. The seminar presentation included not only the traditional recruitment components, such as a description of the mechanical engineering graduate program and financial assistance, but also ongoing research projects conducted in the faculty's research lab at UMBC. The research projects were focused on bioengineering, especially in applications in medicine. A survey was designed by the faculty member, and it consisted of questions about their demographic background, their previous exposure to research, the influence of the seminar on their interest in applying for graduate programs in 4-year universities, and their satisfaction with the event.

Results



We collected 70 surveys from four visits. Results showed that prior exposure to research was low for the participants, around 36% before the faculty's visit. However, the exposure to research was much lower in juniors and sophomores than in seniors. More than 97% of the participants stated that they understood more of the technical content of research than before the seminar. 98% of them stated that they acquired more information on graduate programs. Although the majority stated "neutral", 34% or 23% of the students felt that they are more interested in applying for the graduate program at UMBC or other 4-year universities, respectively. One encouraging thing is that 82% of the students were satisfied

with the visit. 69% of them would like to attend future seminars offered by research faculty, with a higher percentage in juniors and sophomores.

Discussion

Faculty-engaged recruitment addressed the lack of research and program information among college students. Our visits had a positive impact on elevating students' interests in graduate schools. Future visits should target undergraduate students in their early college years.

The use of Biomechanics for a Course-Based Research Experience in a Large Class

Assistant Teaching Professor Val Sawiccy PhD, Student Taylor Wilson MS, Student Saliem Hatsey, Student Julia Wu Student, Professor Andy Karduna PhD

University of Oregon, Eugene, OR, United States

Introduction

Traditional research experiences in undergraduate biomechanics programs can be limited, leaving many students without access and widening equity gaps. Course-based Undergraduate Research Experiences (CUREs) address this by embedding research into coursework. This removes barriers like competitive selection and faculty resource constraints, allowing students to engage in original research and develop professional skills. [1] The goal of this project was to develop a scalable, sustainable CURE model iterated across terms.

Methods

We used a previously developed iPhone app for assessing proprioception. [2] Subjects were prompted to attain a target shoulder flexion angle (50, 70, or 90 degrees) via audio feedback from the phone, which was attached to their arm. Subjects attempted to replicate the target position in the absence of audio cues. Joint position sense errors were calculated as the difference between the angle at the repositioned and target positions. Students worked in pairs and were given an instructional video on using the app. Each group then recruited a subject, resulting in 71 subjects over the span of a week. Additionally, we collected survey data from the students about science self-efficacy and scientific identity. [3]

Results

Despite limited training, a sample of convenience, and scheduling complications, JPS errors followed a very similar pattern as we have seen in numerous lab-based students, with errors highest at the 50 degree target (3.4 degrees) and decreasing as target angles increased to 70 degrees (2.4 degrees) and 90 degrees (0.8 degrees). Survey results showed that students demonstrated an increased sense of belonging in the scientific community and were more likely to view themselves as scientists by the end of the course (Table 1).

Discussion

By integrating CUREs into large classrooms, this project creates a scalable model for embedding research into foundational courses. Outcomes include stronger research skills,

greater science self-efficacy, and increased STEM persistence across disciplines. Early research engagement builds transferable critical thinking and data analysis skills, while student contributions support faculty scholarship, strengthening the link between teaching and research.

Introduction

Attending a scientific conference can be transformative for early-career scientists [1], enabling their integration into a research community and creating professional opportunities. High conference costs limit participation from students who are not part of well-funded research groups, hindering their development of conference-specific skills. This study measured the combined impact of funding and targeted programing on early-career scientists at the 2025 American Society of Biomechanics Annual Meeting.

Methods

Twenty-three awardees were selected from 107 applications; evaluations prioritized barriers to participation and potential career impact. Awardees received travel funding and participated in pre-conference programs on presenting research, planning conference activities, and networking (Figure 1). Impact was measured across surveys administered pre-conference (n=22), after the networking workshop (n=11), and post-conference (n=18). Surveys used a mix of choice- and free-response questions to assess perceived skills, goals, and behaviors. Paired t-tests were used to compare pre- and post-conference responses.

Results

Awardees reported high conference satisfaction (4.78/5.0). They also indicated that they met (12/18) or exceeded (5/18) their top goals, which were networking, pursuing career opportunities, and improving biomechanics skills (Figure 1B). Perceived ability significantly improved for the categories targeted in the three pre-conference programs (Figure 1E). Workshop attendees reported plans to spend more time preparing for network interactions

and introduce themselves with more intentionality. For conference skills that were not targeted with programming (e.g., asking questions after a research talk), no meaningful improvements in were observed.

Discussion

This study demonstrates that funding combined with targeted programming can lead to strong positive outcomes for early-career scientists. Awardees reported accomplishing their top goals and improved skills that were the subject of pre-conference programs. Their improved perceived ability aligns with findings from the prior year [2]. The lack of perceived improvement for other conference skills suggests that conference attendance alone might not be sufficient for gaining conference skills, further supporting the value of pre-conference programming. A key limitation of this study is the lack of a control group with randomized trials. Future conferences should emphasize pairing travel grants with development programming for early-career scientists.

Video-Derived Asymmetry Enhances Prediction of Long-term Patient-reported Outcomes after ACL Reconstruction

Mr. Zhixiong Li MSc[1], Miss Sijia Li BS[1], Mr. Soyong Shin MSc[1], Dr. Evy Meinders PhD[1], Dr. Andrew Sprague PT, PhD, DPT[2], Dr. James Irrgang PT, PhD, FAPTA[2], Dr. Volker Musahl MD[2], Dr. Eni Halilaj PhD[1]

[1]Carnegie Mellon University, Pittsburgh, PA, United States. [2]University of Pittsburgh, Pittsburgh, PA, United States

Introduction

Early identification of individuals at risk of poor recovery after anterior cruciate ligament reconstruction (ACLR) is critical yet challenging. Patient-reported outcomes (PROs), such as the International Knee Documentation Committee Subjective Knee Form (IKDC-SKF) score and the Knee Injury and Osteoarthritis Outcome Score (KOOS), are subjective, while biomechanical and strength testing assess functional capacity but are challenging to collect clinically. Recent advances in markerless motion capture now allow objective quantification of kinematic asymmetry during functional testing without specialized laboratories. This study examined whether integrating video-derived asymmetry at 3 months improves prediction of nine-month IKDC-SKF outcomes.

Methods

Twenty-four participants were assessed at three and nine months post-ACLR. Participants performed three lateral step-down exercises per leg in a clinical setting while six RGB cameras (Sony RX0 II) recorded movement. DeepGaitLab [1], a markerless motion tracking tool, was used to estimate kinematics and extract hip, knee, and ankle asymmetry. Strength asymmetries in knee flexion/extension torque and hip abduction, extension, and external-rotation force were assessed using a Biodex and handheld dynamometers. PROs were assessed using all the KOOS sub-scores and the IKDC-SKF. LASSO, Ridge Regression, and Partial Least Squares models with leave-one-out cross-validation were used to predict nine-month IKDC-SKF scores from four three-month feature sets: PROs only, PROs + strength asymmetries, PROs + video-based asymmetries, and all features.

Results

Video-derived asymmetries improved prediction of nine-month IKDC-SKF scores. Using PROs alone yielded moderate predictive accuracy (Figure 1; $\rho = 0.61$, $p = 0.0008$), and strength measures provided modest gains ($\rho = 0.66$, $p = 0.0004$). PROs and video-derived asymmetries led to better performance ($\rho = 0.70$, $p < 0.0001$), while the combined model

using all the predictors performed the best ($\rho = 0.77$, $p < 0.0001$). The three-month KOOS pain subscore, IKDC-SKF score, hip abduction strength asymmetry, and knee and hip flexion/extension asymmetries were the most influential features.

Discussion

Markerless motion tracking provides clinically meaningful information that enhances prediction of long-term patient outcomes. These passive, scalable assessments could enable timely and low-burden monitoring in homes and clinics, supporting personalized rehabilitation and potentially improving long-term outcomes.

Images (Optional)

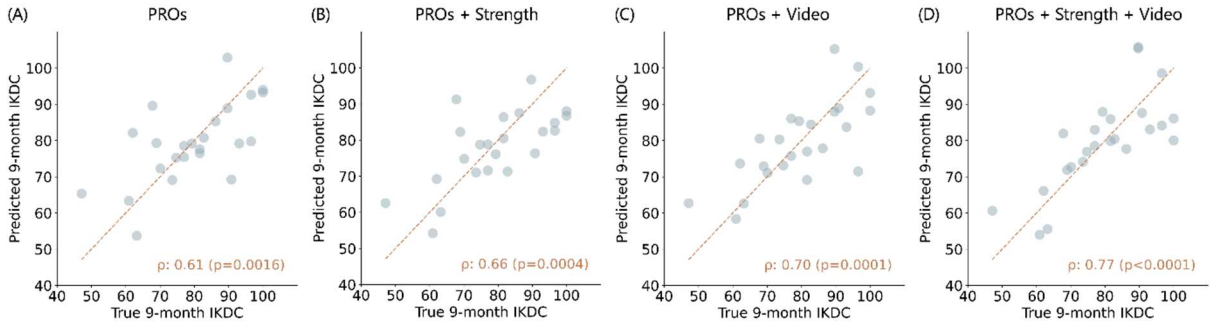

Figure 1. Predictive Model Performance. On left-out participants whose data were not used to train the models, IKDC-SKF scores at nine months could be predicted moderately well with data from the three-month visit. Models were trained using: (A) PROs, (B) adding strength asymmetry, (C) adding video-derived kinematic asymmetry, and (D) all features combined. Integrating video-derived kinematic asymmetry notably improved prediction accuracy compared with PROs alone or PROs combined with strength measures, supporting the clinical utility of scalable motion-tracking solutions.

The Effect of Meniscal Damage and Demographic Factors on Gait Biomechanics After ACL Injury

Mr Harry Battersby, Mr Alan Getgood, Mrs Dianne Bryant, Mr Ryan Evans, Mr Neil Wills, Mr Max Smith, Miss Jillian Neufeld, Mr Derek Pamukoff

Western University, London, Ontatio, Canada

Introduction

Gait biomechanics are altered following ACL injury, and are associated with knee osteoarthritis progression. Concomitant meniscal injury, may further influence gait impairment. The purpose was to compare sagittal plane gait mechanics between limbs and between those with and without meniscal injury.

Methods

151 individuals with unilateral ACL injury participated (78 Females, 73 Males, Meniscus injury: n=96, Age:18.95±3.09 years, time-since-injury: 8.25±12.51 months). Five overground gait biomechanics trials were recorded for each limb at a self-selected speed (1.25m/s±0.14m/s) using force plates (1200Hz) and a 12-camera motion capture system (60Hz). The peak internal hip extension moment (HEM), knee extension moment (KEM), and ankle plantar flexion moment (PFM) were extracted and normalized to a product of body weight (N) and height (m). A 2 (meniscal or no meniscal injury) by 2 (limb) ANCOVA compared gait outcomes, and sex and time since injury were included as covariates.

Results

There were no significant limb × meniscus interaction effects for any gait variable. There was a significant main effect of limb for HEM and KEM. HEM was higher in the injured compared to uninjured limb ($F_{1,147}$=12.12, 0.032 vs. 0.029BW·ht, p<.01,η^2=0.08), but KEM was lower in the injured compared to uninjured limb ($F_{1,147}$=11.84, 0.030 vs. 0.036BW·ht, p<.01, η^2=0.08). There was a main effect of meniscal injury for KEM, and KEM was lower in those with compared to without meniscal injury ($F_{1,147}$=4.73, 0.032 vs. 0.036 BW·ht, p<.01, η^2=0.03). Longer time-since-injury was associated with higher KEM (β=0.001, $F_{1,147}$=7.23, p<.01, η^2=.047), with. Sex was associated with PFM, and females had higher PFM than males (β=0.006, $F_{1,147}$=12.01, p<.01, η^2=.076).

Discussion

Lower KEM and higher HEM in the injured limb suggest both inter- and intra- limb compensatory strategies to offload the knee joint. Lower KEM in those with meniscal injury

indicates additional quadriceps avoidance. In contrast, longer time since injury may reflect progressive restoration of loading capacity. Higher PFM in females indicates sex-specific compensatory strategies to mitigate knee loading. These results emphasize the importance of considering concomitant injuries, sex and recovery timelines when interpreting and managing gait biomechanics after ACL injury.

Female Athletes Exhibit Higher ACL Force than Males in Response to Valgus Moments Due to Increased Coupled Internal Tibial Rotation: A Sex-Specific Computational Modeling Study in 168 Young Athletes

Dr. Andrew Pechstein PhD[1], Ms. Isabella Gomez Hjerthen BS[1], Mr. David Shamritsky MS[1], Dr. Mitchell Wheatley PhD[1], Dr. Mark Amirtharaj MD[1], Dr. Danyal Nawabi MD[1], Dr. Thomas Wickiewicz MD[1], Dr. Michael Parides PhD[1], Dr. Andrew Pearle MD[1], Dr. Bruce Beynnon PhD[2], Dr. Carl Imhauser PhD[1]

[1]Hospital for Special Surgery, New York, New York, United States. [2]University of Vermont, Burlington, Vermont, United States

Introduction

Young female athletes are at higher risk of noncontact anterior cruciate ligament (ACL) injury than their male counterparts. Whether sex-based differences in ACL loading and tibiofemoral kinematics exist due to loads experienced during cutting and pivoting sports, namely compression, valgus, and anterior loads, remains unknown. We investigated (1) whether any of these loads disproportionately increased ACL force in females and, if differences emerged, (2) which tibiofemoral kinematic (internal tibial rotation (ITR), valgus angulation, or anterior tibial translation (ATT)) was most strongly associated with this increase.

Methods

MRI data from 120 female and 48 male high school and college athletes (half sustained noncontact ACL tear, half matched controls) were analyzed. Three-dimensional renderings of bone, cartilage, and meniscal geometries were extracted. Ligament attachments were identified and soft-tissue properties standardized. Knee models were sequentially loaded with axial compression (100N), a valgus moment (8Nm), and an anterior tibial force (30N) at 15° of flexion. ACL force and tibiofemoral kinematics were recorded during each loading step. Potential sex-differences in ACL force at each step were examined using unpaired t-tests. After identifying loading step(s) with male–female ACL force differences, relationships between ACL force increases and changes in ITR, valgus angulation, and ATT were quantified using linear regression.

Results

The valgus moment resulted in a larger increase in ACL force for females than males (72±27N vs 58±24N, p=0.002). ACL force increases were not different for axial compression and anterior tibial force (p>0.05). During the applied valgus moment, ACL force increases were most strongly associated with ITR (R^2=0.60), then ATT (R^2=0.40) and valgus angulation (R^2=0.17).

Discussion

A larger increase in ACL force from valgus moments applied after compression in females is not from increased valgus angulation. Rather, coupled ITR is most strongly associated with increased ACL force. Using subject-specific geometries with standardized soft tissue properties revealed that knee geometry increases ACL force in females. Integrating a clinical dataset with physics-based simulation revealed a distinct ACL loading mechanism in young athletes. Prevention and rehabilitation programs and surgeries that reduce valgus loads or control coupled ITR may reduce ACL loading, especially in females.

Longitudinal Evaluation of Sex Differences in Knee Loading During Gait After ACL Reconstruction

Dr. Alexa Johnson PhD[1], Ms. Reagan Recchia[1], Mr. Ryan Mahoney[1], Ms. Olivia Sunderlik[1], Ms. Fiona Conway[1], Mr. Michael Angelini[1], Dr. Beyza Tayfur PT, PhD[1,2], Dr. Riann Palmieri-Smith ATC, PhD[1]

[1]University of Michigan, Ann Arbor, MI, United States. [2]Kırşehir Ahi Evran University, Kırşehir, Kırşehir, Turkey

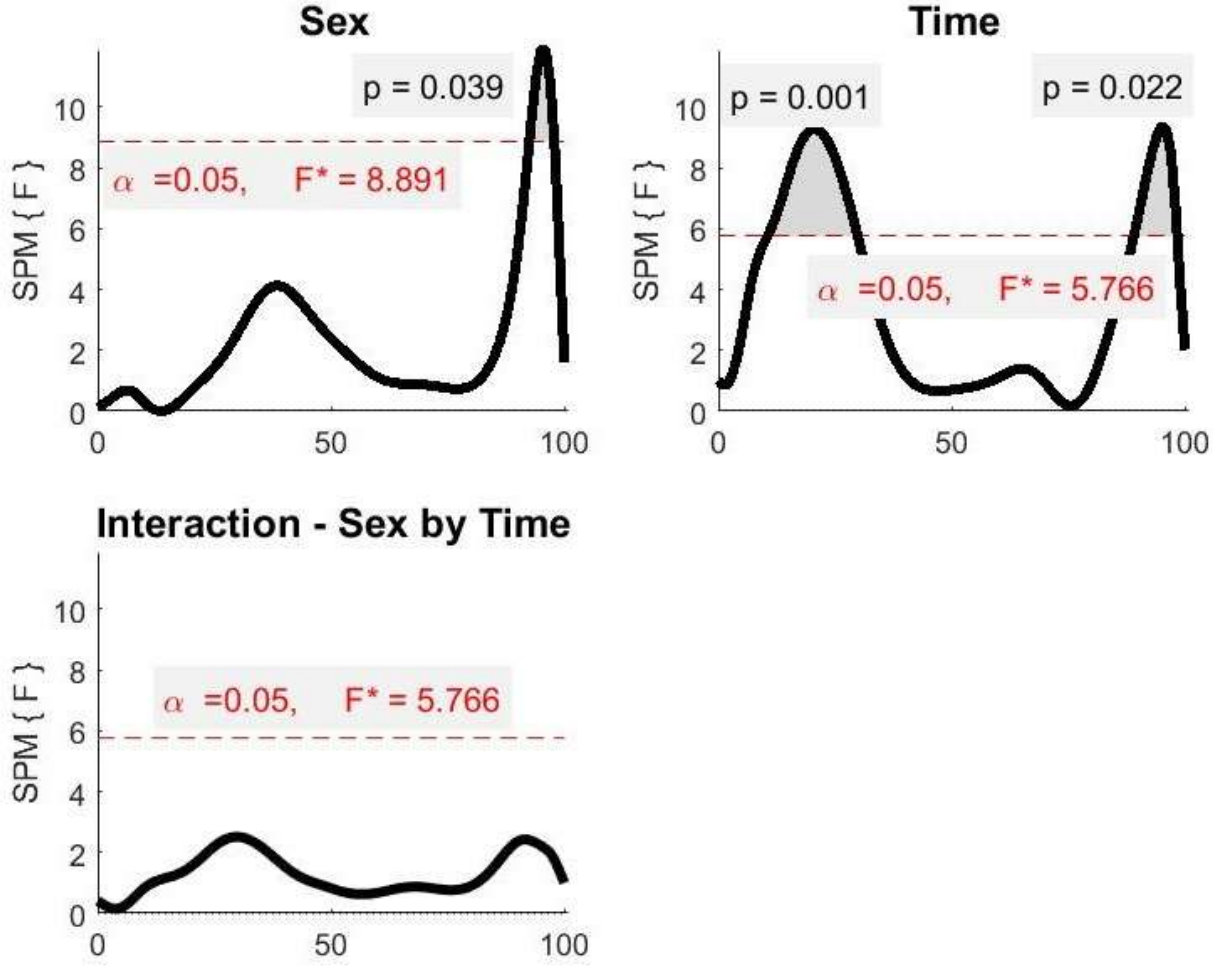
Introduction

Knee loading following ACL reconstruction is one critical component contributing to long-term joint health and the risk of subsequent ACL injury. Altered knee loading during gait can contribute to the development of post-traumatic knee osteoarthritis if not properly addressed in rehabilitation. After ACL reconstruction, females reported lower patient reported outcomes and decreased quadriceps strength compared to males, though there is limited information assessing sex differences in knee loading post-surgery. Identifying sex differences in knee loading trajectories longitudinally may help improve ACL reconstruction rehabilitation programs. Therefore, the purpose of this project was to determine differences in knee loading biomechanics between females and males throughout the rehabilitation process following ACL reconstruction.

Methods

Fifty-four individuals (27 males, 27 females; 21.4±6.7yrs; 1.73±0.9m; 78.7±17.7kgs) had undergone ACL reconstruction (45 bone patellar tendon bone, 6 hamstring tendon, 3 quadriceps tendon grafts) completed gait biomechanics testing three times, 4.4±0.5months, 9.1±0.5months, and 18.0±0.6months post-surgery. Individuals walked overground at their self-selected speed and three-dimensional motion capture and force plates were used to collect lower extremity kinetic data. Joint moments were calculated using inverse dynamics and reported as internal knee joint moments. A 2x3 (sex by time) repeated measure analysis of variance utilizing statistical parametric mapping compared the waveform of the knee moment during stance phase on the ACL limb, with posthoc t-tests run for significant main effects. Significance was set a priori at $p<0.05$.

Results



Statistical parametric mapping identified a main effect of sex between 92-97% ($p=0.039$) of stance (Figure 1), posthoc t-tests identified females had greater knee extension moments on the ACL limb during 92-97% ($p=0.017$) of stance, compared to males. There was also a

main effect for time between 10-30% (p=0.001) and 89-98% (p=0.022) of stance (Figure 1), where posthoc paired t-tests identified no differences in knee moments on the ACL limb across time points.

Discussion

We identified females increased knee loading during terminal stance on the ACL limb during gait, suggesting knee loading may be a contributing factor to sex differences following ACL reconstruction. Further analysis warrants assessing loading differences between females and males, between limbs, as well as during more functional tasks.

Knee Asymmetry Three Months After ACL Reconstruction Is Indicative of Poor Function at Nine Months

Dr. Evy Meinders PhD[1], Mr. Zhixiong Li MSc[1], Mr. Vu Phan MSc.[1], Dr. Andrew Sprague PT, MS, PhD, DPT[2], Dr. Volker Musahl MD[2], Dr. James J. Irrgang PT, PhD, FAPTA[2], Dr. Eni Halilaj PhD[1,2]

[1]Carnegie Mellon University, Pittsburgh, PA, United States. [2]University of Pittsburgh, Pittsburgh, PA, United States

Introduction

Many individuals continue to show asymmetric loading at follow-up visits after anterior cruciate ligament reconstruction (ACLR) [1], and this sustained asymmetry has been associated with poor clinical outcomes. While prior work has focused on linking gait asymmetry at six months following surgery to long-term outcomes [2], earlier risk identification could have greater impact on personalized rehabilitation. We aimed to determine if movement patterns three months post-ACLR provide early insight into knee function at nine months post-ACLR.

Methods

Thirty-six participants at three months post-ACLR walked on an instrumented treadmill and performed a lateral step-down exercise. Marker trajectories (OptiTrack) and ground reaction forces (Bertec) were synchronously recorded. Inverse kinematics and dynamics were performed in OpenSim. Asymmetries in peak joint kinematics and kinetics were used as inputs for a dimensionality reduction task, followed by k-means clustering. The silhouette approach was used to identify the number of clusters. Timeseries asymmetries between clusters were compared using an unpaired t-test with statistical parametric mapping ($p<0.05$). The International Knee Documentation Committee Subjective Knee Form (IKDC-SKF) was completed at three- and nine-months post-ACLR. To date, 22 participants completed the nine months IKDC-SKF. Scores were compared between clusters using an unpaired t-test ($p<0.05$).

Results

Two clusters were identified. Participants in the first cluster (N=15) were more symmetric at the knee (Figure 1A) but less symmetric at the hip (Figure 1B) compared to those in the second cluster (N=21). There were no significant differences in IKDC-SKF scores between clusters at three months (Figure 1C; Median[Q1-Q3]: 56[49-61] vs 56[47-60], p=0.83), but the first cluster had better scores at nine months (91[83-95] vs 75[69-82], p=0.005).

Discussion

We identified two movement patterns in individuals three months post-ACLR that may be more indicative of their long-term function than the IKDC-SKF score. The difference in IKDC-SKF scores at nine months surpassed the minimal clinically important difference [3], showing clinically meaningful differences in knee function between groups at nine months. Early identification of these movement patterns may enable early personalization of post-operative rehabilitation.

Associations Between Medial Tibiofemoral Contact Forces in Walking and Femoral Cartilage Health Over the First Year Following Anterior Cruciate Ligament Reconstruction

Mr. Justin Dennis M.S.[1], Dr. Thomas Birchmeier PhD, ATC[2], Dr. Beth Bacon PhD[1], Dr. Brian Pietrosimone PhD, ATC[1], Dr. Jason Franz PhD[1,3], Dr. Troy Blackburn PhD, ATC[1]

[1]University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, United States. [2]University of North Carolina at Greensboro, Greensboro, North Carolina, United States. [3]North Carolina State University, Raleigh, North Carolina, United States

Introduction

Smaller medial tibiofemoral contact forces (MCF) in the anterior cruciate ligament reconstructed (ACLR) limb <12 months post-ACLR precede radiographic post-traumatic osteoarthritis (PTOA). Femoral cartilage is generally compromised before tibial cartilage, but it is unclear if MCF is associated with cartilage health over the first year post-ACLR and if these associations differ from the contralateral limb.

Methods

Walking biomechanics and magnetic resonance imaging (MRI) (i.e., T1ρ relaxation times indicating proteoglycan density) were assessed 1 and 12 months post-ACLR (Female:45%, age:23±6years, height:1.73±0.933m, mass:74.88±15.01kg). We used a full-body musculoskeletal model with a multi-compartment knee and static optimization to estimate MCF normalized to body weight, and segmented MRIs into femoral weight-bearing regions based on locations of the anterior and posterior horns of the meniscus. Linear mixed-effects models that included both limbs and time points were used for each femoral region to determine the association between peak MCF and T1ρ relaxation times while controlling for gait speed, and whether relaxation time differences exist between limbs and across time.

Results

ACLR and contralateral limb MCF were not associated with T1ρ relaxation times in the posterior, middle, or anterior femur 1 or 12 months post-ACLR ($p \geq 0.183$ for all associations). T1ρ relaxation times did not differ in the ACLR limb from 1 to 12 months in the posterior, middle, or anterior femur ($p \geq 0.472$ for all comparisons). T1ρ relaxation times were longer in the contralateral limb than the ACLR limb in the middle femur 1 month post-ACLR ($\Delta = 3.37$ms, $p < 0.001$), but did not differ between limbs in the posterior or anterior ($p \geq 0.125$) femur. T1ρ relaxation times decreased in the contralateral limb from 1 to 12

months in the middle femur (Δ=3.33ms, p=0.004), but no other limb×time interactions were observed in the posterior (p=0.119) or anterior femur (p=0.632).

Discussion

MCF was not associated with T1ρ relaxation times in either limb 1 or 12 months post-ACLR. However, contralateral limb middle femoral cartilage health was worse than the ACLR limb 1-month post-ACLR but improved from 1 to 12 months. The contralateral limb may experience increased loading demands post-ACLR, which the cartilage adapts to by remodeling (i.e., increasing proteoglycan density).

Knee Cartilage Thickness and Knee Mechanics in Walking Not Associated with Sport History in Young Runners and Swimmers

Ms. Zoey Kearns[1], Ms. Maliheh Fakhar[1], Dr. Gauri Desai[1,2], Dr. Ross Miller[1]

[1]University of Maryland, College Park, College Park, MD, United States. [2]Stanford University, Stanford, CA, United States

Introduction

Exercise in general is an effective measure to prevent initiation and development of knee osteoarthritis (OA). All forms of exercise involve some level of joint loading, but evidence is conflicting as to whether loading is beneficial or detrimental. Loading induced by recreational running participation does not seem to increase knee OA risk, but it is unknown if sports with low levels of loading, like swimming, affect the risk of developing knee OA. Generally, thinner knee cartilage and higher knee adduction moment (KAM) are associated with a greater risk of developing knee OA. Examining these variables in young athletes while cartilage is still adaptable can inform exercise recommendations for athletes to maintain joint health. The purpose of this research was to identify the relationship between sport induced loading, knee cartilage thickness, and biomechanical differences related to sport induced-loading exposure, particularly risk factors for developing knee OA.

Methods

24 young athletes with 11±4 years of experience focusing on their sport (18-29 years, 12 runners, 12 swimmers) walked and ran at three set speeds and had tibiofemoral knee cartilage thickness imaged using ultrasound (Fig. 1). Mann-Whitney non-parametric t-tests were used to identify differences between runners and swimmers in dominant leg cartilage thickness, and in lower limb gait mechanics.

Results

There were no differences between runners and swimmers in medial or lateral cartilage thickness. Swimmers ran with greater knee net work than runners, and runners walked with greater hip extensor moment and hip-to-ankle positive work ratio than swimmers. Swimmers exhibited greater peak ankle plantarflexion than runners in both gaits. There were no group differences in either gait in KAM or knee flexion moment.

Discussion

Swimmers vs. runners did not differ in knee cartilage thickness, or in biomechanical factors associated with knee OA risk, suggesting running vs. swimming history, at least at this age, has not appreciably affected knee joint health, positively or negatively. More sport-based differences were visible at the hip and ankle, which are more affected by age, suggesting that sport history could impact the age-related gait changes, and age is a demographical risk factor for OA.

Stroller Running Slightly Attenuates the Stride Length–Speed Relationship

Dr. Joseph Mahoney Ph.D.[1], Ms. Abby Miller[2], Dr. Allison Altman-Singles Ph.D.[2]

[1]Alvernia University, Reading, PA, United States. [2]Penn State Berks, Reading, PA, United States

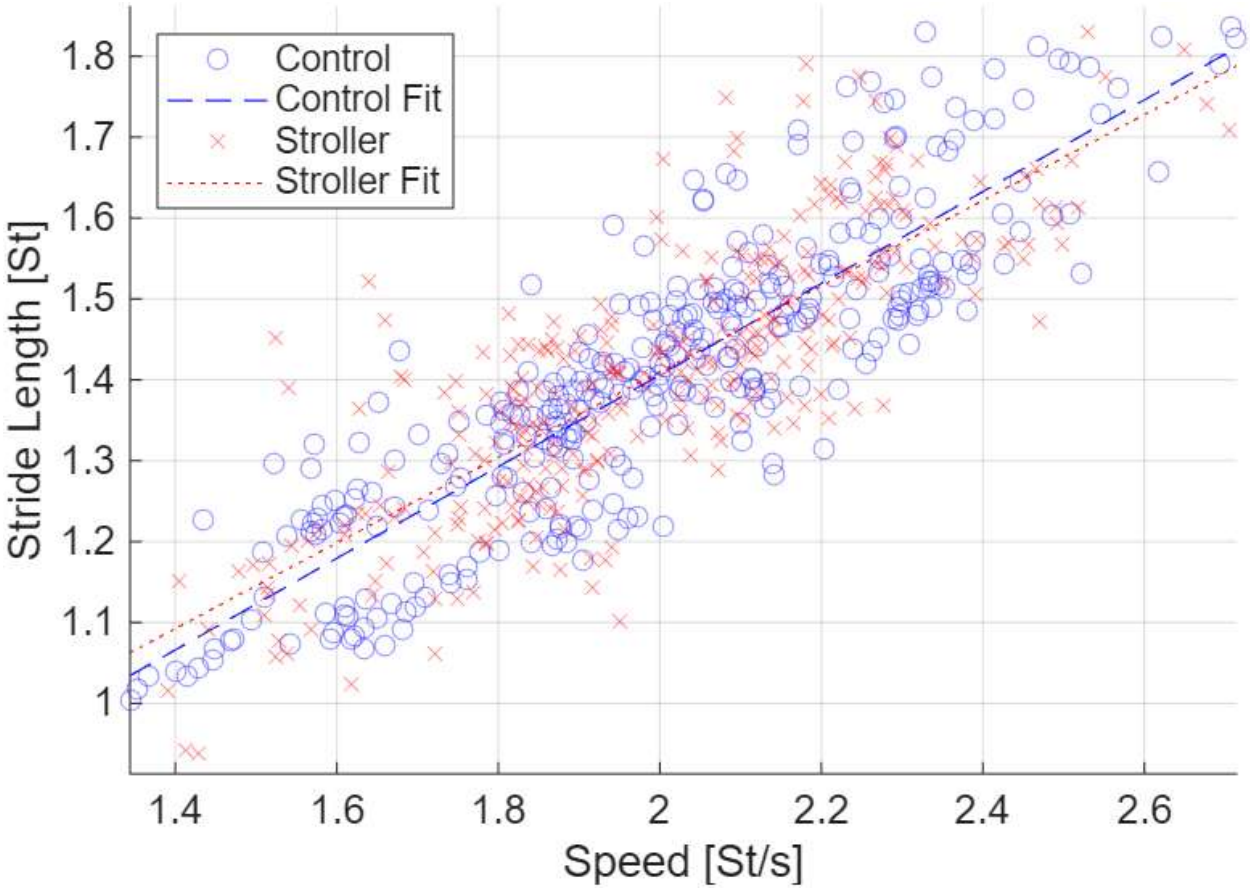
Dr. Joseph Mahoney

Introduction

Pushing a jogging stroller alters running mechanics [1- 3], but its effect on the relationship between running speed and stride length is not well characterized. Overstriding or understriding may influence injury risk and performance, so quantifying stroller effects on stride length is important. Prior work reported either no change in stride length at matched speeds [1, 2] or shorter strides when runners chose slower stroller speeds [3]. However, these analyses compared conditions in aggregate rather than modeling subject-specific speed and stride relationships. The purpose of this study was to determine how jogging strollers influence the relationship between running speed and stride length.

Methods

Thirty-eight adults ran overground with and without a jogging stroller at self-selected speeds. Data collection followed previously published methods for this cohort [1]. Each participant contributed multiple strides across a range of self-selected speeds in each condition. Stride length and speed were normalized by stature. Normalized stride length was modeled as a function of normalized speed, condition (stroller or control), and their interaction using a linear mixed-effects model with subject-specific random intercepts and random slopes for speed. This approach accounted for repeated measures and individual differences.



Results

Normalized stride length increased with normalized speed in both conditions ($p<0.001$). The speed-by-condition interaction was significant ($p<0.001$), with the stroller condition showing an approximately 11% lower stride length–speed slope (95% CI: 5–17%). This corresponded to a slightly compressed stride length range in the stroller condition relative to control, consistent with the fitted lines in the figure.

Discussion

Stride length increased with speed in both conditions, consistent with prior work on running mechanics. Pushing a stroller produced a small but statistically significant reduction in the stride length–speed slope, indicating a subtle change in how runners scale stride length with speed. This effect appears modest over the tested speed range but may still be relevant when interpreting running mechanics in frequent stroller users.

OA142-03

Climbing to Lower Loads: Ground Reaction Force Adaptations in Incline Running

Dr Karen Mickle PhD

University of Newcastle, Newcastle, NSW, Australia

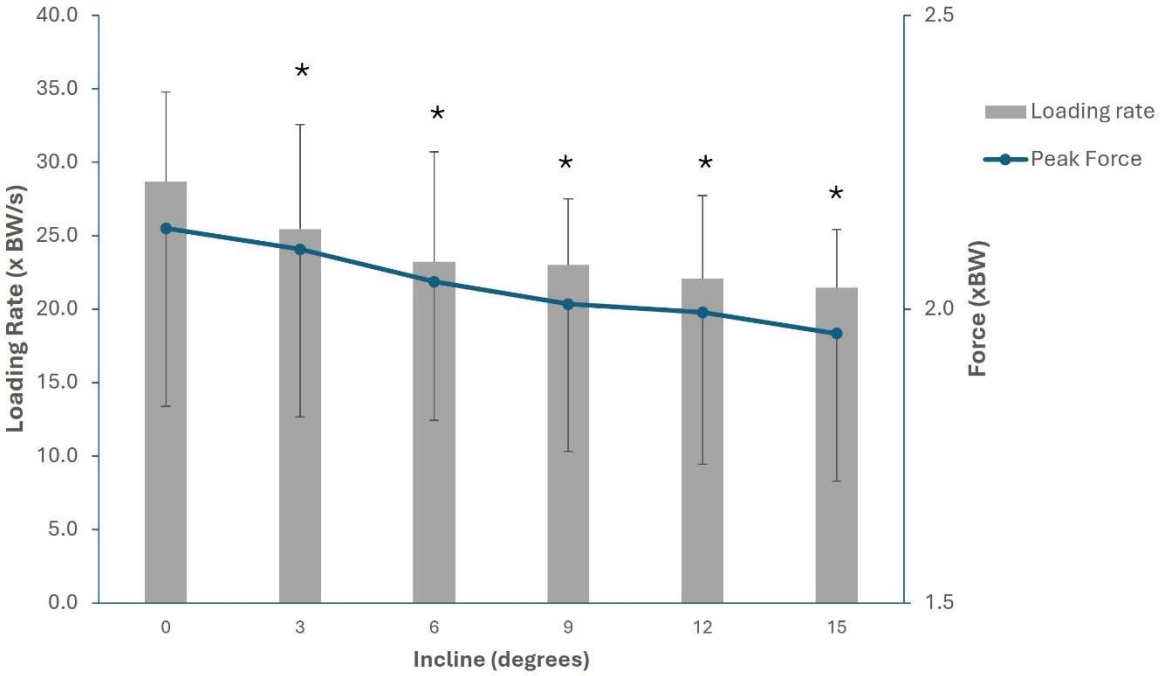
Introduction

Uphill running research accounts for a relatively small proportion of the overall biomechanics literature — most studies focus on level running, with fewer dedicated to uphill conditions. However, interest is increasing as participation in trail and mountain running rises. Trail running participation has seen a growth rate of 15% each year for the past decade, with current estimates at 20 million trail-runners worldwide. Current research lacks systematic investigations into different gradients, particularly those over 10%. This study aimed to investigate alterations to ground reaction forces (GRF) during uphill treadmill running.

Methods

Sixteen recreational runners (9 males and 7 females; mean (± SD) age 41.3 ± 9.4 y, height 170.7 ± 8.0 cm, weight 72.6 ± 10.1 kg) participated in this study. Long-distance runners who run at least 3 times per week, with no injuries in the previous 12 months, were eligible for the study. Following a warm-up, participants self-selected a running pace they could sustain for 1 minute on a 12% gradient. Participants were fitted with an instrumented insole (Loadsol Pro, Novel$_{gmbh}$) and data were recorded for 30s at 0, 3, 6, 9, 12 and 15 degrees in a counterbalanced order. Differences in peak vertical GRF, loading rate, cadence and contact time for the right foot were determined using a repeated measures ANOVA (SPSS, V30).

Results



There was no significant main effect of incline on ground contact time; however, there was a significant main effect of incline on peak GRF, loading rate, and cadence ($p < 0.001$). Peak VGRF and loading rate were significantly lower at all inclines (3-15°) compared to level running (see Figure 1). Conversely, the cadence increased at every incline from level running (167.0 ± 8.5 steps/min) to 15° (176.6 ± 8.2 steps/min).

Discussion

Despite maintaining constant running speed, incline running significantly reduced peak vertical ground reaction forces and loading rates, with slopes above 6° most effective. This aligns with prior evidence that graded running alters loading mechanics and suggests that

uphill running may benefit individuals with load-related injury histories. However, findings are limited to treadmill conditions; future research should examine natural surfaces to confirm ecological validity and inform practical injury-prevention strategies.

The Effect of Foot Progression Angle on Tibiofemoral Joint Contact Forces in the Medial and Lateral Compartments During Running

Ms Amber S Van Nes B.Eng, Ms Katelyn M Roe B.Eng, Dr Stephen FE Mattucci Ph.D, P.Eng, Dr Scott CE Brandon Ph.D, P.Eng

University of Guelph, Guelph, ON, Canada

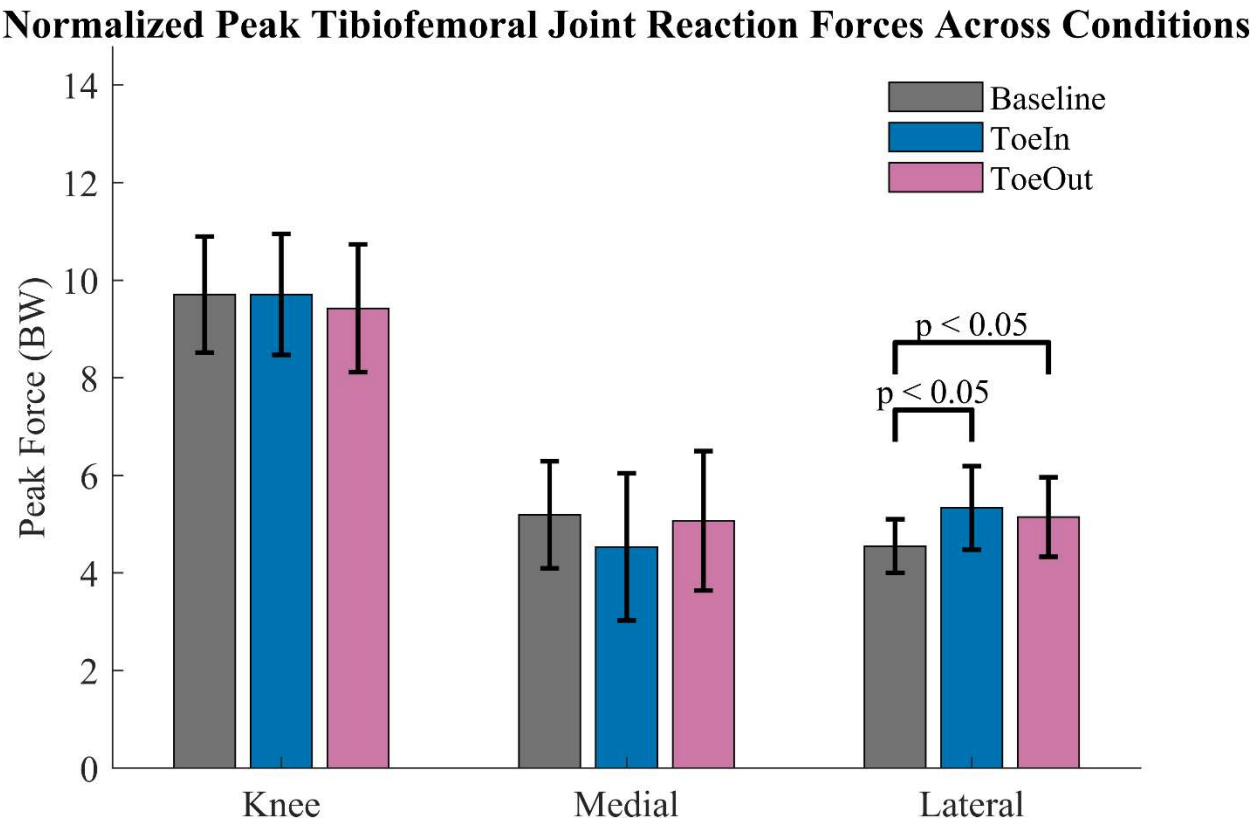
Introduction

Alterations in foot progression angle (FPA) modification is a simple, non-invasive approach for modifying knee joint loading and may reduce knee osteoarthritis risk. While toe-in (TI) and toe-out (TO) gait patterns alter medial knee loading during walking, their effects on compartment-specific tibiofemoral joint contact forces (JCFs) during running remain unclear. This study quantified the effects of TI and TO gait modifications on medial and lateral tibiofemoral compartment JCFs during running. It was hypothesized that TI and TO gait would respectively shift JCFs more medially and laterally.

Methods

Eleven healthy young adults (26.1 ± 2.2 years, 1.76 ± 0.10 m, 70.8 ± 13.7 kg) completed five to eight trials of baseline (BL), TI, and TO running. FPA was modified ±10° from BL measured with a goniometer. Peak tibiofemoral JCFs, normalized to bodyweight, were estimated in the medial and lateral compartments of the right knee using OpenSim (v4.2) with the Bedo-Catelli knee model. A musculoskeletal modelling workflow was applied, including scaling, inverse kinematics, inverse dynamics, static optimization, and joint reaction analysis. Statistical comparisons performed in JASP (v0.95.4.0) between conditions were performed using a two-way repeated-measures ANOVA and Holm post-hoc tests.

Results



Peak tibiofemoral JCFs differ significantly across compartments, with condition-dependent changes in lateral loading. No overall effect of gait condition was present ($p=0.812$); however, a significant condition/compartment interaction was present ($p=0.003$). Post-hoc analyses showed no differences between conditions within the medial compartment (all $p>0.05$). In contrast, lateral compartment forces were significantly higher during TI compared to BL and TO compared to BL ($p<0.05$). Variability across participants was

greater in the medial than lateral JCFs across all conditions, reflecting less consistent load distribution in the medial compartment.

Discussion

FPA modifications during running altered compartmental tibiofemoral joint loading without affecting overall joint force. Contrary to expectations, both TI and TO increased lateral compartment loading, suggesting that medial-lateral compartment load redistribution during running differs from walking and may be constrained by the higher mechanical demands of running. These findings highlight the importance of evaluating gait interventions within the task context and suggest that FPA represents a modifiable parameter for influencing knee joint loading during running when appropriately applied.

Classification of Running Movement Patterns in Service Members with Knee Pain

Mr Adam Bunn MS[1,2], Dr. Madeline Grosklos PhD[1,2], Dr Marisa Pontillo PhD[1,2]

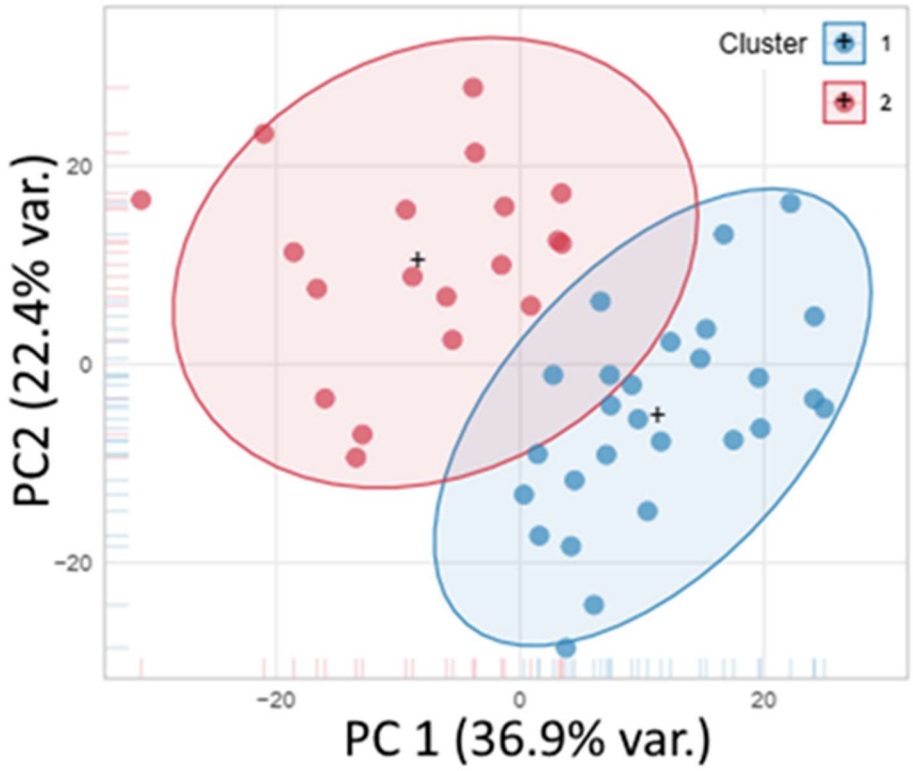
[1]Extremity Trauma and Amputation Center of Excellence, San Diego, CA, United States. [2]Naval Medical Center San Diego, San Diego, CA, United States

Introduction

Understanding movement strategies in runners with knee pain is crucial for developing targeted interventions. Traditional analyses often focus on discrete variables or isolated joint patterns, potentially overlooking coordination across multiple joints and planes of motion. This study hypothesized that distinct movement strategies exist among runners with knee pain and that multivariate functional principal component analysis (MFPCA) combined with Dirichlet Process K-means (DP-means) clustering [1] could identify these strategies.

Methods

Running gait data were collected from 50 active-duty Service members (35 male/15 female; age: 32.3±8.0 years; height: 1.75±0.10 m; mass: 79.5±14.8 kg) with unilateral, non-operative knee pain using an optical motion capture system and an instrumented treadmill. Participants ran at self-selected speeds. Bilateral sagittal plane hip/knee moments, sagittal/frontal plane hip/knee/pelvis angles, and sagittal ankle angles during stance phase [2] were analyzed in Visual3D. MFPCA captured coordination patterns across all variables simultaneously, retaining principal components (PC) to explain 90% of total variance. DP-means clustering was applied to PC scores, stability assessed through bootstrap resampling, generating silhouette coefficients.



Results

DP-means clustering (lambda=1700) revealed that 92% of participants fell into two distinct movement patterns with strong cluster stability (stability score=0.765) and reasonable separation (average silhouette width=0.232). These patterns were distinguished primarily through three PCs, explaining 72.7% of total variance. The primary cluster (n=27) demonstrated a movement strategy characterized by greater frontal plane hip motion with increased sagittal plane flexion throughout the lower extremity, while the secondary cluster (n=19) showed reduced frontal plane hip motion and moments and a more extended posture across hip, knee and ankle joints.

Discussion

This study identified two stable movement patterns among runners with knee pain using MFPCA and DP-means clustering. The emergence of distinct extended versus flexed movement strategies suggests that runners may adopt consistent biomechanical adaptations in response to knee pain. These findings provide an objective foundation for developing targeted rehabilitation approaches based on movement pattern classification.

Tibial Bone Load, Strength, and Dynamic Balance in Initial Return to Run Phase Following Tibial Bone Stress Injury

Ms Megan Peach DPT, Ms Lailah Rosario, Dr. James Becker PhD

Montana State University, Bozeman, MT, United States

Introduction

Tibial bone stress injuries (BSI) are common running related injuries with a one in five recurrence rate. A possible risk factor for recurrent BSI is increased tibial loads in the early return to run phase. Altered strength and balance post injury have potential to influence running mechanics and therefore contribute to variations in tibial load during running. The purpose of this study was to compare tibial forces, strength, and dynamic balance between runners who have recently returned to running following tibial BSI and healthy controls.

Methods

Three runners diagnosed with tibial BSI (2F, 1M, age 25.0±6, BMI 22.5±0.7, speed 2.9±.7 m/s) with an average of 2.67 weeks since returning to running were matched for sex, age, BMI, and self-selected treadmill speed to three healthy controls (2F, 1M, age 22.0±3.5, BMI 21.9±.1, speed 2.9±.4 m/s). Participants ran on an instrumented treadmill for five minutes while kinematic and kinetic data were collected via motion capture. Clinical measures of dynamic balance (Y-balance test), single leg heel raise endurance, and ankle strength assessed via hand-held dynamometry (HHD) were also collected. Ankle joint angles, reaction forces, and moments were used as inputs to a musculoskeletal model to calculate tibial axial force as the sum of Achilles tendon and vertical ankle joint reaction forces. Welch's t-test was used to determine differences in peak tibial force and clinical variables between healthy and injured groups while Hedges' *g* tested for effect size.

Results

Peak tibial force, single leg heel raise endurance, and all other strength measures were not different between injured and healthy runners. However**,** Y-balance composite score was worse in the injured group compared to the healthy controls with a large effect size (Hedges' $g = 3.04$, CI: .83-5.25).

Discussion

Based on preliminary results, runners who recently returned to running after tibial BSI have decreased dynamic balance compared to healthy runners. This deficit has potential to alter running mechanics and therefore tissue load. Additional participants and further investigation are necessary to determine if differences in clinical measures are persistent and if these differences contribute to an increased risk of subsequent BSI.

Menstrual Cycle Effects on Breast Acceleration During Running

Ms Ine Mylle PhD, Mr Ephrem Mekonnen MSc, Ms Jessica Yeoman BSc, Ms Sophia Wisotzki BSc, Mr Christopher Napier Prof

Simon Fraser University, Department of Biomedical Physiology and Kinesiology, Burnaby, British Columbia, Canada

Introduction

Female athletes experience cyclic changes in performance, mood, and injury risk across the menstrual cycle (MC) which also affects breast tissue composition and stiffness, yet its influence on breast biomechanics remains unexplored. During running, breasts move substantially and can cause pain, discomfort, and reduced participation, yet it is unknown whether these cyclic changes modulate breast acceleration.

Methods

Ten naturally menstruating, well-trained female runners (age: 27 ± 5.6 y, BMI: 21.6 ± 1.5; bra size range: 32A-34D) completed three treadmill-running sessions matched to the early follicular (EF), late follicular (LF), and mid-luteal (ML) phases, confirmed by 3-months of MC tracking and ovulation test kits. Participants ran at incremental speed intervals (starting at 50% of the 5k best: 23.83 ± 2.42 min) until failure while capturing accelerations of bilateral breast (nipple), sternum, and sacrum with inertial measurement units (Plantiga Technologies, Vancouver, Canada). Thirty-second sacral sensor recordings were cropped to the middle 30 running steps [Day et al., 2021] and synchronized to the other sensors to calculate mean peak resultant acceleration per speed level. All participants underwent 3D surface scanning (Artec Leo, Artec, Luxembourg) to quantify breast volume [Coltman et al., 2017] per visit. Linear mixed-effects models examined peak resultant acceleration (fixed effects: speed level, menstrual phase, and breast volume; random intercepts: subject). Significance was set to $p<0.05$.

Results

Breast acceleration significantly increased bilaterally with running speed ($p<0.001$; Figure 1). Interestingly, the left breast acceleration decreased significantly during LF and ML phases (−0.13g, $p=0.021$, $d=0.34$ for both phases) relative to EF, while the right breast showed no phase effect (LF: -0.03g, $p=0.555$, $d=0.09$; ML: 0.01g, $p=0.818$, $d=0.03$). The sternum acceleration was not different in LF (0.06g, $p=0.114$, $d=0.23$) but increased in ML (0.10g, $p=0.013$, $d=0.37$). Breast volume contributed minimally to these effects (left: -

0.0003cc, p=0.58; right: -0.0015cc, p=0.01) and left-right breast volumes were highly correlated (r=0.95), indicating asymmetry is unlikely to explain the side-specific response.

Discussion

Breast motion asymmetry during running is common and relates to differential tissue compliance. Menstrual-cycle-dependent changes in breast mechanical properties, rather than volume, may modulate these asymmetries, although hormonally influenced biomechanical factors not captured by the breast IMUs may also contribute.

Images (Optional)

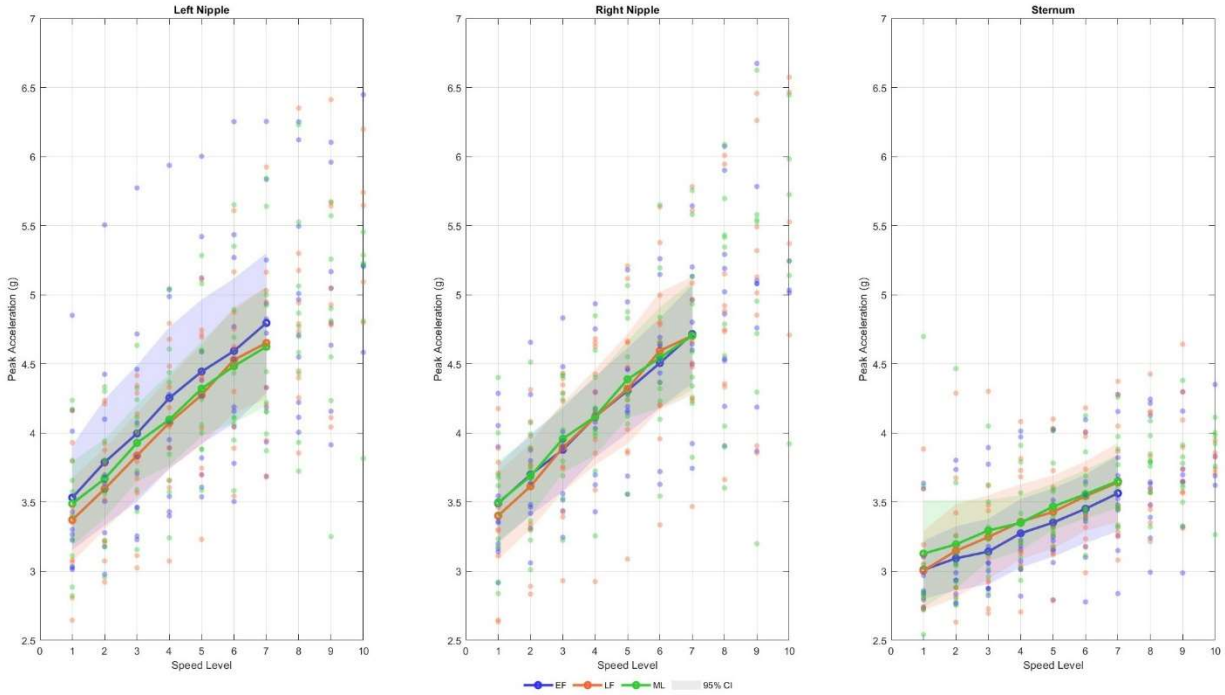

Figure 1. Phase-specific peak resultant acceleration of the left breast (left), right breast (middle) and the sternum (right) during the early follicular (EF; blue), late follicular (LF; orange), and the mid luteal (ML; green) phases. Data are shown as individual data points (faded), mean values, and 95% confidence intervals (shaded area).

Quantifying the Temporal Delay between Breast and Torso Acceleration Data Obtained From Inertial Measurement Units

Ms. Tarini Rajasekar[1,2], Dr. Ine Mylle[1], Ms. Jessica Yeoman[1], Dr. Sian Allen[3], Dr. Christopher Napier[1]

[1]SFU Run Lab, Department of Biomedical Physiology and Kinesiology, Simon Fraser University, Burnaby, BC, Canada. [2]School of Biomedical Engineering, University of British Columbia, Vancouver, BC, Canada. [3]lululemon Athletica, Vancouver, BC, Canada

Introduction

Due to the limited internal support provided to breast tissue, its motion lags the underlying thorax. Previous work using motion capture has described this breast-torso time lag during running (Williams, 2024). Quantifying this during a vertical jump with inertial measurement units (IMUs) would extend current knowledge on the breast–torso relationship, improving the understanding of soft tissue dynamics.

Methods

Ten women (31±4.74y) completed five repetitions of a 30cm vertical jump wearing a low support bra (size 6-10) with IMU sensors (iMeasureU,Vicon,Oxford,UK) placed on the sacrum, sternum, left breast (LB), and right breast (RB). An algorithm was developed to detect start/end (S/E) times for the acceleration data from each sensor after applying a 4^{th} order Butterworth filter with a 6Hz cut-off frequency. The S/E times of the breast were defined as the first instance of acceleration magnitude between 0.05-0.9m/s^2. Ground reaction force (GRF) data was estimated from vertical acceleration of the sacral IMU. First instances when GRF reached the respective stead-state standing force within a ±0.15-5N range were used to define S/E and applied to the torso (sternum) IMU. The time lag was defined as the absolute difference in S/E times between the LB/RB and sternum sensor. Coefficient of variance (CV) of LB/RB time lags within each participant were calculated.

Results

The mean time lags across S/E times and participants were LB:0.532±0.131s and RB:0.572±0.114s. Relative time lag for start times yielded negative values, LB:-0.543±0.183s and RB:-0.567±0.229s; while end times yielded positive values, LB:0.452±0.224s and RB:0.529±0.165s. Mean CV over participants for LB:0.432 and RB:0.480.

Discussion

This framework quantifies the breast-torso time lag of acceleration data and yields a larger lag in comparison to a previously reported vertical 0.05s lag during running (Haake, 2010). This is expected, as the algorithm utilizes acceleration magnitude, taking 3 planes of movement into account. Earlier start times and later end times indicate that breast and sternum motion are unsynchronized and exhibit a nonuniform relationship, as supported by higher CV values. Limitations stem from the inability to distinguish noise levels within breast acceleration.

Images (Optional)

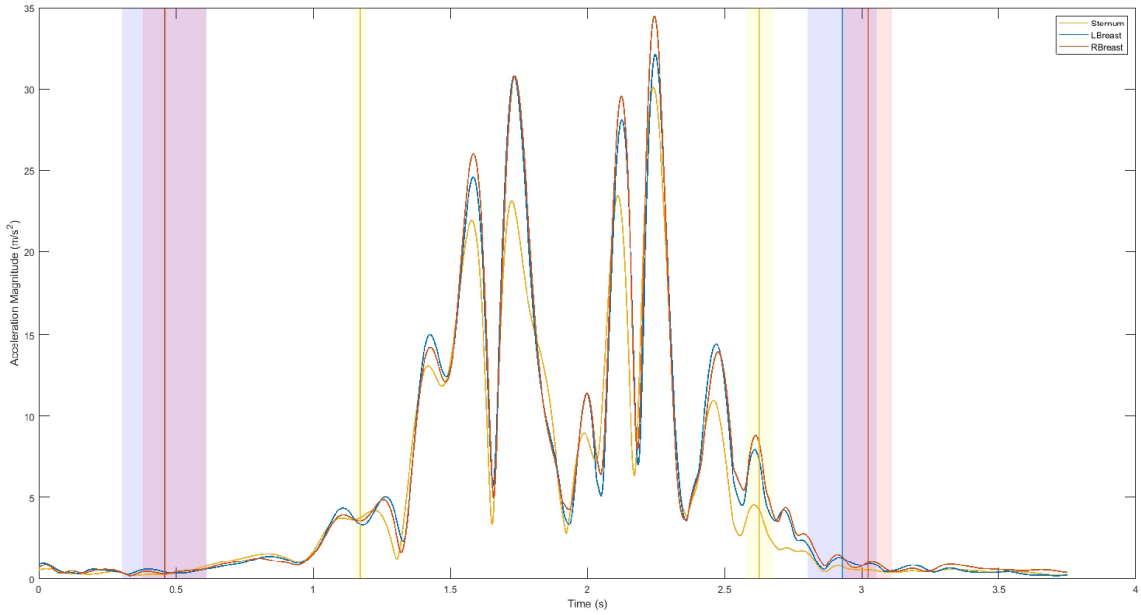

Figure 1. Example IMU acceleration data from one participant for sternum (yellow), left breast (LB; blue), and right breast (RB; red) averaged over three jumps, with mean and standard deviations of Start/End (S/E) times for each sensor (vertical lines).

OA143-03

Frequency and Coherence Analysis of IMU-Derived Breast Motion Across Increasing Running Speeds

Ms. Kaylee White MSc, BSc[1], Mr. Ephrem Mekonnen[1], Dr. Ine Mylle[1], Mr. Amin M. Nasrabadi[2], Dr. Christopher Napier[1]

[1]Simon Fraser University, Burnaby, British Columbia, Canada. [2]University of British Columbia, Vancouver, British Columbia, Canada

Introduction

Female breasts lack anatomical support, resulting in passive multiplanar movement during running [1]. Running-induced fatigue and higher speeds may reduce soft-tissue shock-attenuating properties under repeated foot-strike impacts. As tissue damping capabilities are frequency-dependent, specific impact frequencies may contribute to tissue damage [2]. These concerns may also be applied to the breasts, increasing stress on the tissues and contributing to pain and damage [3]. This study aimed to assess changes in frequency distribution of breast acceleration signals and sternum-to-breast coherence as running speed increased.

Methods

Highly trained, healthy female runners were recruited from a larger study. Five inertial measurement units (Plantiga Technologies, Vancouver, Canada) were attached to the tibias, breasts, and sternum. Participants completed three-minute running intervals at increasing speeds on a treadmill until failure. The first trial and the final trial completed before failure served as the slow and fast trials, respectively. Vertical breast and sternum accelerations were extracted, trimmed to 30-second intervals, stride-segmented, and analyzed with Morlet Wavelet transform [4, 5].

Results

A subset of nine participants (age 25.6 ± 3.9, mass 64.6 ± 8.1 kg, breast volume 365.0 ± 155.6 cm^3) were analyzed. Running speeds for the slow and fast trials were 2.1 ± 0.2 and 3.2 ± 0.3 m/s, respectively. Signal features can be observed at approximately 10 Hz in both slow and fast trials, however the amplitude was higher in the fast trial, and extended later into the stride (Figure 1). Low-frequency (<5Hz) sternum-to-breast coherence was higher early in stride in the fast trial.

Discussion

This exploratory methodology revealed speed-related changes in the breast impact spectral profiles across running strides. Increased sternum-to-breast coherence in the faster trial may be due to increased cadence at faster running speeds, and therefore shorter time-lag between transmitted impacts. However, the higher-frequency spectral changes observed in the faster trial may be due to fatigue-related reductions in damping capabilities, which could contribute to breast tissue stress and pain.

Images (Optional)

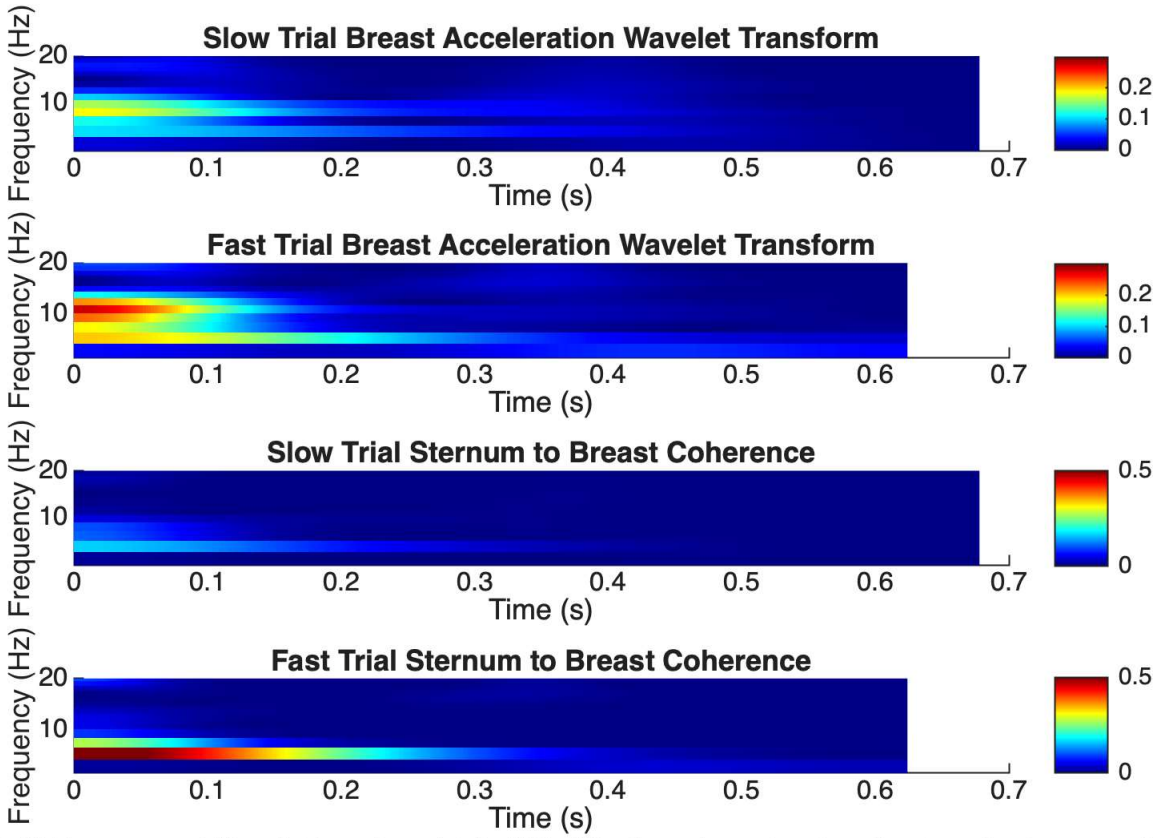

Figure 1. Stride-averaged Wavelet transform (plots 1/2) of the breast acceleration signal, and coherence of sternum-breast (plots 3/4). Increased coherence can be observed at the beginning of stride in the fast trial.

An Exploratory Analysis of Cut-Off Frequency Methodologies for Breast Motion IMU Data During Multiplanar and Uniplanar Movements

Ms Jessica Yeoman[1], Ms Ine Mylle Dr[1], Ms Sian Allen Dr[2], Mr Christopher Napier Dr[1]

[1]Simon Fraser University, Vancouver, BC, Canada. [2]lululemon Athletica, Vancouver, BC, Canada

Introduction

Excessive breast motion during physical activity can contribute to breast pain and discomfort, affecting female performance and participation [1]. Accurately quantifying breast motion is critical for understanding breast biomechanics and designing supportive apparel [1]. While inertial measurement units (IMUs) offer a portable method for capturing breast acceleration in ecologically valid environments, noise and error often affect the raw data [2]. Without a standardised, validated filtering methodology, accurate analysis of breast motion using IMUs remains a challenge.

Methods

Seven female athletes (age: 29.9 ± 6.0y, BMI: 22.0 ± 1.1; bra sizes: 32B-36C) performed five dynamic movements: jogging, vertical jumps, 180-degree jumps, skater jumps, and diagonal cutting. Acceleration was recorded using an IMU adhered to the left nipple. To identify cut-off frequencies, a power spectral density (PSD) analysis using Welch's method [3] was performed on each trial's raw resultant acceleration signal. Cut-off frequencies were determined for each participant and trial using the PSD elbow method [4] and the 95% cumulative power method [5], then averaged across participants. Raw signals were filtered using a zero-lag, fourth-order low-pass Butterworth filter with identified cut-offs. Filtering error was quantified by root mean square error (RMSE) and signal-to-noise ratio (SNR) between raw and filtered signals.

Results

Across all movements, the 95% cumulative power method showed lower RMSE and higher SNR compared to the elbow method, a direct result of higher cut-off frequencies (Table 1). This discrepancy was most pronounced during the vertical jump, where the elbow method produced an SNR 51% lower and an RMSE 222% higher than the 95% cumulative power method.

Discussion

These findings suggest the elbow method may over-filter movements, resulting in signal loss and reduced signal quality. Conversely, the 95% cumulative power method provides a more reliable and conservative approach for determining cut-off frequencies. Establishing a standardised processing protocol based on this method may help future research better inform apparel design, reducing a barrier to activity for women.

Sports Bra Support Modulates Breast-Torso Coupling and Soft-Tissue Oscillation During Dynamic Activities

Ms. Meng Pei BASc[1], Dr. Sian Allen PhD[2], Dr. Nicole Kelp PhD[2], Dr. Adrian Lai PhD[2], Dr. Christopher Napier PhD[3], Ms. Genevieve Bonnor BASc[1], Dr. Calvin Kuo PhD, P.Eng[1]

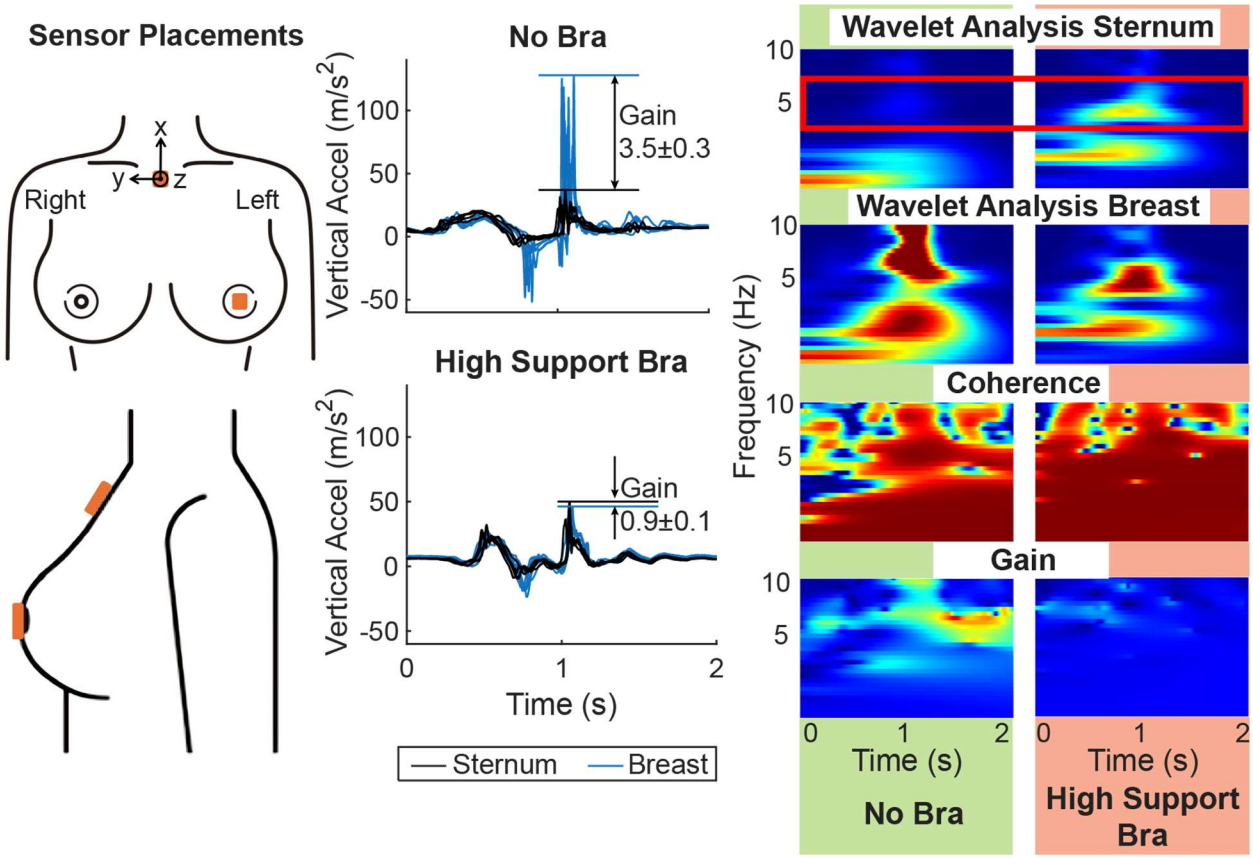
[1]University of British Columbia, Vancouver, British Columbia, Canada. [2]lululemon, Vancouver, British Columbia, Canada. [3]Simon Fraser University, Burnaby, British Columbia, Canada

Introduction

Exercise-induced breast pain affects up to 72% of active women and can reduce athletic performance [1]. Sports bras help reduce pain by limiting excessive breast motion, typically characterized using time-domain metrics. However, the mechanism by which sports bras reduce breast motion by coupling the breast to the torso is understudied. This pilot study aims to use frequency-domain analysis to assess movement coupling between the torso and breast when using sport bras.

Methods

A healthy participant (25F) completed five vertical jumps under no bra and high support bra (lululemon Energy Bra High-Support) conditions while instrumented with IMUs (1000Hz) on the left nipple and sternum. We extracted two-second windows around each vertical jump, centered around the landing impact, and low-pass filtered (fourth-order Butterworth, 100 Hz) vertical acceleration signals. We then computed time-domain peak acceleration gain between nipple and sternum sensors. Wavelet analysis was performed on the windows, and time-varying frequency-domain coherence and gain were computed.



Results

Peak gain dropped from 3.5 (no bra) to 0.9 (high support), indicating the sports bra reduced excessive breast motion relative to the sternum. Wavelet analysis in the no bra condition showed a distinct 4-10Hz oscillation in the left breast not present in the sternum. With the high support bra, this breast-specific oscillation was reduced, whereas a 4-6Hz oscillation was introduced in the sternum. A coherence increase and uniform gain in the 3-10Hz range in the high support bra condition suggests the bra effectively coupled the breast and sternum movements.

Discussion

Breast-torso interaction changed relative to bra conditions during jumps. With no bra, the breast underwent large and independent motion relative to the sternum. The high support bra created more coupled motion between the breast and sternum. However, the bra does not solely restrict breast motion to the baseline sternum, but also causes the relatively large breast mass to introduce greater movements in the sternum. Soft-tissue coupling patterns may vary across individuals, particularly with different breast sizes. However, our frequency-domain analyses show the mechanism of breast-torso coupling through sports bras, where the breast also influences torso movement.

The Effects of Breast Volume Reduction Surgery on Lower-Limb Kinematics in Running

Mr. Charles-Edouard Jarry, Dr. Jill Emmerzaal, Dr. Philippe C. Dixon

McGill University, Montreal, Quebec, Canada

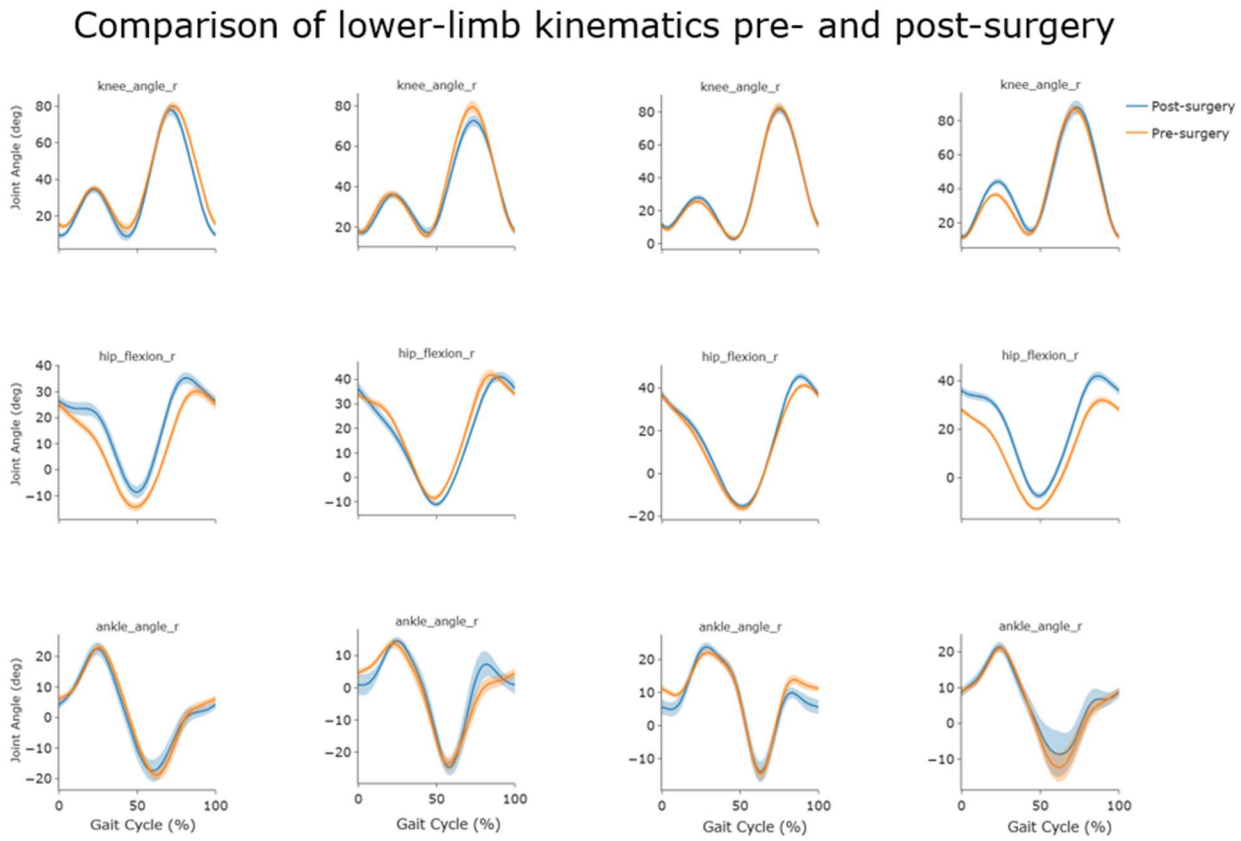
Introduction

There is a complex interplay between breast motion, breast support, and running biomechanics in healthy women. Recent work showed that reducing breast motion increases exercise comfort and improves running efficiency [1]; however, only limited knowledge exists on the effect of breast volume reduction surgery (BVRS) on running biomechanics. Thus, the aim of this study is to compare lower-limb kinematics in running pre- vs post-BVRS.

Methods

Sixteen healthy females (18–45 years) are being recruited for this repeated-measures study (n = 4 to date). Each participant completed two testing sessions: one pre-surgery and one post-surgery. During each visit, kinematics were captured during 2 mins of treadmill running using markerless video-capture [2]. Data were processed using the opencap-processing repository [3] and custom scripts. Ankle, knee, and hip sagittal plane joint angles normalized to 100% of a running cycle were extracted. Given current sample size, visual analysis of the graphs is conducted. Analysis of gait waveforms using statistical parametric mapping paired t-tests is planned once sample size has been obtained.

Results



The mean breast mass was reduced from 2047.5g ±870.7 to 933.8g ±177.6. Preliminary findings suggest distinct compensatory patterns following BVRS. When differences emerge at the ankle, hip and knee kinematics appear visually similar. Conversely, when changes are observed at the hip and/or knee, ankle kinematics tend to remain visually similar (Fig. 1).

Discussion

Adaptations indicate potentially localized or segment-specific compensatory strategies. The study limitations are as follows: (i) participants differed in baseline physical activity levels and breast sizes, factors that may influence gait mechanics and (ii) small sample size, making generalization via statistical analysis difficult. Further work is needed

to fully characterize the effect of BVRS on running biomechanics. Future work will quantify breast kinematics and determine their relationship with running kinematics, spatio-temporal parameters, and dynamics to better understand the impact of BVRS on joint loading, stability, and movement efficiency. The results may assist clinicians in providing more informed guidance regarding postoperative exercise expectations and individualized rehabilitation planning.

Sub-Voxel Vascular Segmentation from Coarse Resolution Medical Imaging

Dr. Numi Sveinsson Cepero[1], Dr. Julie DiCarlo[1], Prof. Shawn Shadden[2], Prof. Charles Taylor[1]

[1]University of Texas, Austin, Austin, Texas, United States. [2]University of California, Berkeley, Berkeley, CA, United States

Introduction

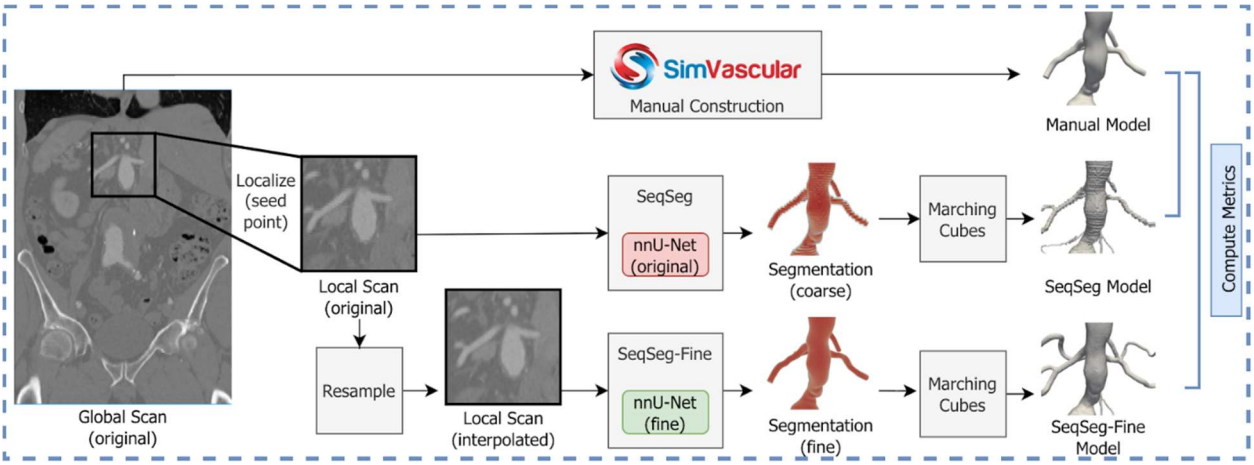
Patient-specific hemodynamic simulations require construction of blood vessel geometries from medical imaging. These models must be single unified bodies that are easily meshed and accurate, as geometry significantly impacts simulation results. Current workflows are cumbersome, require hours of manual input with subjective choices, and lead to inter-user differences. This bottleneck hinders scalable clinical solutions.

Deep learning (DL) offers automated, standardized, and potentially more reproducible model construction. However, most DL segmentation methods produce voxel-based predictions on the image grid. Converting these to surface models creates 'stairstep artifacts' proportional to the image resolution, especially when resolution is non-isotropic. Post-processing smoothing reduces artifacts, but changes volume and results in non-physiologic features, e.g. collapse of small vessels. This is particularly important for coronary modeling where image-based hemodynamic simulations are routinely used in clinical practice.

Methods

We produce finer-mesh ground truth segmentations by resampling training images using zero-padding interpolation. To address the substantial computational cost of processing fine-resolution volumetric data, we utilize the localized segmentation method SeqSeg[1]. By combining upsampled ground truth data with localized segmentation, we train and run inference more efficiently: only a subset of the total volume is processed. This enables the use of lower spacing than most state-of-the-art methods.

Results



We compared abdominal aortic aneurysm vascular models created using both SeqSeg and our novel SeqSeg-Fine method with six manually-constructed ones. SeqSeg-Fine segmentations required less smoothing, allowing minimal loss of smaller vessel features while removing artifacts. Qualitatively, SeqSeg-Fine captured more branches with greater detail. Quantitatively, SeqSeg-Fine achieved superior performance: average surface

distance decreased from 0.444mm to 0.276mm, and 95th percentile Hausdorff distance decreased from 2.04mm to 1.42mm.

Discussion

By enabling sub-voxel training mesh data and local prediction, our deep learning models predicted vascular segmentations that better matched manual segmentation. These models learn to correlate image features with both voxel classification and sub-pixel vascular features. Similar to expert manual construction, surface meshes are built in higher detail than the underlying image resolution based on underlying knowledge of smoothness. Our method enables automated, expert-quality vascular reconstructions at scale, removing a critical bottleneck in patient-specific simulation workflows.

Distinctive Coronary Tree-Level Haemodynamic Features in Spontaneous Coronary Artery Dissection: A Case–Control Imaging Study

Dr Mingzi Zhang[1,2], Dr. Lucy McGrath-Cadell[3], Dr. Stephanie Hesselson[3], Dr. Chi Shen[1], Dr. Ramtin Gharleghi[1], Dr. Nicholas Collins[3], Dr. David Muller[3], Prof Jason Kovacic[3], Prof Robert Graham[3], A/Prof Susann Beier[1]

[1]University of New South Wales, Sydney, NSW, Australia. [2]Torrens University Australia, Sydney, NSW, Australia. [3]Victor Chang Cardiac Research Institute, Sydney, NSW, Australia

Introduction

Spontaneous coronary artery dissection (SCAD) is a major cause of acute coronary syndrome in young women. While genetic predisposition is recognised, the biomechanical environment—particularly endothelial shear stress—has been implicated in arterial remodelling and disease states, such as aneurysm and plaque vulnerability. However, its role in SCAD remains unproven, as prior studies lacked controls and were limited in scope. We hypothesised that SCAD-affected coronary trees exhibit distinctive anatomical and haemodynamic signatures compared to healthy controls.

Methods

Thirty-six women with angiographically confirmed SCAD and 75 controls underwent coronary computed tomography angiography (CTCA). Three-dimensional coronary reconstructions were generated using validated segmentation pipelines. Vessel curvature, torsion, and diameter were quantified, and computational fluid dynamics simulations assessed time-averaged endothelial shear stress (TAESS) and topological shear variation index (TSVI). Tree-level comparisons employed independent t-tests, with effect sizes calculated via rank-biserial correlation. Receiver operating characteristic (ROC) analysis evaluated diagnostic performance.

Results

SCAD-affected coronary trees demonstrated significantly higher curvature (left: 0.45 ± 0.25 vs. 0.19 ± 0.02 $\times 10^3$ mm^{-1}; $p<0.001$) and TAESS (1.80 ± 1.20 vs. 0.99 ± 0.37 Pa; $p<0.001$) compared to controls. TSVI was also elevated (0.17 ± 0.07 vs. 0.13 ± 0.03 mm^{-1}; $p<0.001$), indicating greater variability in shear forces. Diameter and torsion showed no significant differences. Diagnostic accuracy (AUC 0.95–0.97) was high when curvature, TAESS and TSVI were combined, with SCAD trees rarely exhibiting zero adverse features.

Discussion

This study provides the first controlled evidence that SCAD-affected coronary trees are defined by adverse biomechanical conditions—elevated and variable shear stress coupled with geometric complexity. These findings establish a novel haemodynamic fingerprint for SCAD and support the integration of computational modelling into diagnostic workflows. We are currently extending this work to vessel- and segment-specific analyses to identify localised biomechanical biomarkers that predict SCAD occurrence. Such insights will inform predictive modelling and personalised risk stratification.

Introduction

The microstructural analysis in Ascending Aortic Thoracic Aneurysms (ATAAs) remains a relevant aspect in analyzing the pathology evolution. It is well-established that the microstructure is at the basis of ATAAs progression [1]. The Diffusion Tensor Imaging (DTI) is a magnetic resonance (MR) technique providing information on the fibrous structure of tissues, with the potential of in-vivo applications. Recently, we demonstrated the feasibility of DTI analysis with a clinical 3T scanner on ATAAs [2]. This work aims to apply the established pipeline for the analysis of a population of ATAA specimens. The specimens were analyzed in terms of microstructure by assessing the curvilinear tractography and the corresponding fiber angles distributions.

Methods

A total of 20 ring-like ATAA specimens were collected from patients undergoing surgical repair. Before scanning, each specimen was mounted in a container filled with ecographic gel for mechanical support. A 3T clinical MR scanner was adopted with a multi-shot echo planar sequence. The processing workflow foresees segmentation, diffusion tensor estimation, curvilinear tractography and fiber distribution analysis. The resulting fiber angles (ϕ) (ϕ= 0°,180° and ϕ= 90° corresponding to circumferential and longitudinal directions respectively) distributions were discussed.

Results

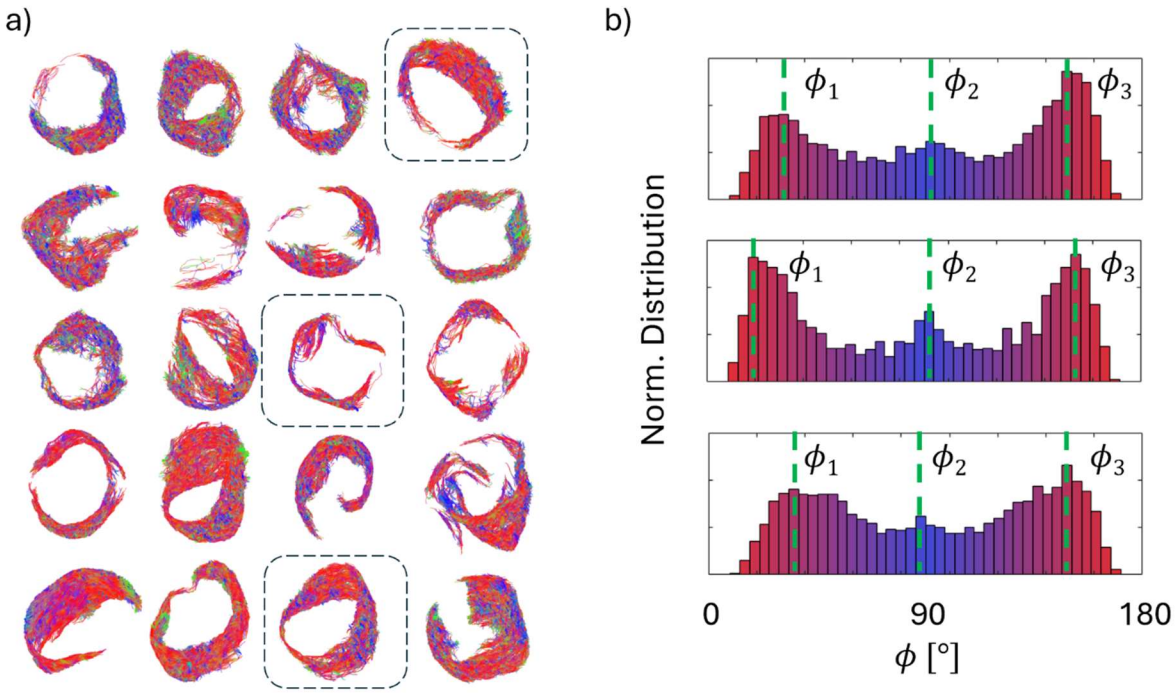

Figure1a represents tractography reconstructions for the ATAAs population. From the analysis of fiber distributions, it emerges that 80% of the cases revealed three peaks ($\phi_{1,2,3}$), as reported in the examples of Figure1b. The side peaks are always leaning towards circumferential direction and symmetric (19.2° < ϕ_1 < 39.4°, 132.5° < ϕ_3 < 160.8°), while the

central peak is parallel to longitudinal direction ($87.9° < \phi_2 < 92.1°$). The peaks are predominant in most cases, confirming the existence of two symmetric fiber families contributing mainly to the circumferential stiffness of the ATAA [3].

Discussion

We successfully applied our DTI pipeline to analyze a population of ATAAs. The microstructural characterization produced significant results in terms of fiber angle distributions, revealing that ATAAs fibers exhibit predominant circumferential orientations. It was shown that clinical MRI scans can provide reliable information about fiber architecture and ATAA pathology inferring.

Aortic Microstructure and Suture Pullout Variability

Ph.D. Candidate Gabrielle X. Lohrenz M.Eng.[1,2], Ph.D. Student Bianca Pourmussa B.A.[1,3], Professor and Vice Chair of Medicine Education, Neurobiology & Anatomy; Assistant Dean, Phase 1 Curriculum Haviva M. Goldman Ph.D.[1], Assistant Professor Brooks A. Lane Ph.D.[4], Associate Professor John F. Eberth Ph.D.[2]

[1]Drexel University, Philadelphia, PA, United States. [2]Virginia Tech, Blacksburg, VA, United States. [3]University of Pennsylvania, Philadelphia, PA, United States. [4]University of Kentucky, Lexington, KY, United States

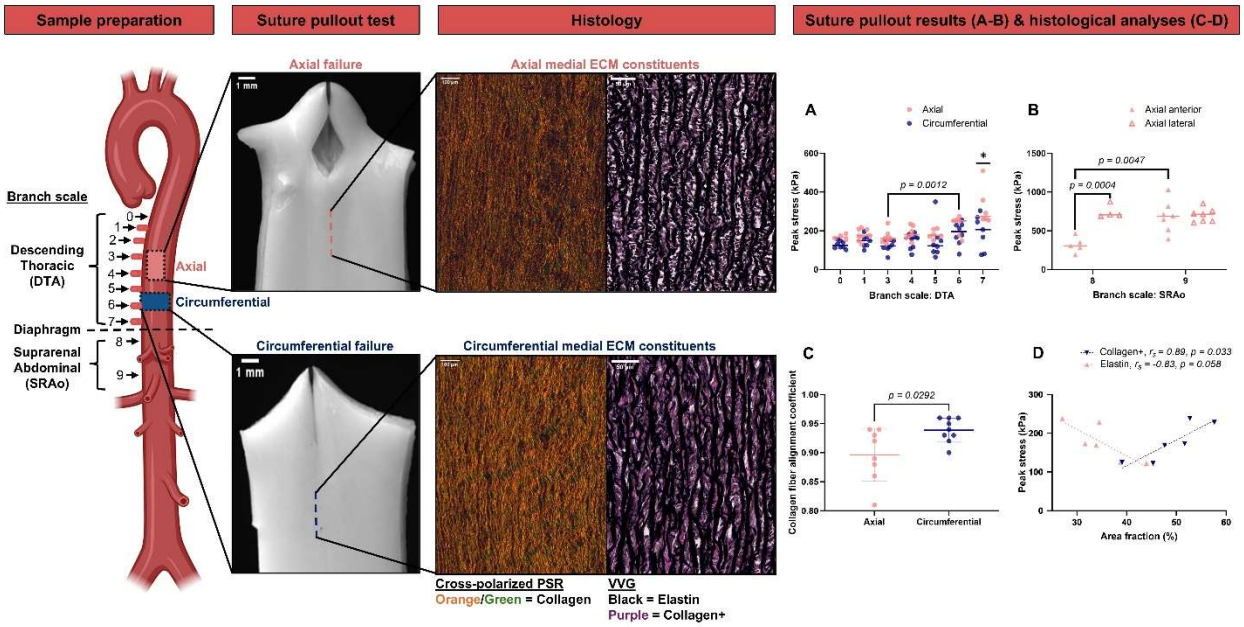
Introduction

Aortic graft sutures experience multidirectional, dynamic loading, and interfacial failure can cause dissection or rupture. Accordingly, suture retention is defined within ISO 7198:2016 as a required test method for demonstrating the safety of vascular prostheses, grafts, and patches. While useful, these tests fail to capture the complex, anisotropic, and regionally heterogeneous properties of the aortic wall necessary for evaluating novel suture-strategies or emerging tissue-treatment technologies. In this study, we used a commercially-sourced porcine model to reveal the critical macro- and micro-structural factors contributing to large artery suture retention/failure.

Methods

Suture pullout tests were conducted on 1x3 cm strips of male and female porcine aortas in the axial or circumferential directions (ISO7198:2016). Strips were cut and grouped by proximity to small descending thoracic (DTA) and suprarenal abdominal aorta (SRAo) branches (n=4 ea; N=106), where axial samples were further separated by local region (anterior/lateral). The lower edge was clamped and 3-0 polypropylene suture inserted 2 mm from the top and pulled to failure at 50 mm/min on a Mark-10 tensile tester. Peak stresses were estimated from the maximum force and initial cross-sectional area. Elastin and collagen were evaluated using VVG and PSR staining with cross-polarization for fiber alignment. Data was analyzed using linear mixed-effect models and Tukey's post-hoc tests.

Results



Sex had no mechanical effect (p=0.404), so male/female data were pooled for greater statistical power. Peak stress (p=0.0197) and strain (p=0.005) were notably higher in the axial than circumferential directions. Longitudinal position influenced peak stress

(p=0.0012), with higher values distally. Anteroposterior position revealed abdominal lateral sections had higher peak stress than anterior sections (p=0.0004). Elastin area fraction trended negatively with peak stress (r_s=-0.83, p=0.058), whereas collagen correlated positively (r_s=0.89, p=0.033). Medial collagen also exhibited better circumferential alignment (p=0.029).

Discussion

Our findings indicate both location and direction, but not sex, significantly influence suture pullout from porcine aortas. Peak stresses were noticeably lower when loaded parallel to the fiber direction (circumferential), where videographs suggested intrafiber slip as a mode of failure. In contrast, transverse tears were produced under perpendicular (axial) fiber loading. Our simplified findings highlight the inherent complexity of soft tissue failure.

Where Do Single Impacts Deform the Brain Most Across Sports? a Voxel-Wise Finite-Element Study

Ms Emily Yik Kwan Chan[1], Mr Isaac Siy[1], Ms Elena Koumantou[1], Dr Chris Jones[2,3], Dr Kieran Austin[2], Prof Mike Loosemore[2,3], Dr Mazdak Ghajari[1]

[1]Imperial College London, London, London, United Kingdom. [2]Sports and Wellbeing Analytics, Swansea, Swansea, United Kingdom. [3]Institute of Sport, Exercise and Health, London, London, United Kingdom

Introduction

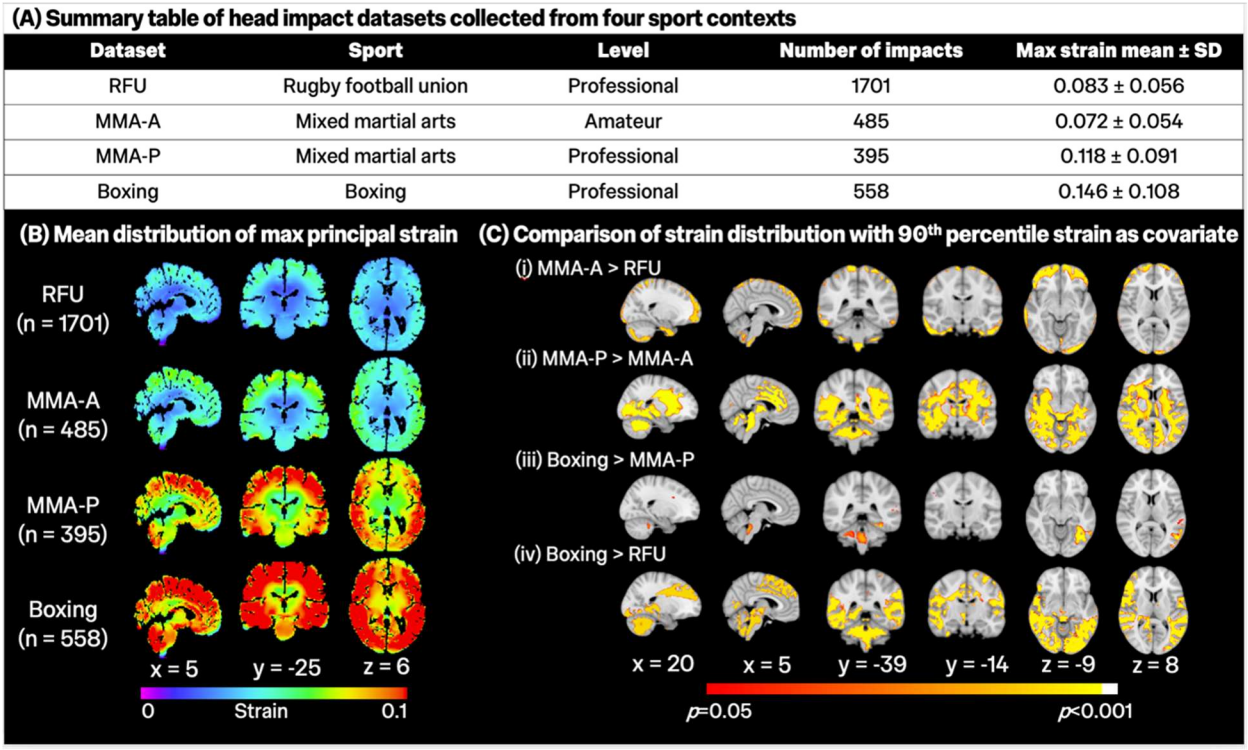
Head impacts in sports can cause traumatic brain injury (TBI). The nature of each sport contributes to variability in head-impact characteristics and consequent brain biomechanical responses. We aim to elucidate how the biomechanical responses of single impacts differ across sports.

Methods

Kinematic data of a total of 3139 head impacts from four sport contexts during competitions (Figure 1A) were collected using the validated Protecht instrumented mouthguards with identical post-processing [1]. These sports include professional boxing, professional and amateur mixed martial arts (MMA), and professional rugby (RFU). Each impact was simulated using the anatomically detailed Imperial College finite element brain model [2]. The brain biomechanics response was represented by the 90th-percentile maximum principal strain per element and extracted as neuroimages. Differences between sports were assessed using voxel-wise general linear modelling with 5000 permutations, including the 90th-percentile strain as a covariate to control overall magnitude. We report mean strain distributions and threshold-free cluster enhancement (TFCE)–corrected *p*-values for pairwise comparisons.

Results

Boxing and MMA-P exhibited higher strain than MMA-A and RFU, with strain concentrated cortically (Figure 1B). MMA-A versus RFU showed proportionally higher strain in sulcal and brainstem regions (Figure 1C-i). MMA-P versus MMA-A showed elevated strain in deep white matter, including corpus callosum (1C-ii). Boxing versus MMA-P showed minimal, scattered clusters (1C-iii). Boxing versus RFU showed widespread significance across inferior frontal and temporal cortices, insulae, thalamus, brainstem, and cerebellum (1C-iv).



Discussion

We found that combat sports, especially professional levels, induced higher and more widespread brain strain. Professional MMA showed significantly higher strains than amateur in deep white matter, indicating professional level may increase brain deformation. To achieve this, we used a detailed brain model for strain predictions and a single mouthguard system for data collection, which minimised device-related confounding. Limitations include the absence of clinical diagnostics. Also, the study focuses on single-impact analysis without accounting for cumulative exposure; higher strain in single impact does not indicate higher injury risk of sport considering inter-impact rest periods. These findings demonstrate sport-dependent brain deformation patterns, which can inform sport-specific TBI thresholds and pitch-side surveillance.

Images (Optional)

(A) Summary table of head impact datasets collected from four sport contexts

Dataset	Sport	Level	Number of impacts	Max strain mean ± SD
RFU	Rugby football union	Professional	1701	0.083 ± 0.056
MMA-A	Mixed martial arts	Amateur	485	0.072 ± 0.054
MMA-P	Mixed martial arts	Professional	395	0.118 ± 0.091
Boxing	Boxing	Professional	558	0.146 ± 0.108

Age-Dependent Intracranial Volume Redistribution and Its Biomechanical Implications for Traumatic Brain Injury: A Multi-Scale Analysis

MSc Claudia Sbriglio, Associate Professor Mariusz Ptak, MD-PhD Artur Kwiatkowski

Wrocław University of Science and Technology, Wrocław, Lower Silesia, Poland

Introduction

Traumatic brain injury (TBI) remains a leading cause of mortality and morbidity in adults over 60. Current computational biomechanics models, widely used to predict injury thresholds, employ static anatomical representations that fail to account for age-related brain atrophy and compensatory cerebrospinal fluid (CSF) accumulation. This 'one-size-fits-all' approach may potentially misassess injury risk in aging populations, where altered intracranial fluid-structure interactions fundamentally modify the biomechanics of impact response.

Methods

This study conducted high-resolution 3-Tesla MRI scanning with automated segmentation (Matlab and FreeSurfer) across 280 healthy subjects. Preliminary statistical modeling was performed on an initial cohort (N=130, age 7-90 years, 60 males, 70 females) using parametric distribution models, with model selection via Akaike Information Criterion. Tissue volumes (gray matter, white matter, CSF) and derived metrics (intracranial volume [ICV], CSF ratio) were quantified. Age division was defined into three groups: Young Adults (<40 years), Middle-Aged Adults (40–60), and Older Adults (>60). These anatomical data are being integrated into subject-specific finite element (FE) head models to simulate impact biomechanics and quantify how volumetric changes alter strain/pressure distributions under loading conditions.

Results

Preliminary analysis revealed CSF ratio exhibits the strongest age correlation. Older adults (>60) demonstrated 92.6% higher CSF volume compared to young adults (<40): 146.8±51.6 ml versus 76.2±24.2 ml. Proportionally, CSF comprised 11.99±4.08% of ICV in older versus 5.93±2.01% in younger cohorts, a 102% increase in fluid capacity. Sex differences in absolute volumes existed ($p<0.032$), but CSF ratios were sex-independent after head-size normalization ($p=0.517$). Complete 280-subject statistical analyses results will be presented at the conference.

Discussion

The near-doubling of intracranial CSF with aging fundamentally alters brain-skull coupling during impact. Increased fluid volume modifies viscous damping, brain displacement kinematics, and time-to-contact with cranial boundaries-mechanisms inadequately represented in generic models assuming static ~120 ml CSF across all ages. This discrepancy potentially overestimates CSF volume by 37% in young adults and underestimates by 22% in older adults, critically affecting injury threshold predictions. Age-specific finite element modeling integrating these anatomical variations is essential for establishing accurate injury tolerance curves and developing targeted protective strategies for vulnerable elderly populations.

The Peculiar Property of Pia Mater on the Prediction of Acute Subdural Hematoma

Mr. Chengbin Li, Professor Svein Kleiven, Dr. Zhou Zhou

Neuronic Engineering, KTH Royal Institute of Technology, Huddinge, Stockholm, Sweden

Mr. Chengbin Li

Professor Svein Kleiven

Introduction

Acute subdural hematoma (ASDH) is a catastrophic injury often associated with the disruption of bridging vein (BV) or BV-superior sagittal sinus (SSS) secondary to cortical motion. Finite element (FE) models have been used to predict the ASDH risk. However, the mechanical role of the pia has been largely overlooked. This study investigates how different pia mater modelling strategies influence cortical responses and ASDH prediction.

Methods

The baseline FE head model was developed by Kleiven [1], including 11 pairs of major parasagittal BVs, originally approximated the pia mater as a linear elastic membrane (Young's Modulus 11.5 MPa; Fig.1A). In this study, we modified the pia mater as a nonlinear simplified rubber with the stress-strain curve derived from pial tension test [2] (Fig.1A). Both models were exposed to an impact loading from published post-mortem human subject experiments known to induce ASDH [3].

Results

Pia mater material modelling substantially affected the cortical motion and BV responses (Fig.1B-D). With the linear elastic pia mater, the cortical motion and maximum BV strain were predicted as 2.0 mm and 0.10, respectively. With nonlinear modelling, the cortical motion increased to 8.8 mm and BV strain to 0.16. When compared with the BV-SSS ultimate strain range (0.29 ± 0.13) [4], a possible ASDH occurrence was only predicted when the pia mater was simulated as nonlinear material. Neither of the predicted BV strains fell within the range of the BV ultimate strain (0.50 ± 0.16) [5].

Discussion

This study highlighted the mechanical role of pia mater on brain responses and the necessity of modelling pia mater with nonlinear material for reliable ASDH prediction. The majority of existing FE head models use a linear elastic material model, representing a higher stiffness than the nonlinear model adopted in this study (Fig.1A). Results indicated such an over-stiffening pia mater modelling approach constrain the brain cortical motion and thereby underestimated the BV response and interpreted ASDH risk.

Images (Optional)

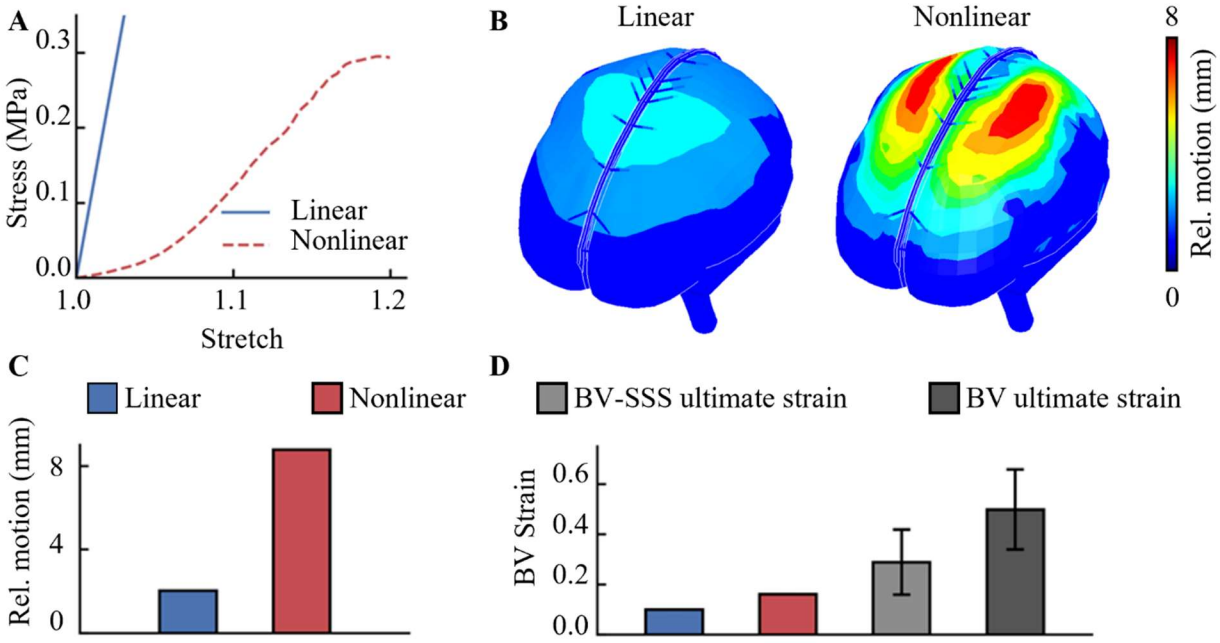

Figure 1. (A) Stress-stretch response of pia mater: linear elastic model (E=11.5 MPa) and nonlinear model [1, 2]. (B) Cortical relative motion captured at the maximum value occurring time. (C) Maximum value of the cortical relative motion. (D) Maximum BV strain plotted together with the BV- superior sagittal sinus (SSS) ultimate strain and BV ultimate strain [4, 5].

In Vivo Brain Deformation Response to Rapid Head Rotation in a Large Animal Model

Mr. Charlie Magarey[1], A/Prof. Mark Plummer[1], Prof. Peter Cripton[2], A/Prof. Claire Jones[1]

[1]Adelaide University, Adelaide, South Australia, Australia. [2]The University of British Columbia, Vancouver, British Columbia, Canada

Introduction

Synchronous measures of head kinematics and *in vivo* brain deformation during rapid head rotation could advance understanding of traumatic brain injury (TBI) mechanisms, inform protective equipment design, and provide data for validating computational models. Brain deformation has been measured in cadaveric tissue (high rate), or *in vivo* participants (low-rate); however, brain tissue strain response is rate dependent and changes rapidly postmortem. The aims of this study were to develop sonomicrometry methods to measure *in vivo* multipoint brain motion in a sheep model of rapid head rotation, assess the repeatability of brain displacement measurement, and quantify the *in vivo* brain deformation during rapid head rotation.

Methods

Three anaesthetised female adult sheep were instrumented with a skull mounted kinematics sensor array (sampled at 51.2 kHz). Up to 14 sonomicrometry transceivers (~3mm diameter, sampled at 1034 Hz) were implanted into the cerebral hemispheres, 10 were rigidly attached to the inner cranial vault (Fig. 1B-C). A custom apparatus produced repeatable rapid sagittal plane head rotation (without head impact) about the second cervical vertebra (Fig. 1A); two to five rotations were completed per animal. Head kinematics, three-dimensional brain displacement, and strain, were quantified and assessed for repeatability. Relative motion between transceivers and brain tissue was assessed with computed tomography imaging before/after each rapid head rotation.

Results

Brain displacement was tracked at up to 13 locations in each of 11 head rotations. Maximum brain displacement and strain were 2.47 mm and 18%, respectively. Brains displayed decaying rotational oscillation in the sagittal plane at 37.3±3.7 Hz (Fig. 1E), and associated oscillating tension-compression waves throughout the cerebrum, for ~100 ms from head acceleration initiation. Head kinematics and brain displacement had good-to-

excellent (CORA>0.86), and excellent (CORA=0.99) repeatability, respectively. The brain transceiver position change from pre- to post-test was negligible (mean=0.024 mm).

Discussion

Sonomicrometry was successfully applied in live anaesthetised sheep to provide repeatable measurements of brain displacement and deformation during rapid head rotation. The sheep brain rotational oscillation resembled that observed in rapid human cadaver head rotation, although the magnitude was lower and frequency was higher. These data may be used to improve validation of computational models of TBI.

The Influence of Angular Acceleration Versus Deceleration Ratio on Regional Brain Strain Response

Dr. Tyler F. Rooks PhD, Dr. Narayan Yoganandan PhD

Medical College of Wisconsin; Department of Neurosurgery, Milwaukee, WI, United States

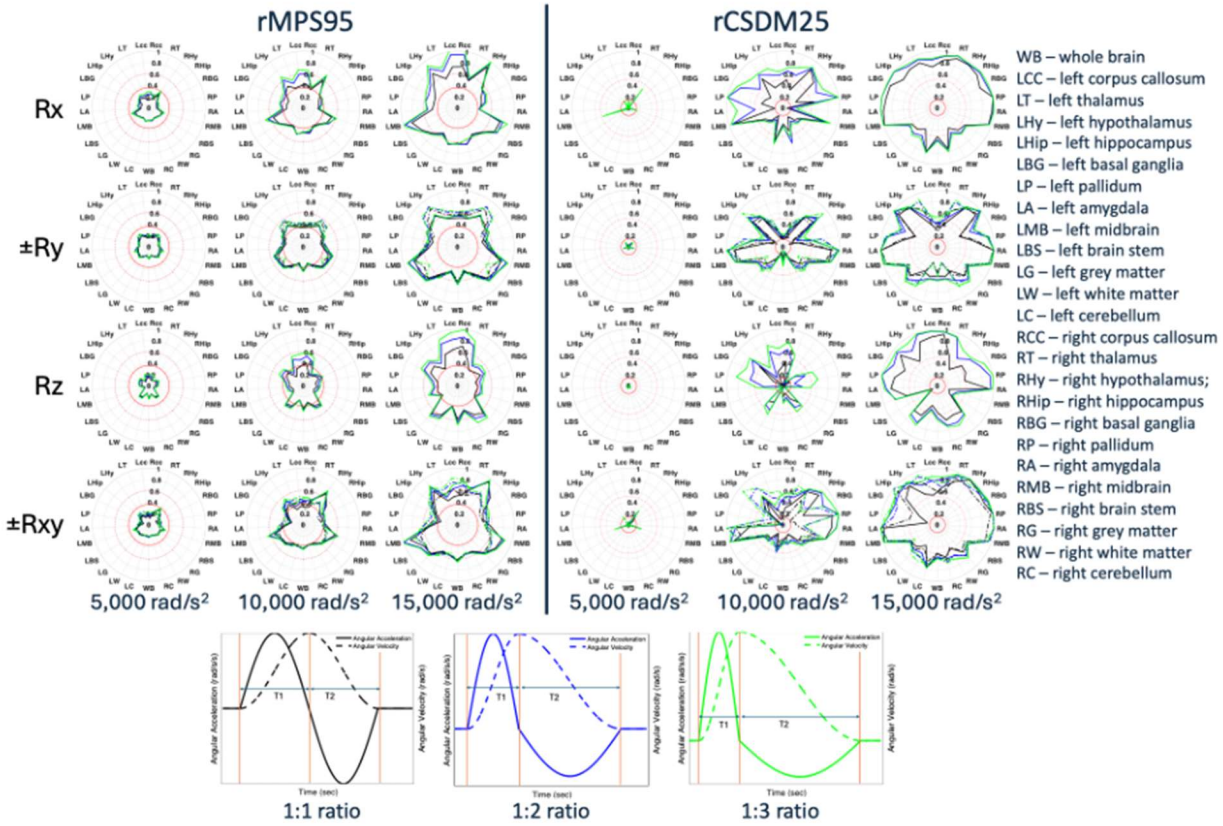
Introduction

Brain injury remains a concern in sports, military training, and vehicle crashes. Brain injury simulations are used to understand injury mechanisms and mitigation approaches using model-based whole-brain injury metrics, such as cumulative strain damage measure (CSDM) and maximum principal strain (MPS). Research using simplified two-dimensional brain models or whole-brain models has shown that exposure duration and the ratio of acceleration versus deceleration affects brain strain responses. The objective of this study was to investigate the effect of exposure parameters on regional brain strain distribution using an anatomically accurate model.

Methods

The study used an existing model with 12 regions of interest (ROI). ROIs are symmetric about the midsagital plane with separate components for left and right sides. Material properties were obtained from literature. Head rotations were simulated about primary axes of motion (coronal [Rx], sagittal [Ry], and axial [Rz]) and combined axes (Rxy). Sagittal rotations included positive and negative directions (Ry and -Ry, or Rxy and -Rxy). Idealized angular acceleration exposures used a sine wave with varying duration for acceleration versus deceleration (i.e., acceleration:deceleration ratio). Duration ratios included 1:1, 1:2, and 1:3. Multiple severities were assessed. Regional CSDM (rCSDM) was calculated for strains >0.25 for each ROI. Regional MPS (rMPS95) was calculated for each ROI.

Results



Increasing deceleration duration resulted in increases in both rCSDM25 and rMPS95 for many ROIs. The deeper structures (e.g., basal ganglia, corpus callosum, pallidum, amygdala, hypothalamus, thalamus, hippocampus) were most affected by changes in the duration ratio with large changes in response. The effect of rotational direction was inconsistent with some directions resulting in large changes (Rx) while others had smaller effect (Ry and -Ry). The rCSDM25 metric was more susceptible to changes with large

increases in many regions compared with rMPS95. The largest increases occurred when increasing the duration ratio from 1:1 to 1:2 at a peak angular acceleration of 10k rad/s^2.

Discussion

The study showed that regional brain strain response was sensitive to changes in the acceleration:deceleration duration ratio and to rotation direction. Understanding the relationship between brain strain distributions and exposure parameters may inform how exposures can influence symptoms of concussion.

[5]Faculty of Medical and Health Sciences & Centre for Brain Research, Auckland, Auckland, New Zealand. [6]Brain Health Research Insitute, Auckland University of Technology, Auckland, Auckland, New Zealand

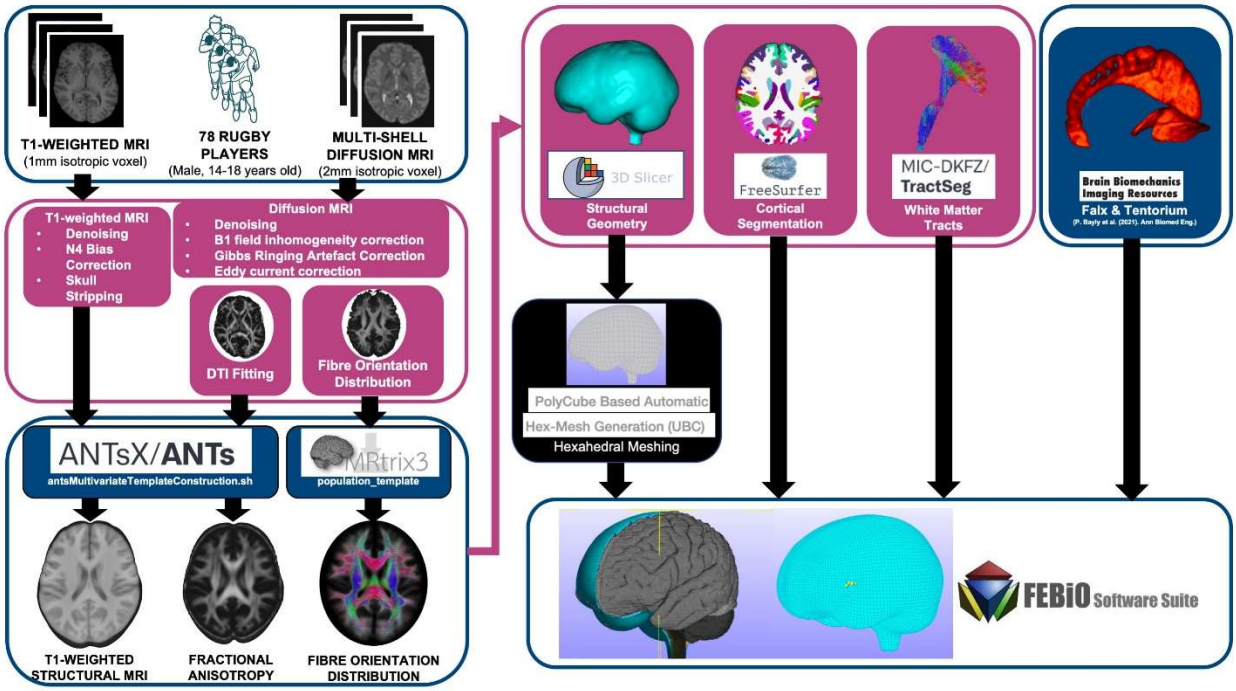
Introduction

Traumatic brain injury (TBI) is a global health concern. Despite high prevalence and substantial socio-economic impact, the biomechanical mechanisms underlying TBI remain poorly understood. Accurate quantification of strain propagation within brain tissue is critical for improving our understanding of injury mechanisms. Finite element (FE) models have been widely used for this purpose, and several laboratories have developed detailed head models with high biofidelity. However, generating study-specific models that accurately reflect cohort-specific neuroanatomy, tissue properties, and geometry remains challenging. Addressing this, we developed a pipeline capable of generating a study-specific FE head model directly from structural and diffusion MRI.

Methods

Seventy-eight male high-school rugby players underwent T1-weighted and multi-shell diffusion MRI (dMRI) brain scan. T1-weighted images were denoised, corrected for N4-bias field, and skull-stripped. dMRI data underwent denoising and corrections for B1-field nonuniformity, Gibbs ringing, and susceptibility distortions. Fractional anisotropy (FA) maps and fibre orientation distributions (FODs) were estimated, and a cohort-specific template was generated using ANTs and MRtrix3 from the T1 images, FA maps, and FODs. The template T1 and FOD maps were automatically segmented to derive cortical parcellations and major white-matter tracts. Due to the difficulty of segmenting the falx

and tentorium, these structures were obtained from an open dataset by Bayly et al. and registered to our study template. A whole-brain hexahedral mesh was generated using Polycube, and an in-house script assigned each element to anatomical structures using the segmented maps. Material properties were assigned in FEBio Studio based on our previous work, and fibre orientations were incorporated from the FOD map (Figure 1).



Results

The pipeline successfully produced a study-specific FE head model comprising 92,712 elements. The brainstem, cortex, cerebellum, falx, and tentorium were represented as distinct anatomical parts.

Discussion

This pipeline demonstrates a feasible approach for generating MRI-derived, study-specific FE head models that better capture cohort-specific geometry and neural structure. Ongoing work focuses on validating the model and simulating head impacts recorded through instrumented mouthguards worn during the playing season. The broader aim is to integrate FE-derived strain predictions with machine learning to link real-world impact exposure with localized structural changes, ultimately improving biomechanical understanding of TBI injury.

Polyphenol-Eluting Sutures to Improve Vascular Mechanostability

Ph.D. Candidate Gabrielle X. Lohrenz M.Eng.[1,2], Assistant Professor Brooks A. Lane Ph.D.[3], Advanced Cardiac Surgery Fellow Yuta Kikuchi M.D., Ph.D.[4], Professor, Hunter Endowed Chair Naren Vyavahare Ph.D.[5], Associate Professor John F. Eberth Ph.D.[2]

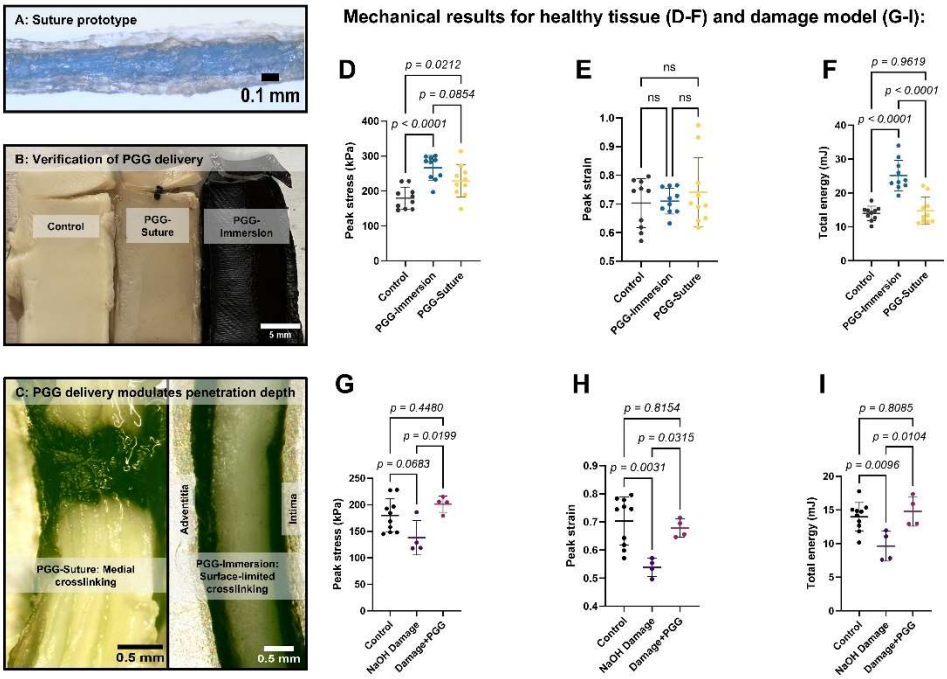
[1]Drexel University, Philadelphia, PA, United States. [2]Virginia Tech, Blacksburg, VA, United States. [3]University of Kentucky, Lexington, KY, United States. [4]Thomas Jefferson University, Philadelphia, PA, United States. [5]Clemson University, Clemson, South Carolina, United States

Introduction

Stress concentrations occur around permanent sutures in tension, increasing a tissue's susceptibility to inflammation and tearing. For large arteries, microtears can progress to dissection, pseudoaneurysms, intimal-medial hyperplasia, or even rupture; complications associated with significant morbidity and mortality [1]. Pentagalloyl glucose (PGG), a non-toxic, naturally occurring polyphenolic tannin, binds both collagen and elastin, strengthening structural proteins and reducing their susceptibility to proteolysis. PGG is an antioxidant, anti-inflammatory, anti-calcific, and antimicrobial small molecule, making it a compelling adjunct for the repair of aortopathies. Delivery of PGG at therapeutically effective concentrations can be challenging given the thick and heterogeneous large-artery wall, and the high-tension, blood-facing environment. Here, we report on a novel, suture-based, aortic PGG delivery system.

Methods

ISO 7198:2016 suture pullout tests were conducted on 1Í3 cm axial strips of porcine descending aorta from age/sex-matched pigs (n~10). Experimental groups include: (i) untreated controls, (ii) PGG-suture, from plasma-treating 3-0 polypropylene and attaching calcium-crosslinked PGG (1 mg) in alginate, and (iii) PGG-immersed, by incubating aortic strips in 0.15% PGG at 37°C for 24-hours. To model damage (n~3), strips were incubated in 0.25M NaOH for 24-hours and (iv) tested directly (NaOH damage), or (v) immersed in PGG (Damage+PGG). PGG release was quantified with Folin-Ciocalteu, and drug delivery confirmed by FeCl3 staining. Group differences were assessed by one-way ANOVA with Tukey's post-hoc.



Results

70% of PGG was released from coated sutures in 1-hour with the PGG-suture (p=0.0212) and PGG-immersed (p<0.0001) samples exhibiting higher peak stresses than controls. Similar peak strains were observed across groups in the non-damage model. For NaOH damage, PGG significantly increased peak stress (p=0.020), strain (p=0.032), and energy (p=0.010).

Discussion

Suture-based delivery of PGG represents a promising strategy to strengthen the anastomotic junction, especially in structurally compromised tissue, by delivering the drug directly to key structural proteins, evenly distributing tension across the wall. While the long-term biological effects of this application, especially in bloodstream circumstances, are currently under investigation, our study reveals immediate mechanical benefits that are likely to improve postoperative outcomes without increasing procedural complexity.

Gestational Hypobaric Hypoxia Induces Long-Term Biomechanical Remodeling of the Thoracic Aorta

Mr. Álvaro Navarrete PhD[1], Mr. Adolfo A. Paz[2], Mr. Claudio García-Herrera PhD[1], Mr. Carlos Godoy-Guzmán PhD[1], Mr. Emilio A. Herrera PhD[2], Mr. Andrés Utrera MSc[1]

[1]Universidad de Santiago, Santiago, Metropolitana, Chile. [2]Universidad de Chile, Santiago, Metropolitana, Chile

Introduction

High-altitude gestation exposes the fetus to chronic hypobaric hypoxia, a condition known to impair vascular development and increase long-term cardiovascular risk [1]. Despite extensive evidence of pulmonary and systemic functional alterations, the long-term biomechanical consequences for large elastic arteries remain poorly defined. Given that arterial stiffness and residual stress are key mechanobiological markers of cardiovascular disease [2], this study tested the hypothesis that gestational hypobaric hypoxia induces persistent biomechanical and structural remodeling in the descending thoracic aorta (DTA) of adult offspring.

Methods

Pregnant guinea pigs were exposed to normoxia (N, n=6) or hypobaric hypoxia (H, n=6; equivalent to 3,800 m) throughout gestation. Offspring matured under normoxia until one year of age. DTA specimens were evaluated through:

Biomechanics: ring-opening test (residual strain), axial pre-stretching, and planar biaxial tensile testing.
Ex-vivo function: dose–response curves for K^+-induced vasoconstriction and methacholine-induced vasodilation using wire myography.
Histology: elastin and collagen quantification, smooth muscle nuclei density, endothelial cell linear density.
Appropriate parametric or non-parametric statistics were applied ($p \leq 0.05$).

Results

Hypoxic DTA exhibited greater circumferential residual strain and a significant reduction in physiological axial pre-stretch in the proximal thoracic region. Planar biaxial testing showed higher mean stiffness at low and high deformation levels (E_1, E_2) in hypoxic tissue. Functionally, hypoxic arteries showed greater maximal K^+-induced contraction and reduced methacholine-mediated vasodilation. Histologically, hypoxic DTA displayed wall

thickening, higher elastin content, and reduced endothelial cell density, consistent with outward hypertrophic remodeling.

Discussion

The combination of increased stiffness, elevated residual strain, reduced endothelial cell density, and impaired vasodilation demonstrates that gestational hypobaric hypoxia produces persistent maladaptive arterial remodeling into adulthood. These findings align with prior reports linking developmental hypoxia to vascular dysfunction and future cardiovascular risk [1,3]. The observed outward hypertrophic remodeling and functional impairment support a mechanobiological shift toward a pro-hypertensive phenotype, suggesting altered set-point regulation of wall stress. Further studies integrating computational analysis may help determine whether these remodeling patterns are adaptive or maladaptive long-term.

Indentation Size Effects Dominate Aortic Tissue Nanoindentation and its Dynamic Mechanical Analysis

Prof Michele Conti, Dr. Gabriele Greco, Eng. Giulia Formenton

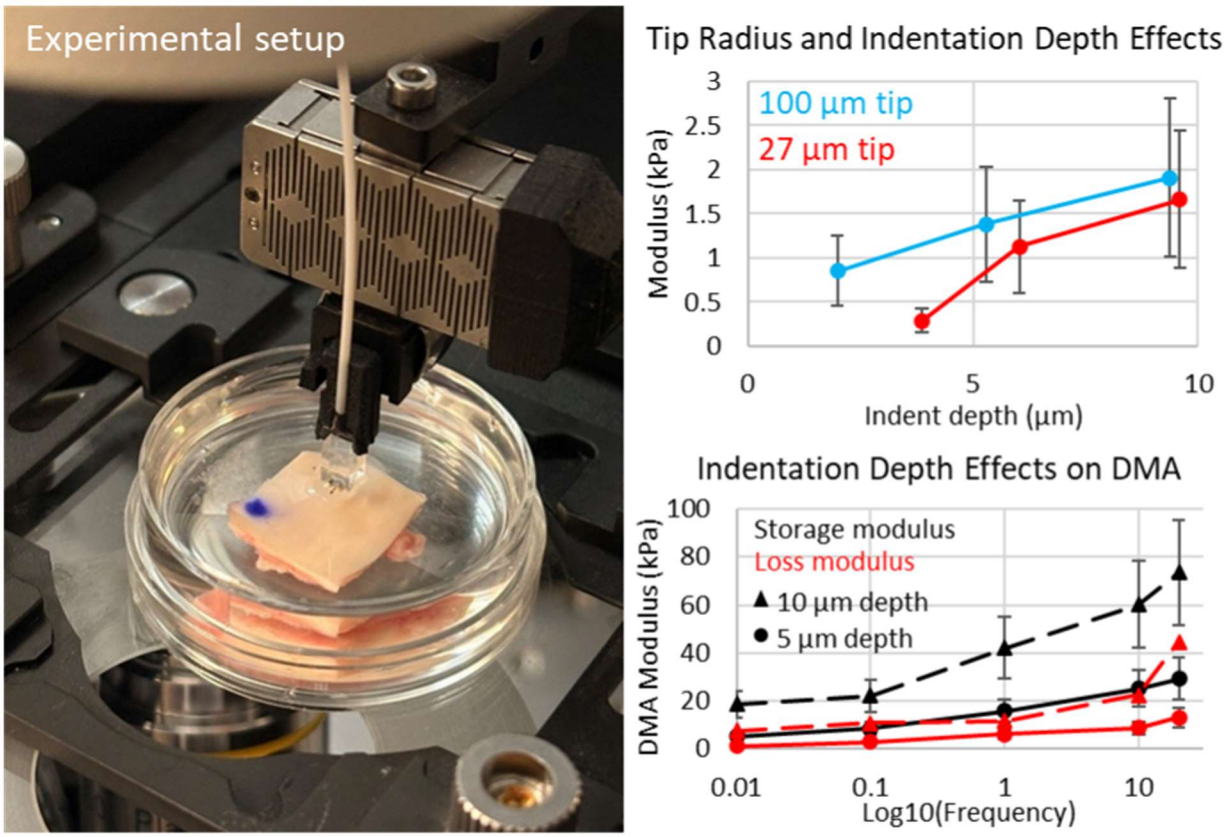
University of Pavia, Pavia, IT, Italy

Introduction

Nanoindentation is a powerful technique for probing the local mechanical properties of biological materials; however, its application to cardiovascular tissues remains limited and often inconsistent. Existing studies on aortic tissue employ highly heterogeneous protocols, which differ in indentation depth, tip geometry, loading conditions, and surface preparation. This makes results difficult to compare and frequently incompatible with classical analytical models. The intrinsic structural complexity of aortic tissue, characterized by irregular surface topography and heterogeneous composition, further complicates the interpretation of nanoindentation data.

Methods

In this work, we carried out an extensive nanoindentation campaign on porcine aortic tissue from multiple animals, employing 80 different experimental conditions. By systematically varying key parameters—including indentation depth (1–15 μm), indenter tip radius (25–100 μm), loading rate (0.1–10 μN/s), indentation speed (1–10 μm/s), and surface preparation—we identified the main sources of variability that compromise the validity of the Hertzian model and strongly influence the extracted Young's modulus.



Results

Our results demonstrate that even modest deviations from standard protocols can lead to large discrepancies in measured mechanical properties, underscoring the urgent need for methodological standardization. The strongest effects arise from indentation depth and tip radius, known as indentation size effects, which profoundly influence the scaling of the tissue's mechanical response. For instance, using a 27 μm indenter tip yields apparent Young's moduli ranging from 0.3 to 1.7 kPa when the indentation depth is varied between 4 and 10 μm.

Discussion

Building on these findings, we propose a robust and reproducible nanoindentation protocol tailored to cardiovascular soft tissues. This protocol minimizes violations of model assumptions, reduces experimental variability, and improves the comparability of data across studies. We further extended our analysis to dynamic mechanical nanoindentation, testing different combinations of indentation depth (5–10 µm), frequency (0.01–20 Hz), and oscillation amplitude (0.3–2.5 µm). Again, we observed a strong dependence on indentation size effects, which dominated the mechanical response. Overall, our study provides a solid foundation for the future standardized mechanical characterization of aortic tissue. These insights open new opportunities for multiscale mechanical modeling and facilitate the data integration into advanced in-silico frameworks.

Hamstring Muscle Strain During Accelerated Sprints Following Repeated Sprints

BSc Leon Lobe[1,2], PhD Evy Meinders[3], Associate Professor David John Saxby[4], Professor Rod Barrett[4], Associate Professor Laura Diamond[4], Professor Arnold Baca[1], Associate Professor Hans Kainz[1,2], PhD Basílio Gonçalves[1,2]

[3]Musculoskeletal Biomechanics Lab, Mechanical Engineering, Carnegie Mellon University, USA, Pittsburgh, Pennsylvania, United States. [4]Australian Centre for Precision Health and Technology, Griffith University, Australia, Gold Coast, Queensland, Australia

Introduction

Hamstring strain injuries (HSI) happen frequently during repeated sprinting with increasing incidence [1]. Hamstring strain peaks during late swing in sprinting [3] with repeated sprints exacerbating muscle fatigue [4]. Here we investigate the effects of repeated sprinting on hamstring strain. We hypothesized hamstring strain during sprinting would increase following repeated sprints.

Methods

Forty-three active recreational athletes completed 12x30m maximal sprints on a non-motorized treadmill while 3D body motions, ground reaction forces, and electromyographic signals from 12 muscles were recorded [5]. Joint angles, moments, and muscle-tendon kinematics were calculated using Opensim [6] and served as input to a calibrated electromyography-informed neuromusculoskeletal model to estimate muscle dynamics for biceps femoris long head (bflh), semitendinosus, and semimembranosus [7]. We applied statistical-parametric-mapping to test for within-participant differences in angles, moments and forces, and paired t-tests for running speed and peak strain ($\Delta l/l_0$) between pre- and post-sprint protocol.

Results

After repeated sprints, we observed a significant ($p<0.01$) reduction in running speed (16%±9%), magnitude of sagittal plane joint angles and moments, as well as semimembranosus muscle force, but no significant change in forces of bflh and semitendinosus. Peak strain significantly decreased ($p<0.01$) for bflh (17%±26%) and semitendinosus (20%±15%), but not semimembranosus (2%±39%). Peak strain increased for 5(12%), 4(9%), and 11(26%) participants in their bflh (38%±33%), semitendinosus (12%±2%), and semimembranosus (45%±49%), respectively.

Discussion

The average reduction in peak muscle strain may reflect a change in motor control, which may prevent excessive strain under fatiguing conditions. However, in some individual an increases in muscle strain occurred, which in line with previous research [3], may contribute to an increased HSI risk. Applying the workflow of this study to sprint-related sports could help identify athletes at higher risk of HSI.

Images (Optional)

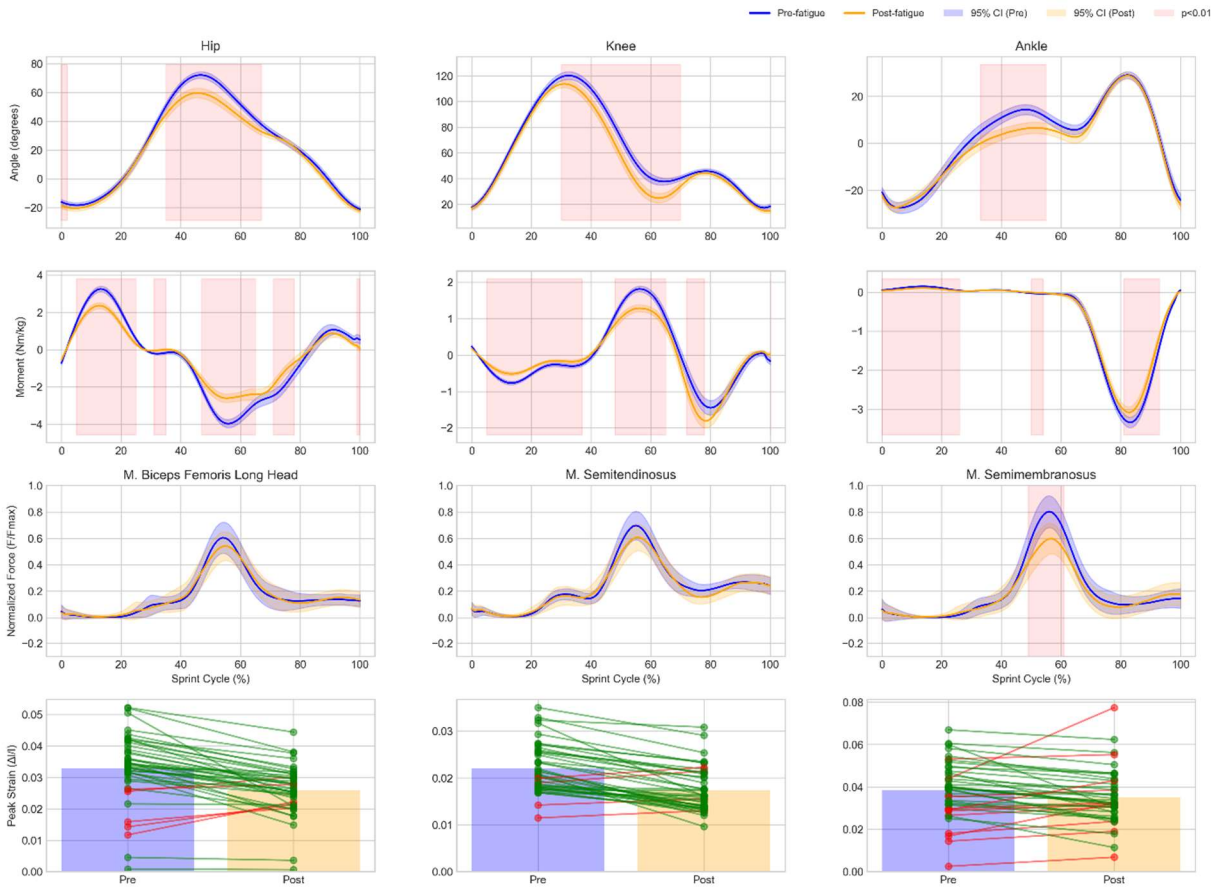

Fig. 1: Ensemble averages (n = 43) of hip, knee, and ankle angles, moments, normalized muscle forces, and peak muscle strain for a sprint cycle pre (solid blue) and post (solid orange) a repeated sprints protocol. Shaded regions indicate 95% confidence intervals. Red shaded regions denote statistically significant differences (p<0.01, Statistical Parametric Mapping). The bottom row shows individual participant responses (connecting lines) and group means (bars) for peak muscle strain. Green connecting lines indicate a decrease in peak strain, while red lines indicate an increase. Sprint cycles are defined from toe-off to toe-off and all data were normalized to 101 points (0-100%).

Influence of a Demanding 10 Km Run on Multi-Segment Foot Joint Kinetics and Kinematics

Professor Hannah Rice[1], Mr. Jonatan Riise[1], Mr. Patrick Mai[1], Ms. Naomi Frankston[1], Dr. Robert Schuster[2], Assoc. Prof. Luke Kelly[2]

[1]Norwegian School of Sport Sciences, Oslo, Oslo, Norway. [2]Austrialian Centre for Precision Health and Technology (PRECISE), Gold Coast, Queensland, Australia

Introduction

Humans are suited to endurance running, facilitated in part by the function of the foot, which can store and return energy and stiffen during the push-off phase of running stance. Running-induced fatigue has been shown to alter the distribution of vertical forces under the foot and may also influence the mechanics of the joints within the foot. There is limited understanding of how within-foot joint kinetics change as a result of prolonged or demanding running. This study aimed to quantify how the biomechanical function of the foot is influenced by completion of a demanding 10 km run.

Methods

Twenty-eight male and female runners ran barefoot at a self-selected speed over a runway pre- and post- a 10 km shod treadmill run conducted at 105% of estimated race time. Kinematic, ground reaction force and plantar pressure data were collected during the barefoot running trials. The foot and shank were modelled in OpenSim as six rigid segments. Three independent forces acting on the rearfoot, midfoot and forefoot regions were obtained from the force and pressure data; these were used for inverse dynamics analyses to quantify ankle and within-foot joint moments. Peak joint moments, the forces under each foot region and stance phase time-series kinematics were compared statistically between pre- and post-10 km run.

Results

Peak ankle plantarflexor and internal rotation moments were reduced post- compared to pre-10 km run but there were no differences in peak moments generated about any of the joints within the foot. Total vertical ground reaction forces were lower post- than pre-run, despite a consistent average running speed. Vertical forces under the forefoot region were also reduced post- compared with pre-run. There were no changes in within-foot kinematics post- compared with pre-run.

Discussion

The biomechanical function of the foot appears to be robust to running-related fatigue, in contrast to the ankle joint, perhaps due to the greater degrees of freedom available within the foot.

Dr Marcella Pazzinatto

Introduction

Increased peak hip adduction during running has been consistently observed in runners with knee pain and is thought to increase patellofemoral joint loading and symptom development. Despite well-established sex differences in the incidence of knee pain and lower-limb running biomechanics, it remains unclear whether increased hip adduction is prospectively associated with worse symptoms in males and females with a history of knee surgery.

Aim: To compare peak hip adduction during running between males and females with a history of knee surgery and to evaluate its association with knee symptoms at baseline and 2-year follow-up.

Methods

One hundred eight runners (53 females, aged 35 (8) years, body mass index 22.6 (2.7) kg/m^2; and 55 males, aged 36 (7) years, body mass index 24.2 (2.3) kg/m^2) with a history of knee surgery were included. Three-dimensional running biomechanics were assessed during overground running at 3-3.5m/s. Peak hip adduction during stance was extracted for the surgical limb. Knee symptoms and function were assessed using the combined four-

subscales Knee injury and Osteoarthritis Outcome Score (KOOS4) at baseline and 2-year follow-up. Independent t-test was used to compare peak hip adduction between males and females. Unadjusted linear regression models were performed to evaluate associations between peak hip adduction and KOOS4 for: all participants, females only, and males only.

Results

Females had higher peak hip adduction compared to males (mean difference [95% confidence interval]= 3.64° [2.35; 4.94]). At baseline, no associations were observed between peak hip adduction and knee symptoms (KOOS4). At the 2-year follow-up, greater baseline peak hip adduction was associated with worse knee symptoms (KOOS4) in all participants (R^2= 0.123, β= −1.25, [−2.3 to −0.2]; p= 0.017) (Table 1). Although the magnitude of association was larger in females (R^2= 0.131, β= −1.77 [-3.83; 0.30]), sex-stratified analyses did not reach statistical significance in either females or males.

Discussion

Greater peak hip adduction during running at 3-3.5m/s was associated with worse knee symptoms at 2-year follow-up in runners with a history of knee surgery, regardless of sex. This finding suggests that altered frontal-plane hip mechanics during running may be clinically relevant to longer-term symptom outcomes.

Knee Cartilage Structure Before and After Running in Habitual Masters Runners With and Without Knee Osteoarthritis

Dr Jesse Charlton PhD[1], Ms Michaela Khan MSc[1], Ms Natasha Krowchuk BSc[1], Dr Anthony Gatti PhD[2], Dr Jean-Francois Esculier PT, PhD[3,1], Dr Michael Hunt PT, PhD[1]

[1]University of British Columbia, Vancouver, British Columbia, Canada. [2]Stanford University, Stanford, California, United States. [3]The Running Clinic, Lac-Beauport, Quebec, Canada

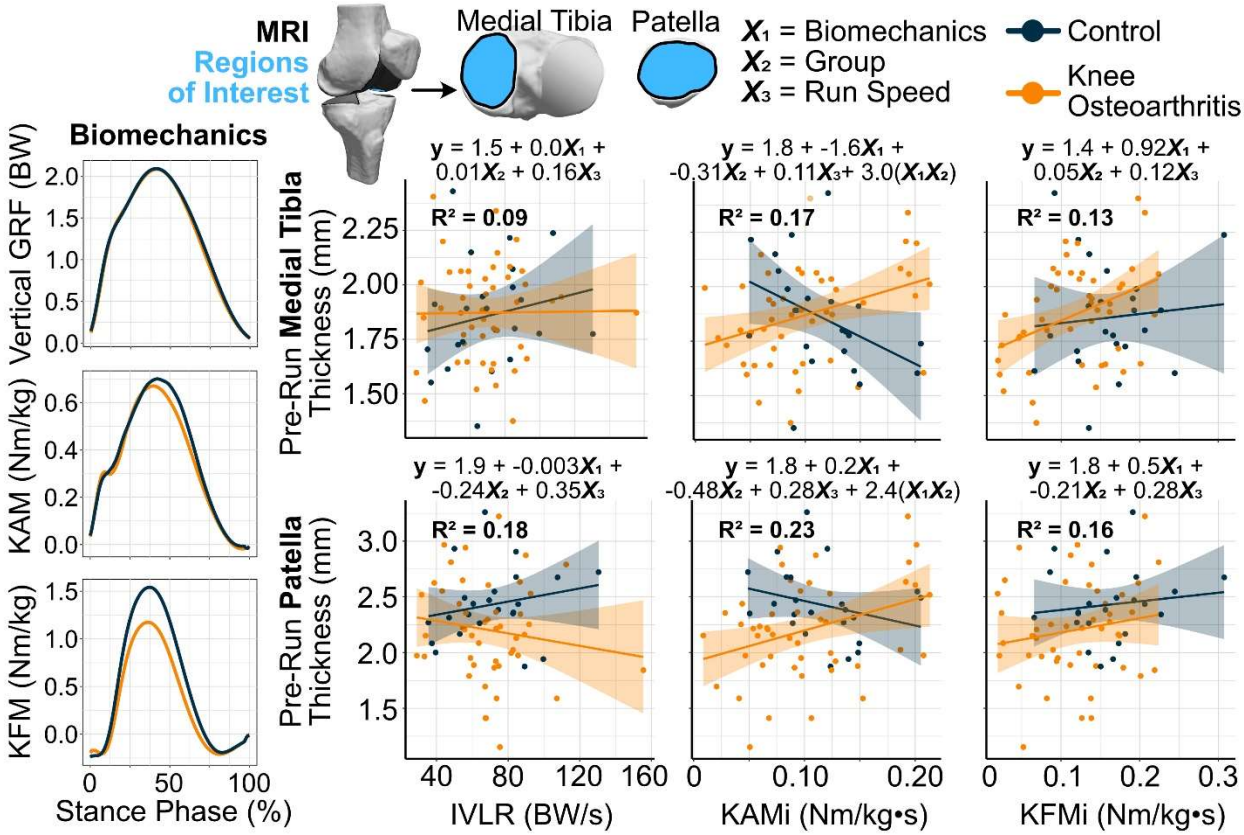
Introduction

More older adults than ever before are participating in running, but data are lacking to inform the appropriateness of running in this population, especially those with knee osteoarthritis. Prospectively, higher joint loads during walking are related to cartilage degradation, but it is unclear if this holds true for running. Therefore, we explored associations between running biomechanics and knee cartilage outcomes before and after a 30-minute run.

Methods

We used the baseline data (NCT04325334) of 70 runners with (KOA) and without (CON) painful radiographic knee osteoarthritis. We recorded the final 30 seconds of a 5-minute run on an instrumented treadmill (markers trajectories: 200 Hz, forces: 2000 Hz), applied a scaled 6DOF musculoskeletal model, and performed inverse dynamics. For biomechanical predictors, we calculated the instantaneous vertical loading rate (IVLR) and the time integral of the knee adduction (KAMi) and flexion moments (KFMi). Our cartilage outcomes were mean thickness and T2 relaxation times for the medial tibial and patellar regions acquired with magnetic resonance imaging (3-Tesla, 16 channel coil) before and after a 30-minute, self-paced treadmill run. We fit linear models (α=0.05) to cartilage outcomes (pre-run, post-pre change) predicted by biomechanics, group (KOA, CON), and running speed. The KAMi-by-group interaction was also assessed for cartilage thickness.

Results



The runners had a mean±sd age=56±9 years, body mass=66.3±12.6 kg, and the KOA group had mild (n=37) and moderate (n=10) structural signs of osteoarthritis. Few biomechanical predictors were associated with cartilage outcomes (Figure). The KAMi-by-group interaction for the medial tibia (p=0.042) showed KOA and CON had opposite associations with tibia thickness (positive vs negative, respectively). Speed was a significant predictor in

most thickness models (all $p<0.022$). No predictors were associated with T2 in either compartment (all $p>0.165$) or any post-pre cartilage change (all $p>0.071$).

Discussion

Running biomechanics were poorly associated with cartilage outcomes; however, KAMi had a differential effect on pre-run thickness between groups. An acute running bout did not generate changes in cartilage that were associated with biomechanics or group. Together, these results indicate that habitual masters-aged runners generally show positive knee cartilage adaptations to loading, lending support for running continuance in this population.

Effects of Unisensory and Multisensory Augmentation on Standing Balance in Chronic Stroke Survivors

Ms. Isabelle Museck[1], Dr. Jesse Dean PhD[1,2]

[1]Medical University of South Carolina, Charleston, South Carolina, United States. [2]Ralph H. Johnson VA Health Care System, Charleston, South Carolina, United States

Ms. Isabelle Museck

Introduction

People with chronic stroke (PwCS) often experience mediolateral balance deficits that increase fall risk and reduce quality of life. The delivery of artificial sensory feedback in response to real-time body movements, known as sensory augmentation, has potential to improve balance outcomes and reveal sensory mechanisms underlying balance control [1]. Our preliminary work demonstrated that vibrational feedback scaled to mediolateral center of pressure (CoP) velocity can influence postural control in control participants [2]. However, it remains unknown whether similar effects occur in PwCS and whether augmenting multiple feedback sources provides additional benefits. This study applied real-time vibrational feedback to PwCS to evaluate whether augmentation delivered at single (unisensory) or multiple (multisensory) locations reduced mediolateral sway.

Methods

PwCS (>6 months post stroke) completed unisensory (n=35) and multisensory (n=34) augmentation sessions. Participants wore vibrating tactors at the lateral trunk, hip abductors, medial/lateral ankle tendons, and foot sole – locations at which vibration can elicit mediolateral sway. During 1-minute trials, participants stood on a force plate undergoing unpredictable mediolateral translations in a sum-of-sines pattern (0.1-0.9 Hz). Translation amplitude was individualized to evoke a 20 mm/s mediolateral CoP RMS velocity, standardizing difficulty. Tactor feedback was scaled to real-time CoP velocity and participants completed three sessions. The first two sessions assessed unisensory augmentation using randomized trials with five non-vibration and five vibration trials at each location. The third session evaluated multisensory augmentation, using six randomized trials with either non-vibration or simultaneous vibration at all locations. Mediolateral sway was quantified using CoP standard deviation (CoPstd). Paired t-tests

compared no-vibration and vibration conditions within the unisensory and multisensory sessions.

Results

For unisensory vibration, CoPstd did not differ significantly from non-vibration conditions ($p>0.27$), (**Fig. 1**). In contrast, multisensory augmentation significantly reduced CoPstd relative to non-vibration conditions ($p=0.003$).

Discussion

These findings indicate that simultaneous vibrotactile feedback from multiple body locations is more effective than single-site feedback for improving postural stability during dynamic balance challenges in PwCS. Future work will develop wearable multisensory augmentation devices that deliver real-time predictive feedback to improve clinical balance training outcomes.

Discordance Between Video-Based Measures of Balance Ability and Perception Is Associated With Fall History in People With Diverse Balance Abilities

Ms. Hannah Heigold MS, Ms. Ariana Rodrigues, Mr. Parker Ruth BS, Dr. Scott Delp PhD

Stanford University, Stanford, California, United States

Introduction

Alignment of perceived and true balance ability is important for reducing falls. Longhurst et al. quantified this by defining "discordance" as the difference between an individual's reported Activities-Specific Balance Confidence Scale (ABC) and their predicted ABC based upon their Timed Up and Go score, demonstrating it related to retrospective falls in people with Parkinson's disease [1]. To further examine discordance, we developed the StaBLE (Stanford Balance Level Evaluation) performance score, an 18-activity balance assessment using smartphone video. We then (1) computed discordance for a sample with varying balance abilities using the novel StaBLE performance score; and (2) evaluated if StaBLE-based discordance is related to functional outcomes, including fall risk and self-reported retrospective falls.

Methods

We had 153 participants with varying balance abilities complete StaBLE and the ABC. We computed discordance using the predicted ABC from StaBLE performance scores instead of TUG. We performed logistic regression to predict a fall risk label (true if ABC < 67, CDC Stay Independent 12-question tool > 3, or worried about falling) and self-reported 1-year retrospective falls using StaBLE-based discordance, StaBLE performance score, age, and sex.

Results

The StaBLE performance score ($p = 0.001$) and StaBLE-based discordance ($p < 0.001$) were both significant predictors of fall risk. The logistic regression model had a fall risk prediction accuracy of 85% (sensitivity 80%, specificity 86%) in a held-out test set. StaBLE-based discordance was the only significant predictor ($p = 0.017$) of retrospective falls, with a prediction accuracy of 67% (sensitivity 50%, specificity 72%). Density plots of discordance demonstrate individuals with fall risk had more extreme discordance magnitudes compared to the no-risk group (KS test, $p<0.01$), while individuals with a reported fall had more negative discordances (KS test, $p<0.001$).

Discussion

Since the StaBLE-based discordance was computed from a diverse cohort with an objective balance assessment, the regression line likely approximates concordance better than linear regression in a high fall risk cohort. Discordance was the only significant predictor of retrospective falls. This emphasizes the important interplay between perceived and measured abilities for real-world outcomes and suggests that StaBLE-based discordance may have clinical utility for fall reduction.

Images (Optional)

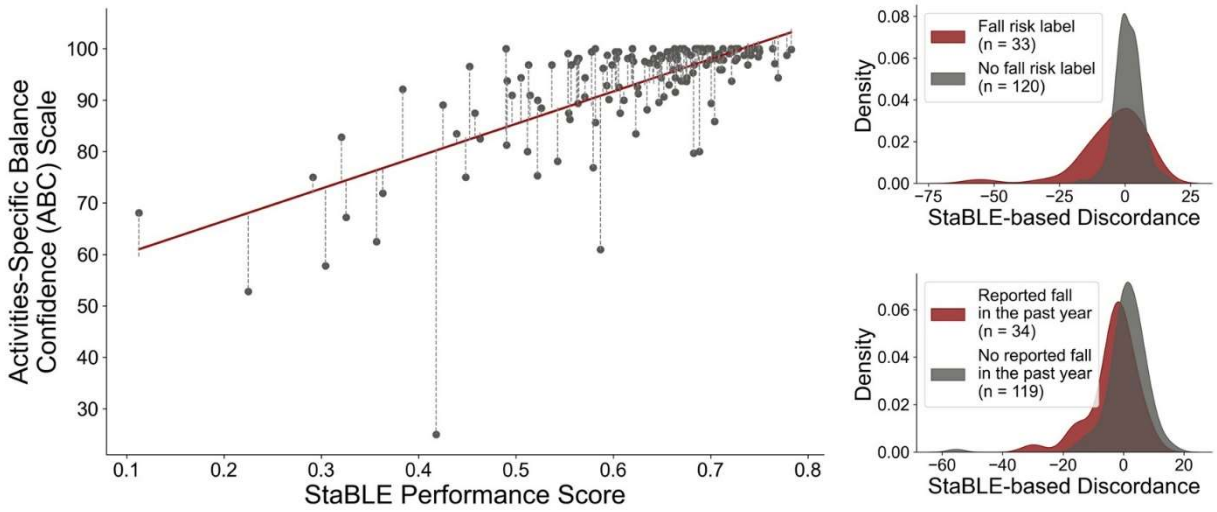

Figure 1: (Left) Linear regression of StaBLE performance score and Activities-Specific Balance Confidence Scale (ABC), with discordance computed as the residual vector from the line of best fit to the data point (min=16.1, max=-55.3, mean = 0.00, std =7.71). Underconfident participants (negative discordance) are below the regression line, and overconfident participants are above the line. A participant with a shorter residual line is more concordant (smaller magnitude of discordance). (Right Top) Discordance density across the dataset with participants identified as having fall risk in red. (Right Bottom) Discordance density across the dataset with participants who reported a fall in the past year in red.

OA148-03

User-Independent, Deep-Learning Estimates of Center of Mass Kinematics to Enable Autonomous Exoskeleton Control for Balance Augmentation

Dr Kristen Jakubowski[1,2], Dr Aaron Young[2], Dr Gregory Sawicki[2], Dr Lena Ting[1,2]

[1]Emory University, Atlanta, GA, United States. [2]Georgia Institute of Technology, Atlanta, GA, United States

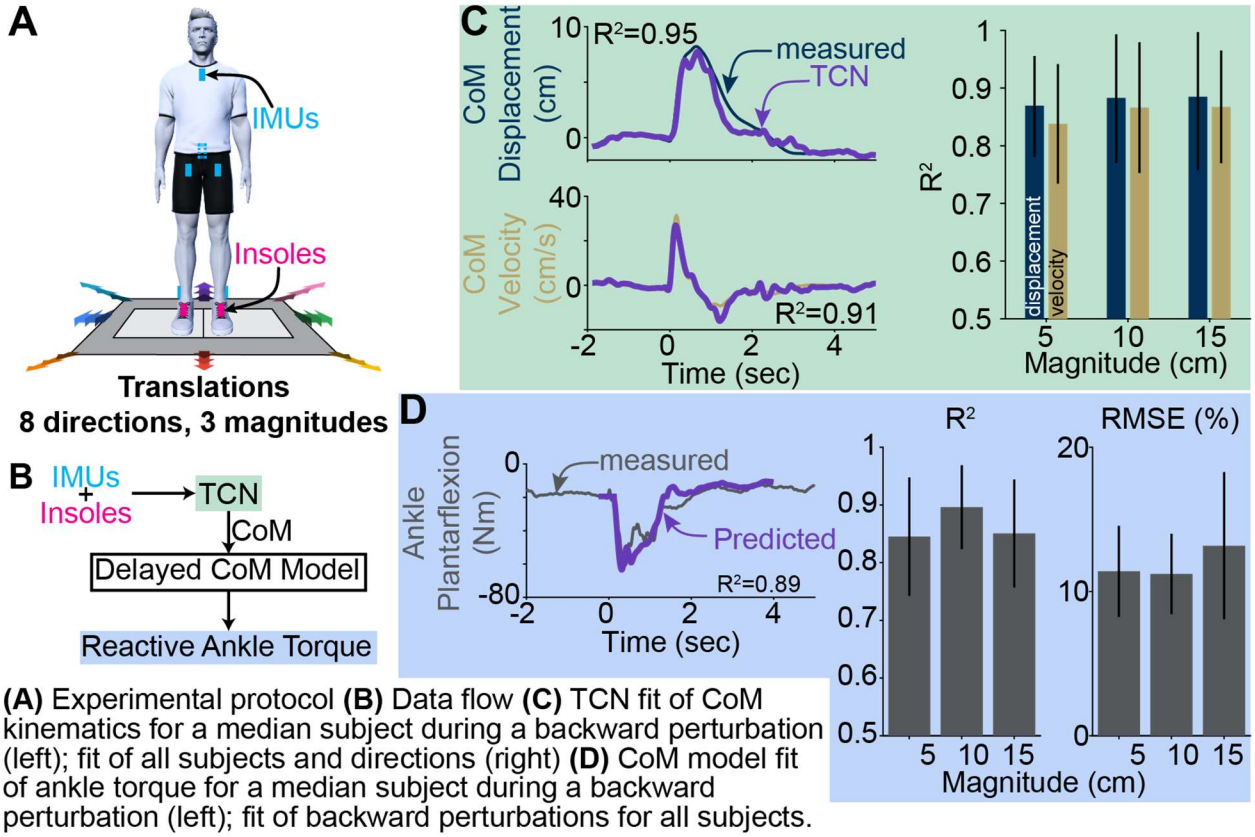
Introduction

Maintaining balance in response to perturbations requires precise control of center of mass (CoM) kinematics, accomplished by modulating joint torques based on CoM state [1]. Real-time estimation of CoM kinematics could be used to autonomously control a lower-limb exoskeleton designed to assist balance. However, predicting CoM kinematics in real-time outside the lab remains challenging. Here, building on a similar approach for real-time exoskeleton control [2], we developed a deep learning model to estimate CoM kinematics from wearable sensor data during multidirectional standing balance perturbations. We evaluated whether the predicted CoM kinematics could reconstruct ankle torques using a previously developed delayed CoM feedback model [3].

Methods

Fourteen healthy young adults maintained standing balance during randomized support surface translations in 8 directions (every 45°) at 3 magnitudes (5, 10, 15cm). Participants wore a “Sensor Suit” with 6 six-axis IMUs and two pressure insoles (Fig-1A). Using data from a lab-based motion capture system, we quantified CoM kinematics relative to the base of support, joint kinematics, and joint kinetics using OpenSim. We trained a leave-one-subject-out temporal convolutional network (TCN) that used Sensor Suit data to estimate CoM kinematics. To test the feasibility of this approach for controlling an ankle exoskeleton, the TCN-predicted CoM kinematics were used to estimate ankle torque via a delayed CoM feedback model (Fig-1B).

Results



Our user-independent deep learning model accurately predicted CoM kinematics and, more importantly, the TCN-predicted CoM kinematics reconstructed ankle torques with high fidelity. Across all directions, a 14-fold leave-one-subject-out deep learning model accurately predicted CoM kinematics with high R2 (Fig-1C; Displacement: 0.88±0.11; Velocity: 0.86±0.11). Using the TCN-predicted CoM kinematics as input into a user-

independent delayed CoM feedback model, we accurately reconstructed the ankle torque response (Fig-1D; R2=0.89±0.11; RMSE=12±4% of total torque).

Discussion

Using deep learning, we can turn wearable sensor data into balance-correcting joint torques that work across multiple users. If implemented on an exoskeleton, this could enable real-time control of a fully autonomous user-independent exoskeleton for balance augmentation, a capability that has not yet been realized.

Human-in-the-Loop Optimization of Postural States Between Sensory Conditions

Mr. Amin M Nasrabadi M.Sc.[1], Dr. Calvin Kuo Ph.D.[2], Dr. Jean-Sébastien Blouin Ph.D.[1]

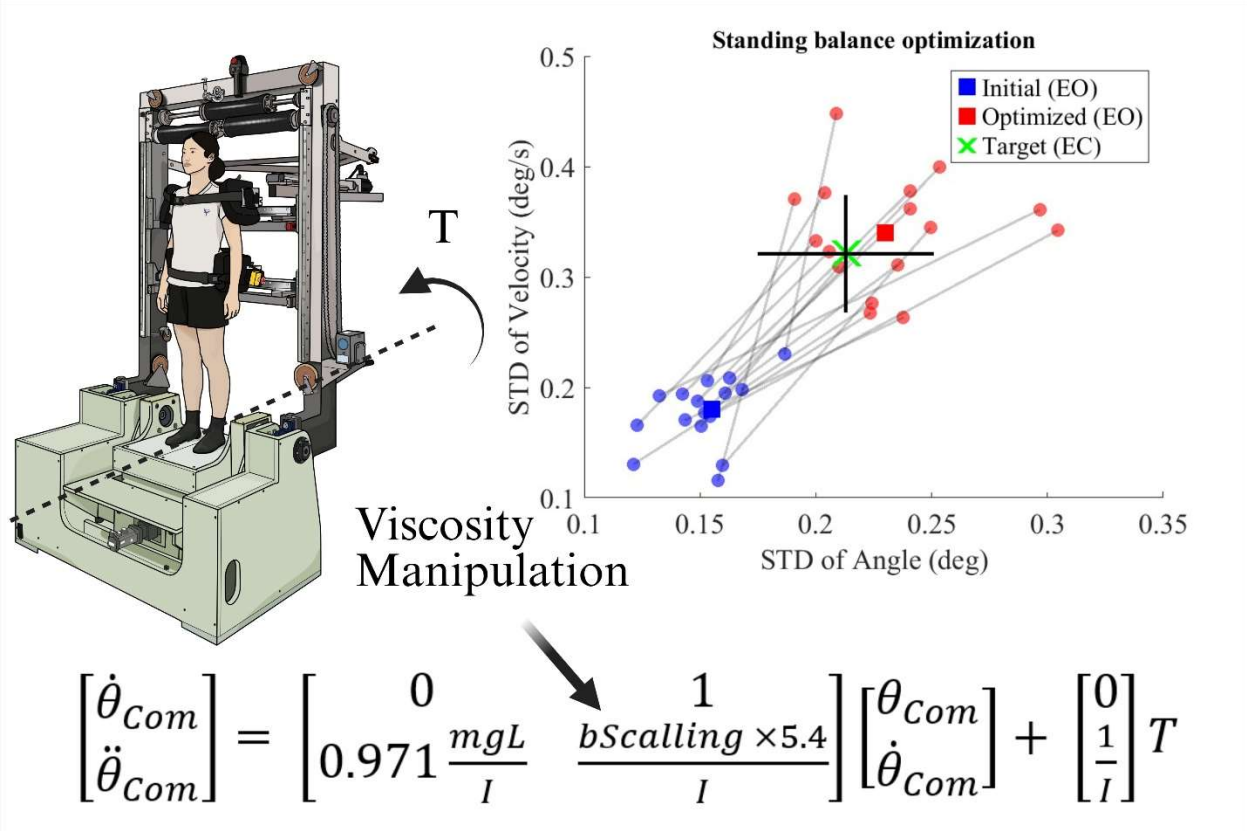
[1]The School of Kinesiology, University of British Columbia, Vancouver, BC, Canada. [2]The School of Biomedical Engineering, University of British Columbia, Vancouver, BC, Canada

Introduction

Given its simple dynamics, the control of standing balance is an ideal model for uncovering sensorimotor integration principles underlying bipedalism. As we face distinct environments, it has been argued that the reliability of sensory signals and statistics of motion may explain modulations in control gains needed to remain upright. Unfortunately, the distinction between these mechanisms remains difficult because the statistics of balance motion often covary with the availability of sensory cues. Here, we present a human-in-the-loop optimization method to modulate and control the statistics of balance motion.

Methods

Sixteen participants (8 female) stood on a robotic platform reproducing the dynamics of their upright stance. Negative viscosity was used as a tunable parameter to modify the statistics of whole-body motion [1], i.e. SD of Centre-of-Mass (CoM) angle and velocity, from an initial Eyes Opened (EO) state towards a target Eyes Closed (EC) state while keeping EO. The iterative procedures were guided by a gradient-descent optimization: we computed the error between the current and target states after each trial to estimate a numerical gradient to adjust the viscosity parameter. The process continued until the statistic of balance with EO converged to those observed with EC. The stop criteria were defined as either 10 steps of optimization or <0.5 viscosity change for 2 successive steps.



Results

The optimization algorithm matched the statistics of the standing balance of EO to EC when participants had EO. The error to the target CoM angle SD reduced from 0.11±0.02 deg to 0.02±0.03 deg, and for CoM velocity SD from 0.16±0.04 to 0.04±0.05 deg/sec. On average, the process to optimize took 8 optimization steps.

Discussion

Our findings demonstrate a method to control the statistics of balance through manipulations in body viscosity via gradient-based optimization. This framework provides a powerful tool to test neuromechanical hypotheses.

A Privacy-Preserving, Device-Free Fall Detection System via Wi-Fi Channel StateInformation

Mr Nathaniel Im

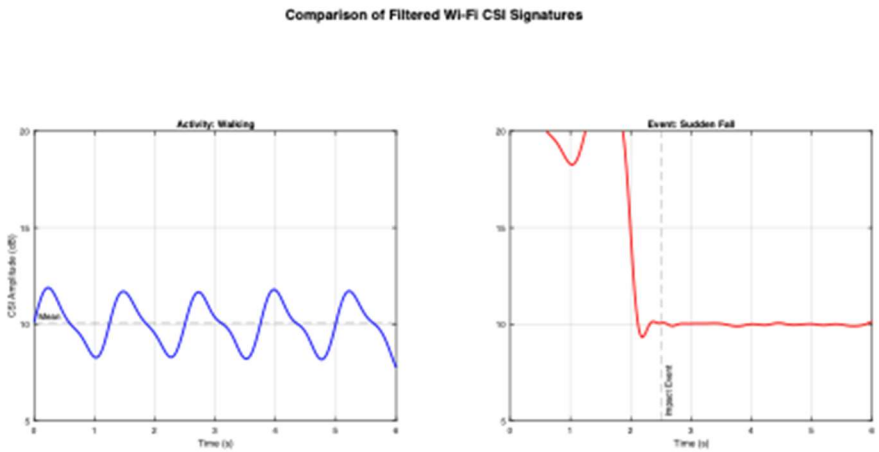
Portsmouth Abbey School, Portsmouth, Rhode Island, United States

Introduction

Falls in the aging population represent a critical public health challenge, often leading to severe injury or mortality. Current monitoring solutions, such as optical cameras or wearable devices, suffer from privacy intrusion and low user compliance. To address these limitations, we propose "WiSafe," a novel, low-cost system utilizing Wi-Fi Channel State Information (CSI) to detect falls without on-body sensors or cameras.

Methods

The system utilizes two ESP32 microcontrollers configured as a transmitter and receiver to capture fine-grained CSI data. Unlike Received Signal Strength Indicator (RSSI), CSI provides amplitude and phase information across multiple subcarriers, enabling the detection of subtle human movements. We implemented a data acquisition pipeline that logs CSI packets at a high sampling rate. The raw signal is processed using a Butterworth low-pass filter to eliminate high-frequency noise. We designed a protocol to capture signal patterns for "Fall" events (simulated onto soft mats) versus "Activities of Daily Living" (ADL), including walking, sitting, and standing. Feature vectors, including variance, standard deviation, and interquartile range (IQR), are extracted from 5-second sliding windows to train k-Nearest Neighbors (k-NN) and Support Vector Machine (SVM) classifiers.



Results

Initial validation of the hardware pipeline confirms the successful extraction of stable CSI streams in a 4m x 4m controlled environment. Preliminary signal analysis demonstrates that fall events generate a distinct high-amplitude transient signature followed by a static period, contrasting sharply with the rhythmic, periodic fluctuations observed during walking. Feature extraction analysis indicates that the variance and IQR of the CSI amplitude are significantly higher during the impact phase of a fall compared to ADLs. These distinct kinematic signatures suggest that the proposed machine learning models can achieve high classification sensitivity.

Discussion

WiSafe demonstrates the feasibility of using commodity Wi-Fi hardware for robust, privacy-preserving health monitoring. By leveraging the ubiquity of Wi-Fi signals, this system offers a scalable solution to support aging-in-place while overcoming the limitations of current invasive or wearable technologies.

Balance Assessment via Markerless Motion Capture: Evaluating Center of Mass and Center of Pressure Estimations Against Gold-Standard Measurements

Dr. Milad Nazarahari

University of Alberta, Edmonton, Alberta, Canada

Introduction

Clinical characterization of balance in clinical settings currently relies on observational tests such as the Berg Balance Scale; however, outcome metrics are inherently subjective and prone to ceiling effects. While instruments, like force platforms and marker-based systems, provide ground-truth measurements, their use is restricted by high costs, limited availability, and the need for expert operators. Open-source markerless motion capture systems (MMCS) have emerged as an easy-to-use, accessible alternative This study introduces a multi-view MMCS framework utilizing OpenPose to estimate the center of mass (COM) and center of pressure (COP). This approach facilitates objective balance quantification by estimating the COM and deriving the COP via inverse dynamics.

Methods

The introduced MMCS was validated through an experimental study with twelve healthy individuals. The protocol included five balance tasks: quiet standing under varying sensory conditions (hard and soft surfaces under eyes open and eyes closed) and a weight-shift task. To establish concurrent validity, COM and COP were compared against gold-standard measurements from a marker-based system and a force plate, respectively. The study systematically investigated the influence of model complexity on COM and COP estimations by comparing performance across single-, three-, six-, and eight-segment biomechanical models.

Results

COM trajectories estimated via the MMCS demonstrated good agreement with the marker-based gold standard across all models (Pearson's correlation coefficient: CC>0.90; root-mean-square error: RMSE<3.0 mm in quasi-static tasks). For the COP estimation, the six- and eight-segment models showed the highest performance with force plate data (CC=0.95–0.98, RMSE=2.2–8.5 mm in the anteroposterior (AP) direction using eight segments). A consistent directional trend was observed across all models, wherein AP correlations generally exceeded those in the medio-lateral (ML) direction, except for the weight-shift task. Fig. 1 shows COP trajectories from the MMCS, the marker-based system, and the force plate for one participant.

Discussion

Across all tasks, increasing model complexity from a single segment to six segments showed significantly improved performance, evidenced by higher correlation coefficients and reduced RMSE, underscoring the necessity of multi-segment modelling for accurate COM and COP estimation within the MMCS framework. These results validate the MMCS as a valuable, cost-effective tool for quantitative balance assessments.

Images (Optional)

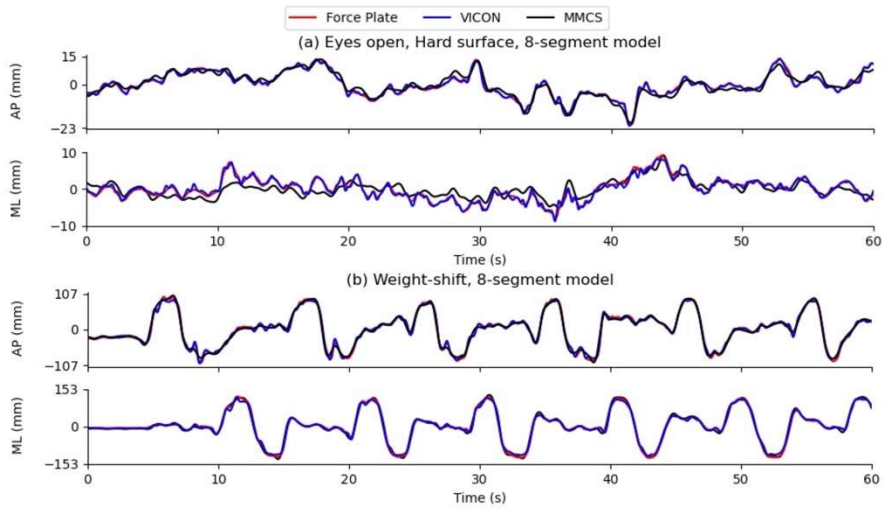

Fig. 1: Comparison of COP trajectories derived from marker-based and markerless (MMCS) systems against force plate measurements for a single participant. Both systems utilized an eight-segment model via inverse dynamics. **(a)** Results for a quiet standing trial (eyes open, hard surface). Marker-based results: RMSE (AP = 0.6 mm, ML = 0.5 mm), CC (AP = 0.99, ML = 0.98); MMCS results: RMSE (AP = 1.7 mm, ML = 1.7 mm), CC (AP = 0.96, ML = 0.80). **(b)** Results for a weight-shift task. Marker-based results: RMSE (AP = 3.9 mm, ML = 4.8 mm), CC (AP = 0.99, ML = 0.99); MMCS results: RMSE (AP = 6.0 mm, ML = 7.0 mm), CC (AP = 0.99, ML = 0.99).

Osteoarthritis Progression Alters Collagen Network Reorganization in Cartilage upon Mechanical Loading

MSc Yixuan Zhang[1], Dr Seyed Ali Elahi[1], Dr Olga Shebanova[2], MSci James Rowe[3], MSc Joudi Altaleb[3], Dr Nick Terrill[2], Prof. Alexander Liddle[3], Prof. Richard Abel[3], Prof. Ilse Jonkers[1]

[1]KU Leuven, Leuven, Vlaams-Brabant, Belgium. [2]Diamond Light Source, Didcot, Oxfordshire, United Kingdom. [3]Imperial College London, London, Greater London, United Kingdom

Introduction

Cartilage load-bearing capacity relies on an organised collagen network, which is progressively disrupted in osteoarthritis (OA) [1]. This study applied synchrotron small-angle x-ray scattering (SAXS) to quantify collagen orientation and alignment under varying compressive loading in human OA cartilage, providing structural perspectives on collagen degeneration in OA.

Methods

SAXS measurements were performed at the Diamond Light Source beamline I22 [2]. Osteochondral plugs (n=24) with different OA severity were collected from 6 donors (IRAS 337246, REC 24/YH/0194) and subjected to unconfined compression–relaxation at 20%, 40%, and 60% strain, encompassing physiological to injurious levels. SAXS images were acquired at the articular surface and at ¼, ½, and ¾ cartilage depth during loading. Azimuthal intensity profiles around the 5th-order diffraction peak were extracted via radial integration in DAWN. Each profile was fitted with a two-peak Gaussian model in MATLAB to derive preferred collagen orientation (mean) and degree of disorganization (standard deviation) [3]. To determine depth-dependent alterations in collagen network alignment (alignment factor) changes in organization under load were quantified relative to the unloaded state.

Results

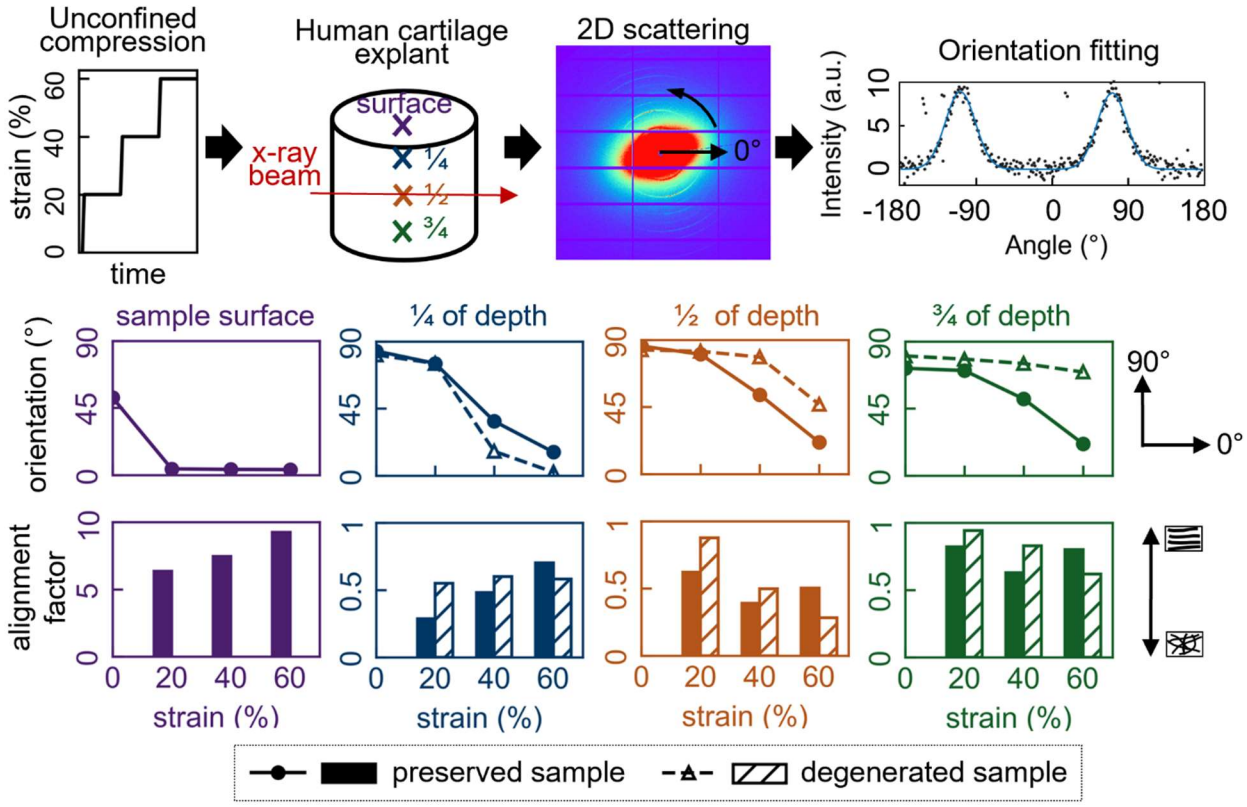

Figure 1 shows data of osteochondral plugs from the same donor in preserved (thickness=2.1mm) and degenerated (thickness=1.3mm) hip cartilage. In the preserved sample, collagen at the articular surface was oriented parallel to the surface and became more aligned (>1) upon 20% strain, while deeper zones showed minimal orientation change but reduced alignment (<1). With increasing strain, reorientation propagated through the full depth, extending surface-parallel alignment into deeper zones. In the degenerated sample, similar behaviour was presented in the proximal tissue (surface data missing,

confirmed up to ¼-depth), but deeper zones exhibited little reorientation even at 60% strain.

Discussion

These findings highlight depth-dependent collagen reorganization in cartilage under load. Orientation changes up to 90° occur under high compressive loading, potentially resisting lateral expansion. Under supra-physiological loading, preserved cartilage reorganizes collagen throughout its depth, whereas degenerated tissue shows less reorientation, which does not extend into the deep zone, confirming that collagen network disruption altered load-bearing behaviour in OA cartilage.

Knee Joint Loading Differences Affect the Mechanoregulation of Cartilage Gene Expression and Distinguish Healthy, Non-Progressor, and Progressor Knee OA Subjects

Dr. Seyed Ali Elahi[1], Dr. Satanik Mukherjee[2], PhD Candidate Yixuan Zhang[1], Dr. Bryce Killen[1], PhD Candidate Ikram Mohout[1], Dr. Miel Willems[1], PhD Candidate Ali Abedi[1], Prof. Liesbet Geris[1], Prof. Ilse Jonkers[1]

[1]KU Leuven, Leuven, Flemish Brabant, Belgium. [2]Washington University in St Louis, St. Louis, Washington, United States

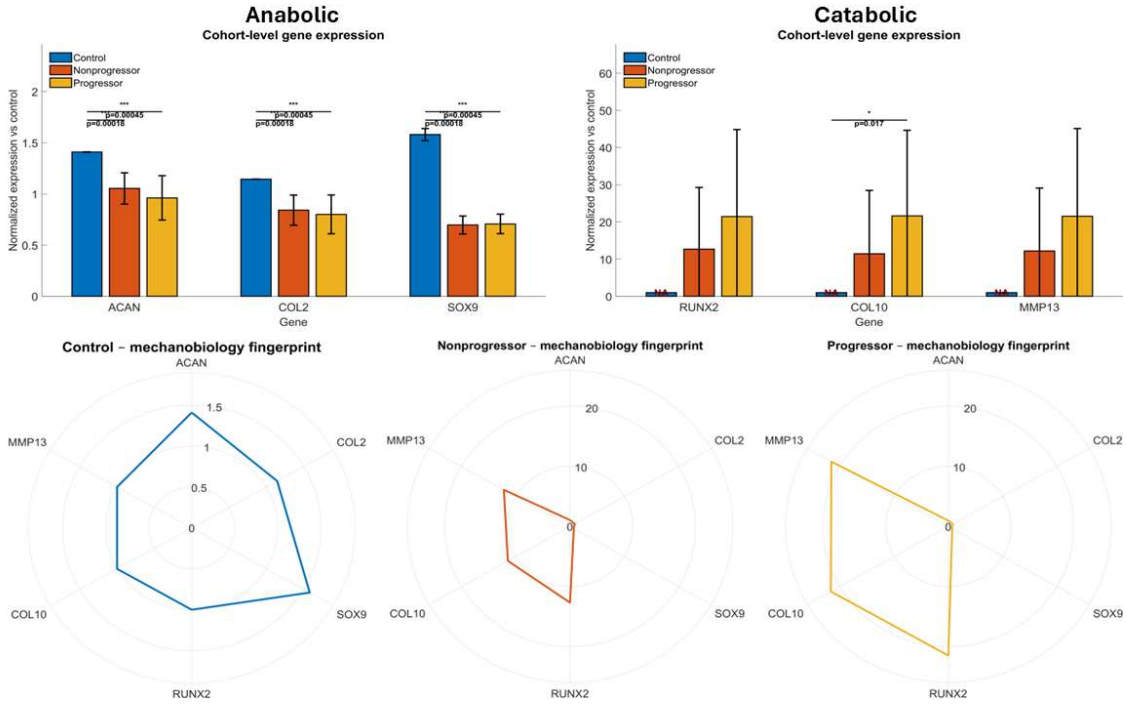
Introduction

Osteoarthritis (OA) progression is driven by changes in cartilage mechanobiology, yet patient-specific mechanoregulatory patterns remain poorly defined. This study integrates tissue- and cell-scale mechanics with a gene regulatory network (GRN) to test whether mechanically driven anabolic and catabolic signalling differs among healthy controls, knee OA non-progressors, and progressors.

Methods

3D gait analysis was performed for 10 controls, 10 knee OA non-progressors, and 8 knee OA progressors, classified using 2-year changes in Kellgren–Lawrence scores. Subject-specific gait data were used in a generic musculoskeletal modeling workflow to estimate medial compartment contact pressures, which served as boundary conditions for fibril-reinforced poroelastic finite element models of medial tibial cartilage (Abaqus) [1]. The mean deformation gradient of the top 10% most-loaded elements was transferred to a cell-scale representative volume element (Abaqus) [2], and the resulting chondrocyte total force was used as input to a stochastic GRN (MATLAB) [3] for ACAN, COL2, SOX9, RUNX2, COL10, and MMP13. Pro-inflammatory cytokine exposure was modeled for both OA groups. Gene expression was normalized to the unloaded, control baseline, and group differences were assessed using Kruskal–Wallis tests with post-hoc comparisons.

Results



Controls consistently upregulated all anabolic genes, indicating a robust protective response to mechanical loading. OA non-progressors showed selective ACAN upregulation, accompanied by COL2 and SOX9 downregulation; whereas progressors downregulated all anabolic markers. Variability in anabolic responses increased in both

OA groups. Catabolic genes remained inactive in controls but exhibited substantial, heterogeneous upregulation in OA, most prominently in progressors. Spider plots highlighted a near-homeostatic, mildly anabolic profile in controls versus a strongly catabolic profile in both OA subgroups.

Discussion

This multi-scale tissue–cell–GRN framework reveals distinct mechanobiological signatures across knee OA phenotypes, characterized by diminished anabolic activity and variable catabolic activation in OA, particularly in progressors. These mechanoregulatory patterns may support phenotype-specific OA stratification and inform the development of targeted mechanobiological interventions.

OA149-03

Combining Raman Spectroscopy and Nanoindentation to Correlate Changes in both Mechanical Properties and Molecular Structure during Osteoarthritis Progression

Dr Sarah Davis, Dr Jurgita Zekonyte, Dr Priyanka Dey, Professor Gordon Blunn, Dr Katerina Karali

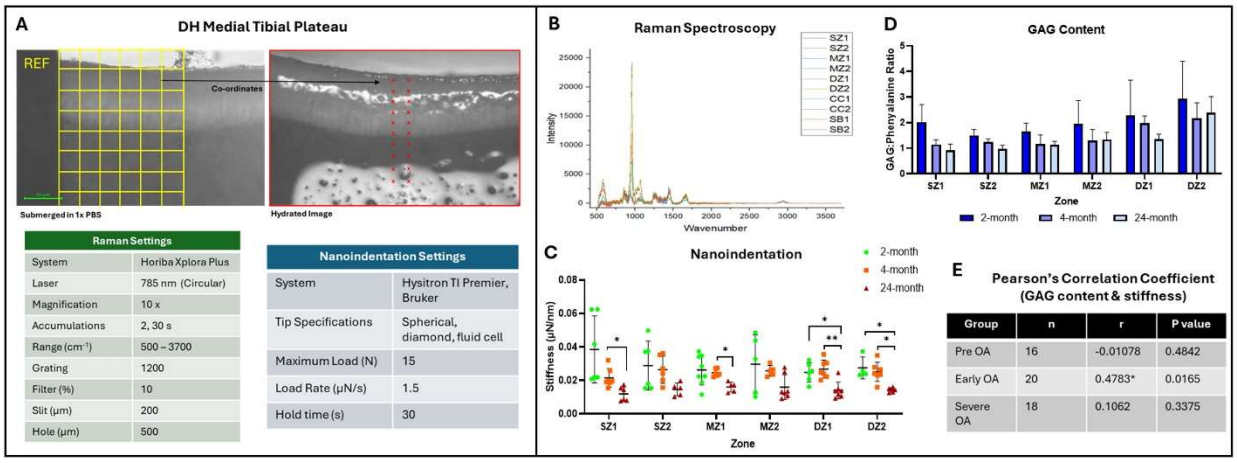
University of Portsmouth, Portsmouth, Hampshire, United Kingdom

Introduction

Osteoarthritis (OA) is linked to progressive, depth-dependent molecular and microstructural changes across the cartilage-bone interface that may alter tissue micromechanics before gross structural degeneration is observed. This study aimed to explore how compositional changes in OA influence the mechanical behaviour throughout hyaline articular cartilage (HAC), calcified cartilage (CC) and subchondral bone (SB). This may allow the early detection of OA-related tissue degeneration and contribute to the development of targeted treatments for preserving joint health.

Methods

Tibias from female Dunkin-Hartley (DH) guinea pigs at 2, 4, and 24 months of age (n = 4), representing pre-OA, early-stage OA and severe OA respectively [1], were cut longitudinally using a previous method [2]. Load-controlled quasi-static nanoindentation and Raman spectroscopy were performed across the osteochondral unit (Figure 1A) whilst submerged in PBS at room temperature. Reference markers around the central region of the medial tibial plateau ensured that measurements were performed on the same X-Y coordinates (Figure 1A). The medial condyle of the contralateral hindlimb was used for histology and modified-Mankin scoring.



Results

24-month specimens had a significant reduction in stiffness across all zones of HAC (SZ *p = 0.0107; MZ p = 0.0281; DZ **p = 0.0048, compared to 4-month specimens, Figure 1C). GAG content increased throughout the depth of HAC from the superficial zone (SZ) to the deep zone (DZ) and was reduced in both early and severe OA (Figure 1D). Pearson's Correlation Coefficient suggested that the decrease in stiffness during OA progression is related to a reduction in GAG content during the early stages of the disease only (r = 0.04783, *p = 0.0165, Figure 1E).

Discussion

Ongoing work will include correlating immunohistochemical analysis, histology and Micro-CT to assess the microstructure of osteochondral tissues during OA progression. By combining these techniques, this study offers a multimodal strategy for investigating the relationship between molecular composition, local mechanical properties and characteristic features of OA progression, to yield deeper insights into the complex mechanisms underlying the onset of OA.

[3]University Medical Center Utrecht, Utrecht, Utrecht, Netherlands. [4]University of Calgary, Calgary, Alberta, Canada. [5]University of Oulu, Oulu, North Ostrobothnia, Finland

Introduction

Obesity is a risk factor for osteoarthritis. High-fat and high-sucrose (HFHS) diets in rodents mimic human metabolic syndrome. Obesity-induced effects on cartilage and bone may differ on the obesity-onset age. Here, we investigated how diet-induced obesity, initiated in weanling and adult rats, affects patellar articular cartilage mechanics and T_1-relaxation time – a biomarker for cartilage composition.

Methods

Male Sprague-Dawley rats were assigned a chow or a HFHS diet (Fig. 1A). Cohorts consisted of two age groups: 3-week-old weanlings ($WEAN_{14}$; diet maintained for 14 weeks; N_{HFHS} = 5, N_{CHOW} = 6) and 12-week-old adults ($ADULT_{24}$; diet maintained for 24 weeks; N_{HFHS} = 6, N_{CHOW} = 6). For the first seven weeks the HFHS weanlings received a protein-supplemented diet. After the diet interventions, animals were sacrificed, and the patellae harvested. Patellar cartilage biomechanics were tested in an indentation setting (Fig. 1B) via stress-relaxation (4 steps, 5% amplitude, 20%/s ramp rate, 200 s relaxation) followed by a sinusoidal test (2 Hz, 2% amplitude, 4 cycles) at final strain. Cartilage equilibrium modulus, dynamic modulus, and phase difference were analyzed. Subsequently, the patellae were magnetic resonance imaged at 11.7 T with variable flip angle zero echo time sequences (flip angles 2°, 5°, 13°; voxel size 25 μm^3). T_1-relaxation time was estimated using non-linear fitting. Depth-wise T_1-relaxation time profiles (0–100% cartilage depth) were analyzed from a 1 × 1 mm^2 region (Fig. 1C), and the profiles were then interpolated to 10 points. Statistical analyses were done with a linear mixed model (LMM).

Results

The cartilage equilibrium modulus, dynamic modulus, and phase difference were similar between the $WEAN_{14}$ and the $ADULT_{24}$ rats in the CHOW and HFHS groups (Fig. 1D). In the HFHS group, the $ADULT_{24}$ group rats had a longer cartilage T_1-relaxation time than the $WEAN_{14}$ group rats (Fig. 1E).

Discussion

Cartilage mechanics did not differ between the $WEAN_{14}$ and $ADULT_{24}$ rats, indicating similar mechanical properties regardless of diet. Longer T_1-relaxation times in the older HFHS-fed rats, but similar T_1-relaxation times in the CHOW-fed rats, suggest that HFHS-induced obesity has an increased effect on cartilage molecular composition in aged rats without corresponding mechanical deterioration.

Images (Optional)

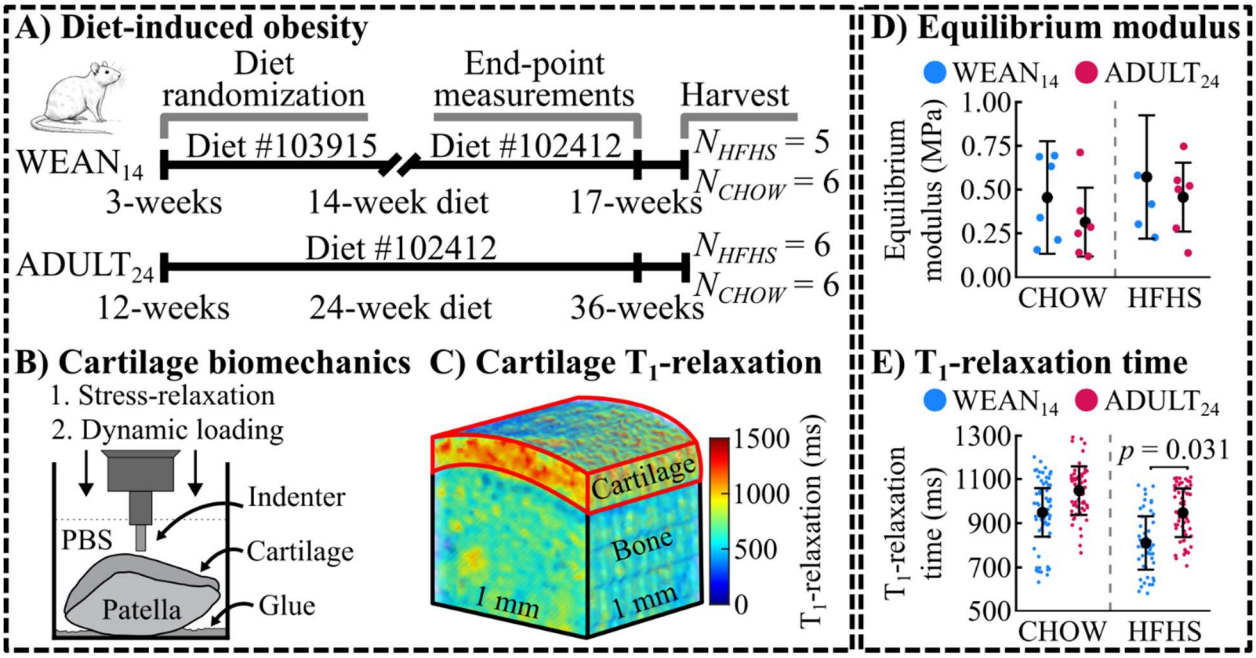

Figure 1. A) a high-fat/high-sucrose (HFHS) diet or a normal chow (CHOW) diet was maintained on 3-week-old weanling ($WEAN_{14}$) and 12-week-old adult ($ADULT_{24}$) male Sprague-Dawley rats. B) Stress-relaxation and dynamic loading were done under indentation. C) T_1-relaxation time was measured using micro-magnetic resonance imaging. D) Equilibrium modulus for the $WEAN_{14}$ and $ADULT_{24}$ groups. E) T_1-relaxation time for the $WEAN_{14}$ and $ADULT_{24}$ groups. Data is shown as mean ± 95 % CIs from LMM.

Validating a Force Measuring Glove for Use in Distal Upper Limb Ergonomic Assessment Tools

Mr. Tyler Brown MSc Candidate[1], Mr. Daniel Cousins PhD Candidate[1], Mr. Ryan Porto[2], Dr. Michael Holmes PhD[1]

[1]Brock University, St. Catharines, Ontario, Canada. [2]General Motors, Warren, MI, United States

Introduction

Despite advances in ergonomics, hand and wrist injuries still constitute a significant portion of workplace injuries. Evaluating force, posture, and repetition are common inputs for distal upper limb assessment tools, such as the revised strain index (RSI). Obtaining accurate hand force measurements is one of the most challenging assessment tool inputs for ergonomists. As a result, it is common to rely on subjective ratings of exertion as a surrogate for force in assessment tools when evaluating gripping tasks. The purpose of this study was to validate a force sensing glove against a laboratory-grade load cell.

Methods

Fourteen participants were fitted with a force sensing glove which offers a novel solution containing seven embedded sensors that continuously record forces at the fingertips and palm. Participants completed various isometric finger flexion and palm push contractions (10 second duration) against a load cell (Sunrise Instruments, Ann Arbour, MI) while wearing the glove. For each of the seven glove sensors (four fingers, three palm), participants completed three trials at each of five force conditions (20, 40, 60, 80 and 100% MVC). Force levels were randomized, and rest was provided between contractions.

Results

When considering all force levels and sensors, the glove consistently overestimated forces (3.8 ± 0.6N; $p < 0.001$). The glove significantly overestimated forces at all force levels except for 20% MVC, and the largest differences were seen in the 60% (5.7 ± 1.4N) and 80% (4.5 ± 1.4N) MVC conditions. The mean difference ranged from 0.6 ± 1.7N for the distal palm to 7.9 ± 1.7 N for the index finger sensor.

Discussion

The mean absolute error across all conditions was significantly different than the load cell, however, this difference was only 3.8N. Considering most assessment tools work in ranges/bins, this error appears to be within acceptable limits and is likely more accurate than subjective methods. The glove reliably overestimated forces which may be corrected with offset values. Further research is needed to identify how to integrate these forces into current ergonomic assessment tools.

Multimodal Physiological Monitoring of E-sports Gaming

Ms. Yookyeong Sa, Ms. Subin Kim, Prof. Gwanseob Shin

UNIST, Ulju-gun, Ulsan, Korea, Republic of

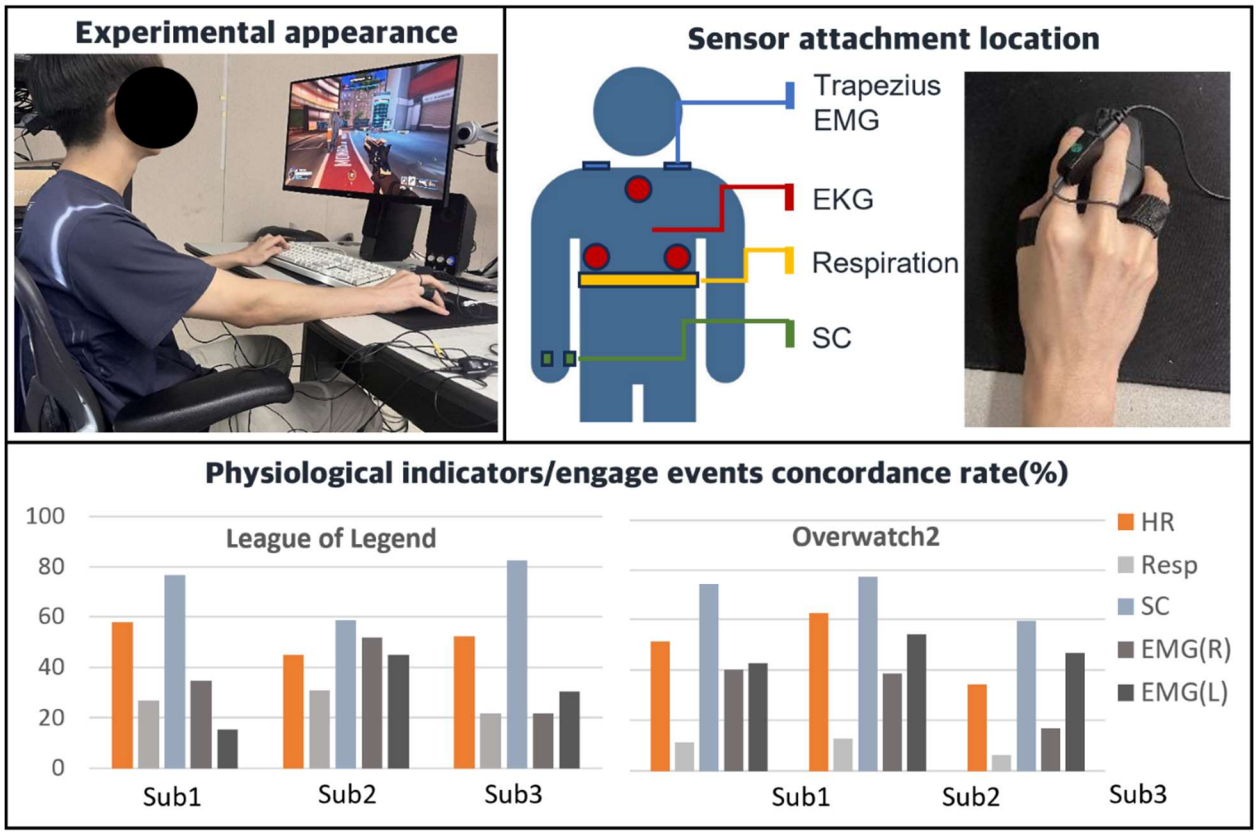
Introduction

Esports involves a high level of cognitive and physical activity despite its outward appearance as a static task. Professional and casual players are repeatedly exposed to prolonged static posture, sustained concentration, rapid perceptual·cognitive processing demands, and acute stress. These increase the risk of musculoskeletal strain and mental fatigue. However, quantitative research on physiological changes during gameplay is limited. This study aims to establish a foundational framework for multimodal physiological monitoring during esports by examining how various physiological signals correspond to in-game events and whether these physiological patterns are consistent across individuals

Methods

15 participants in their twenties who played the target game for over 100 hours were recruited. Four sensors were attached to subjects: bilateral trapezius EMG, ECG (for HR, HRV), respiration, and skin conductance(SC) sensors on the right thumb and ring finger. Participants performed two rounds each of League of Legends and Overwatch 2 in randomized order, with rest and recovery periods between tasks.

'Events' were segmented with rest-engagement-rest phases based on the kill/death log by allies and enemies. Then, the physiological signal peaks exceeding surrounding values were matched to the events. Signal-event concordance rates were calculated as the proportion of detectable physiological signal peaks to whole engagement events



Results

In both games, SC showed the highest concordance with engaged events, followed by HR. Trapezius EMG responses varied by game: right EMG concordance was higher in Overwatch, whereas left was higher in League of Legends. Respiration showed the lowest concordance across all conditions. HRV (RMSSD) changes did not show a clear pattern across pre-, mid-, and post-task periods.

Discussion

This study demonstrates HR and SC are the most reliable indicators for monitoring physiological responses during gameplay. EMG responses influenced by game characteristics (POV, control method) and Respiration were less sensitive to the event. Physiological signals show consistent patterns within individuals. RMSSD had limitations in detecting rapid state changes during gameplay due to temporal resolution and individual variability. This study provides fundamental data for the development of a multimodal monitoring framework that can be utilized for workload management and real-time feedback for professional players, stress prevention in general gamers.

Identifying and Quantifying Manual Wheelchair Propulsion Patterns in the Wild

Ms. Kathylee Pinnock Branford[1], MSPH Meegan G. Van Straaten[2], PhD Omid Jahanian[2], PhD Hannah Houde[3], PhD Melissa M. B. Morrow[3], PhD Stephen Cain[1]

[1]West Virginia University, Morgantown, WV, United States. [2]Mayo Clinic, Rochester, MN, United States. [3]University of Texas Medical Branch, Galveston, TX, United States

Introduction

Poor manual wheelchair (MWC) propulsion mechanics can increase shoulder strain and the risk of overuse injuries. Clinical Practice Guidelines recommend a semicircular pattern, which reduces overuse risk by producing fewer strokes per distance traveled, decreasing wrist impact, and increasing push time [1]. Because of the importance of propulsion patterns in reducing injury risk, the objectives of this study were to develop a wearable sensor-based approach to identify MWC propulsion patterns in the real-world and to demonstrate the utility of our approach by quantifying propulsion patterns used during daily mobility in a small sample of MWC users.

Methods

Two MWC users with spinal cord injury (SCI) wore three inertial measurement units (IMUs; Axivity AX6; ±16 g, ±2000°/s; 100 Hz) placed on the dominant wrist, upper arm, and wheel for seven consecutive days of daily life. We identified steady-state propulsion cycles using the upper arm elevation angle, requiring steady-state cycles to exhibit similar arm excursion and cycle duration compared to at least one adjacent cycle. For steady-state cycles, we integrated linear acceleration from the wrist IMU to calculate wrist position (Fig1) using an approach similar to a zero-velocity update to remove integration drift. For each cycle, we calculated the duration and distance traveled and classified the propulsion pattern as either arc (not recommended), semicircular, or other.

Results

Steady-state cycles represented less than ~17% of the total time each participant spent moving (Fig1). Participant 1 primarily used an arc pattern, whereas Participant 2 primarily used a semicircular pattern.

Discussion

Calculating wrist position trajectories from IMUs during MWC propulsion enables classification of propulsion patterns outside laboratory settings. Our findings reveal that participants only utilized steady-state propulsion cycles ~17% of total mobility time,

suggesting that knowledge from laboratory-based studies of propulsion, which utilize analyses of steady-state propulsion on a treadmill or ergometer, may have limited use for understanding the demands of real-world MWC mobility. Personalized measurement of propulsion patterns in daily life could guide interventions aimed at improving propulsion mechanics and promoting long-term upper-extremity health in wheelchair users.

Images (Optional)

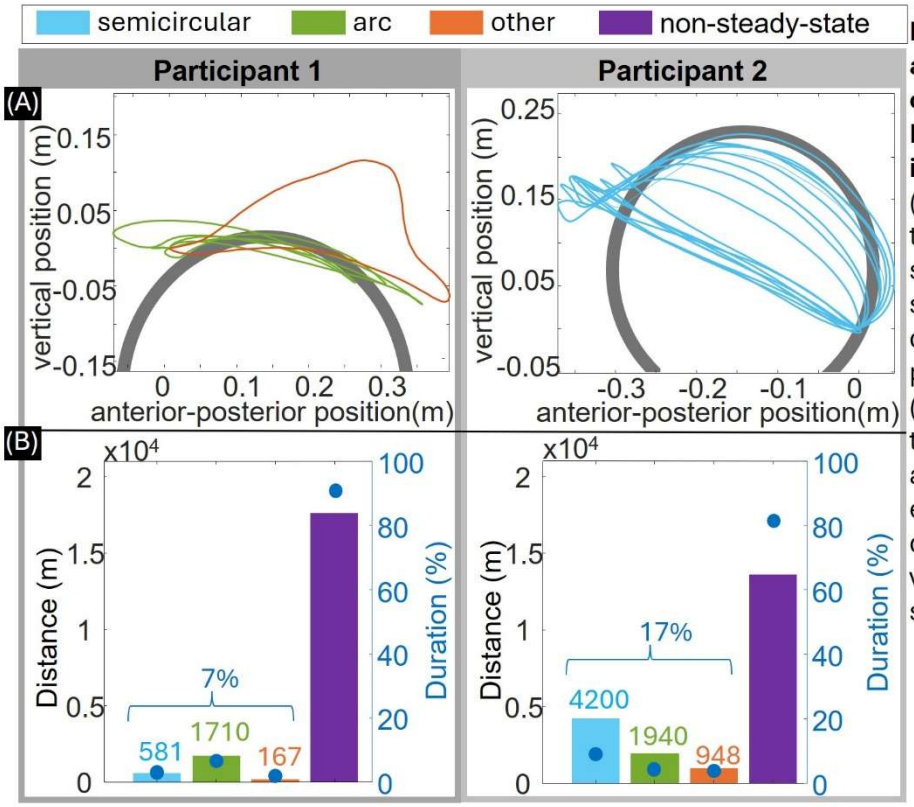

Figure 1. Wrist position and propulsion characteristics during MWC use for two individuals with SCI. (A) Wrist position trajectories in the sagittal plane during steady-state propulsion, demonstrating distinct propulsion techniques. (B) Weekly distance traveled by MWC user and time spent using each propulsion style during steady-state versus non-steady-state.

The Effects of Mental Fatigue on Movement and Muscle Activity During Cyclic Pushing

Ms. Molly Malette BSc, Mr. Ryan Chhiba MSc, Dr. Peter Keir PhD

McMaster University, Hamilton, Ontario, Canada

Introduction

Mental fatigue can impair physical performance resulting in elevated muscle activity and reduced task accuracy, leading to increased injury risk in the workplace [1]. Modern work environments often require sustained attention, multitasking, and fast-paced work, yet the combined impact of cognitive demands and physical effort on task execution and muscle activity is not well understood. This study aimed to quantify the influence mental fatigue has on task accuracy and upper-extremity muscle activity during four dynamic pushing tasks.

Methods

Twenty-two participants completed four pushing tasks following a control condition (watching a documentary) and a mental fatigue task (Stroop test). Tasks required pushing handles from 10% to 80% of maximum reach with 4 kg resistance. The tasks were (i) 15 cycles/minute, (ii) 30 cycles/minute, (iii) 15 cycles/minute with 30% handgrip, and (iv) 30 cycles/minute with 30% handgrip. Participants were instructed to reach targets accurately without over or undershooting. EMG was collected from seven upper-extremity muscles bilaterally, along with right hand grip force, displacement, and ratings of both physical and mental fatigue.

Results

Higher mental fatigue and exertion ratings were reported across all tasks in the Stroop condition. Changes in muscle activity after the Stroop task were observed for many muscles, however, variability was quite high. Muscle activity for the right forearm flexors and extensors rose from less than 10%, to over 20% when handgrip was added to the 15 and 30 cycles/minute push trials. The left forearm flexors and extensors remained around 10% with an increase in the extensors in the Stroop condition. The anterior deltoids had the highest activities across all muscles but decreased with mental fatigue.

Discussion

A brief (12 minute) mentally fatiguing task elevated activity in some muscles but reduced it in others, suggesting that some muscles may be more susceptible to mental fatigue. Preliminary analyses have not shown an increase in errors, suggesting that there may not be visual signs of impairment. These findings highlight a potential interaction between mental fatigue and dual tasks, which can have implications in risk for both acute and chronic occupational injuries.

Cornell University, Ithaca, NY, United States

Introduction

Supraspinatus tendon (SST) tears are common and heal with mechanically and structurally inferior scar tissue.[1] The Murphy Roths Large (MRL/MpJ) mouse strain heals tendon injuries, including SST, more effectively than canonical strains.[1] Patellar tendon healing in canonically healing mice is improved by treatment with 29 proteins of interest (POIs) that are highly upregulated in MRL/MpJ healing.[2] In vitro, these POIs similarly shift rat and mouse tenocyte behavior,3 suggesting cross-species efficacy yet to be shown in vivo. We hypothesize that POIs will retain therapeutic impact and improve mechanical properties of rat SST following acute injury wherein there is a need to reconstitute the tendon-to-bone enthesis.

Methods

Under IACUC approval, left SSTs of 10-month-old female Sprague-Dawley rat were surgically fully detached from their insertion and an osmotic pump was placed subcutaneously delivering POIs (n=6) or PBS carrier control (n=10) for 3 days. Additional rats (n=9) received injury without a pump. Injured and contralateral uninjured limbs were mechanically tested under tensile loading after euthanasia on day 42. Paired t-tests compared injured limbs to contralateral controls.

Results

Injured and uninjured limbs typically failed at the enthesis or midsubstance, respectively. Treated limbs had significantly increased cross sectional area (CSA) (Fig 1A) and decreased maximum stress (Fig 1B) and Young's modulus (Fig 1E) compared to contralateral controls. POI treatment restored hysteresis (Fig 1D), maximum force (Fig 1C), and linear stiffness (Fig 1F) to uninjured levels, while PBS-treated and no pump controls did not.

Discussion

Injured limbs in all treatment groups increased tissue deposition in an attempt to improve function. Only POI treated limbs restored material properties of linear stiffness and maximum force, allowing healed tendons to meet normal physiological demands. Hysteresis restoration shows POIs also promote recovery of protective viscoelastic

properties which was not observed in PBS or no pump treatment groups. MRL/MpJ inspired POIs are a promising therapeutic across species for healing acute tendon injuries. Future work will consider sexual dimorphism of response and optimize dosing to improve structural properties of the healed tendon.

Biomechanical and In-Vitro Testing of Braided, Long-Term Biodegradable Scaffolds for Anterior Cruciate Ligament Tissue Engineering

Dr.-Ing. Caroline Emonts[1], Dr.-Ing. Benedict Bauer[1], M.Sc. Saskia Hesse[1], M.Sc. Viktoria Kiaulehn[2], Dr.-Ing. Max Praster[2], Prof. Dr. rer. nat. Mersedeh Tohidnezhad[3], Prof. Dr. Thomas Gries[1]

[2]Department of Orthopaedic, Trauma and Reconstructive Surgery, RWTH University Hospital, Aachen, NRW, Germany. [3]Department of Anatomy and Cell Biology, RWTH University Hospital, Aachen, NRW, Germany

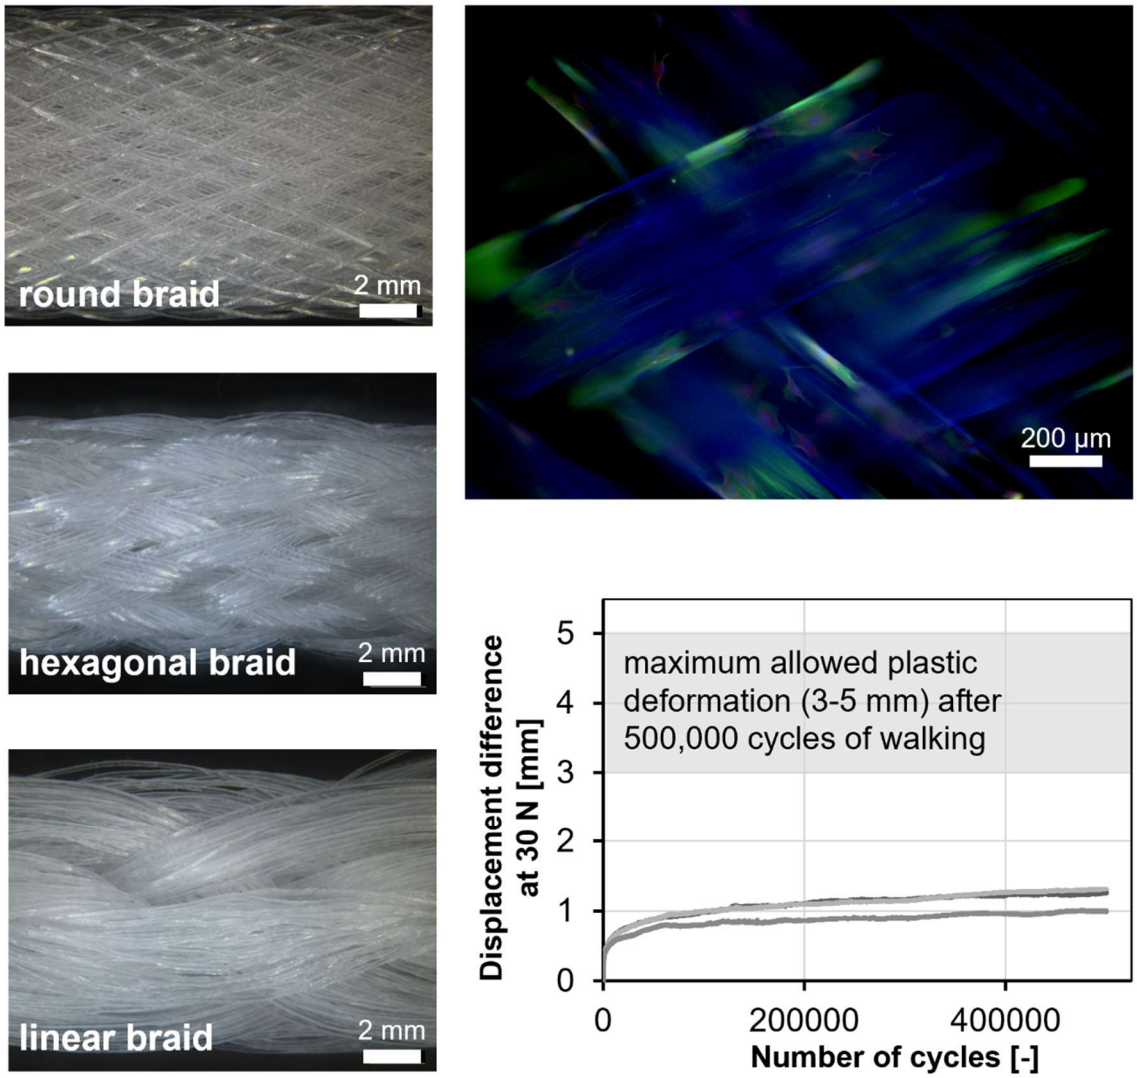
Introduction

Anterior Cruciate Ligament (ACL) injuries are a common sports injury. Tissue engineering offers a new approach by using scaffolds that provide temporary mechanical stability and promote cell ingrowth. Braided scaffolds offer a reproducible, scalable three-dimensional structural design with high strength and sufficient porosity. This study investigates the biomechanical properties and cell-ingrowth on long-term degradable scaffolds for ACL replacement.

Methods

The scaffolds were fabricated using round, hexagonal, and linear braiding with melt-spun PCL monofilaments [1]. Uniaxial tensile testing was performed corresponding to the length of the ACL. A cyclic tensile test with the load of walking was performed for 500000 cycles with 1,6 Hz. Porosity and pore size were quantified using µCT imaging. In addition, rat tenocytes were cultured on the scaffolds for 14 days to evaluate cell adhesion, proliferation and viability.

Results



The braided scaffolds exhibited tensile strengths between 3460 - 4110 N, substantially exceeding the tensile strength of the native ACL (734–2160 N) [2,4]. The stiffness within the linear region (186–212 N/mm) corresponded closely to the physiological stiffness values of the ACL (180–242 N/mm) [2,4], indicating that the constructs fulfill the primary mechanical requirements for initial ligament substitution. Regarding cyclic loading, the laxity of the synthetic ACL caused by creep must not exceed 3-5 mm. [3] The plastic deformation is below 1.3 mm for all tested scaffolds [4]. In-vitro analyses confirmed that rat tenocytes were able to attach, proliferate, and remain viable on all scaffold types. Expression of tenogenic markers was detectable across all conditions. Cellular orientation along the

fiber axis was observed, suggesting that the scaffold topography provides appropriate cues for alignment.

Discussion

The results demonstrate the suitability of the scaffolds in terms of initial mechanical properties and cyclic loading within the physiological range. In addition, cell compatibility with relevant cell types was demonstrated. Next, the scaffolds will be tested in ex-vivo porcine knees and subsequently in in-vitro animal models.

Assessing Efficacy of Systemic Tacrolimus Immunosuppression to Improve Tendon Reconstruction: A Pilot Study

Mr. Trent Hardwick[1], Mr. Atharva Bhagwat[1], Ms. Sonia Patel[1], Ms. Jaclyn Brendenkamp[1], Ms. Elena Woo[1], Mr. Evan Fry[1], Mr. Brady Huggins[1], Mr. Alvin Patel[1], Mr. Fuad Bin Enam[1], Ms. Eeshana Bhuvanesh[1], Dr. Jeremy Eekhoff[2], Dr. Brian Mailey[1], Dr. Koyal Garg[1], Dr. Alex Reiter[1]

[1]Saint Louis University, St. Louis, Mo, United States. [2]University of Pennsylvania, Philadelphia, PA, United States

Introduction

Tendon ruptures risk poor healing and adhesion formation, often resulting in long-term deficits despite surgical advances.[1,2] Tacrolimus, a calcineurin inhibitor, exhibits anti-inflammatory and anti-fibrotic effects. Previously, tacrolimus has been shown to improve functional outcomes in a flexor tendon repair case study.[3] In a murine model of Achilles tendon rupture, tacrolimus has improved histological outcomes.[4] This pilot study examined the effects of tacrolimus on functional, mechanical, and histological outcomes in a rat model of Achilles rupture.

Methods

Forty-two female Sprague Dawley rats (10-12 weeks old, 200-275g, Inotiv) were divided into three groups: Achilles rupture with systemic tacrolimus treatment, Achilles rupture with vehicle, and naïve control. Following rupture and repair, limbs were immobilized in a cast for two weeks, and tacrolimus (2mg/kg+DMSO+saline) or vehicle (DMSO+saline) were injected intraperitoneally daily. Passive ankle range of motion (ROM) (n=5-12/group) was assessed via manual manipulation and goniometer immediately following euthanasia. Tendons were prepared for mechanical (n=10/group) and histological analysis (n=4/group). Mechanical testing consisted of preconditioning, 10-minute stress relaxation at 6% strain, and a quasistatic ramp-to-failure. Data were analyzed in MATLAB. One-way ANOVAs with Tukey post-hoc tests assessed group differences (p<0.05). Histological analysis is ongoing.

Results

Tacrolimus treatment significantly improved ROM compared to vehicle but remained reduced from control (Fig. 1A). Maximum force, stiffness, cross-sectional area, maximum

stress, tangent modulus, and percent relaxation in both injury groups were significantly different from control but not each other (Fig. 1B-G).

Discussion

While ROM data suggests tacrolimus had a modest improvement on function following injury, mechanical testing revealed no differences between injury groups. The substantial mechanical deficits in rupture groups at 2 weeks post-injury compared to controls are consistent with previous work showing a ~85% reduction in force and ~80% reduction in stiffness[5]. It is possible the early 2-week post-injury time point with full immobilization may mask any potential long-term benefits of tacrolimus treatment on tendon mechanics.

Images (Optional)

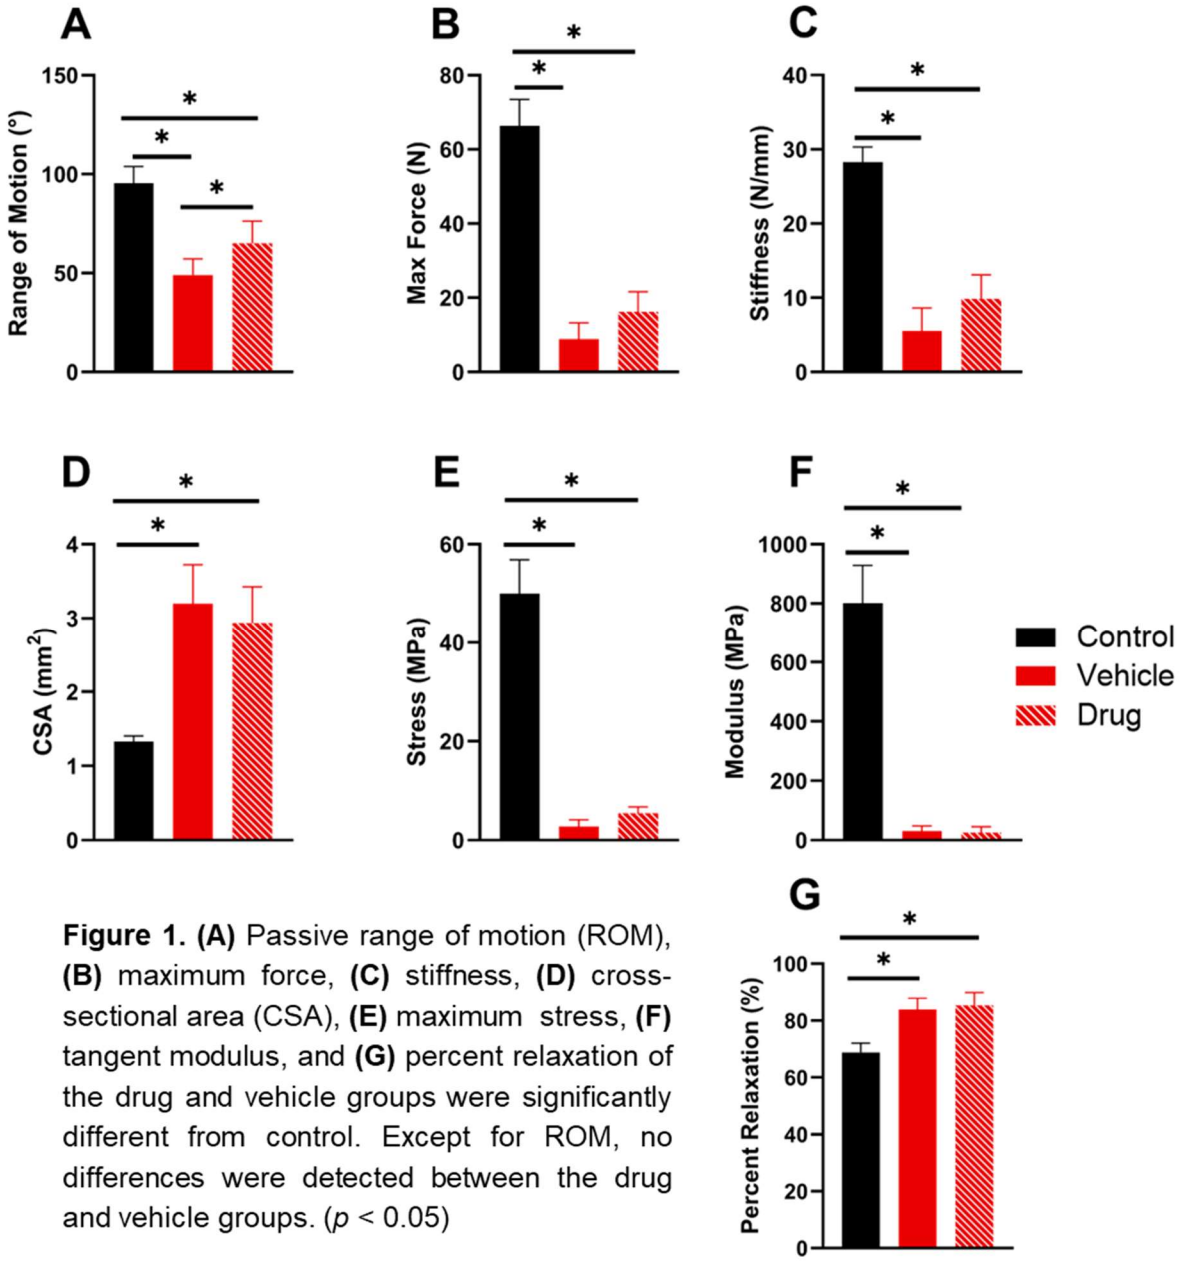

Figure 1. (A) Passive range of motion (ROM), **(B)** maximum force, **(C)** stiffness, **(D)** cross-sectional area (CSA), **(E)** maximum stress, **(F)** tangent modulus, and **(G)** percent relaxation of the drug and vehicle groups were significantly different from control. Except for ROM, no differences were detected between the drug and vehicle groups. ($p < 0.05$)

Implant Cross-Sectional Profile Affects Tendon-Implant Interactions Over Initial Cycles of Tendon Loading

Ms. Gabriella Justen, Dr. Michael Pavol, Prof. Ravi Balasubramanian

Oregon State University, Corvallis, Oregon, United States

Introduction

Tendons may bend and slide across orthopedic implants, such as volar plates at the distal radius. Tendon damage from these interactions can lead to impaired function or rupture. To better prevent these consequences, this study investigated how "implant" cross-sectional profile affects its interactions with a tendon over the initial cycles of tendon tensile loading.

Methods

Twenty-four extensor digitorum communis tendon bundles from New Zealand white rabbits were wrapped 160° around a submerged titanium rod with one of three profiles of equal contact length: blunt, circular, or knife. The circular profile was of radius 1.5 mm. The blunt profile had an 80° central section of 2.7-mm radius with 50° sections of 0.3-mm radius to either side. For the knife profile, these radii were reversed. One end of the bundle was attached to an anchor point via a cord, spring (stiffness: 1.44 N/mm), and load cell in series. The other end was attached to a linear actuator via a cord and load cell in series. Slow (2.5 mm/s) triangle-wave motion of the actuator exposed the tendon bundle to repeated cyclic tensile loading over an actuator-side force excursion from 0.5–4.5 N. Anchor-side force excursion was analyzed as a measure of force transmission and tendon sliding across the rod, and its rate of change across cycles was used to determine the transition cycle at which a near-steady-state excursion was reached.

Results

One minute into loading, the circular profile exhibited a larger anchor-side force excursion than the other profiles (Table). Anchor-side force excursion rapidly decreased thereafter until tendon failure (n =2) or transition to a near-steady-state excursion that did not differ between profiles (p =.24). This transition occurred after more cycles for the circular profile (Table).

Discussion

Regardless of rod profile, anchor-side force excursion rapidly dropped to a near-steady-state of ~6% of actuator-side excursion, with minimal (~0.2 mm) tendon sliding. However, the circular profile maintained a larger anchor-side excursion for ~1300 more loading cycles. The results suggest circular profiles should be used over blunt or knife profiles in implant designs involving tendon-implant interactions, but other measures to reduce tendon damage are likely needed.

Images (Optional)

Intracellular Basal Coupling Modulates Coordination in Computational Models of Autonomously Beating Cilia

Ms. Alexis Rivera BS, MS, Dr. Louis Woodhams PhD, Dr. Philip Bayly PhD

Washington University in St. Louis, St. Louis, MO, United States

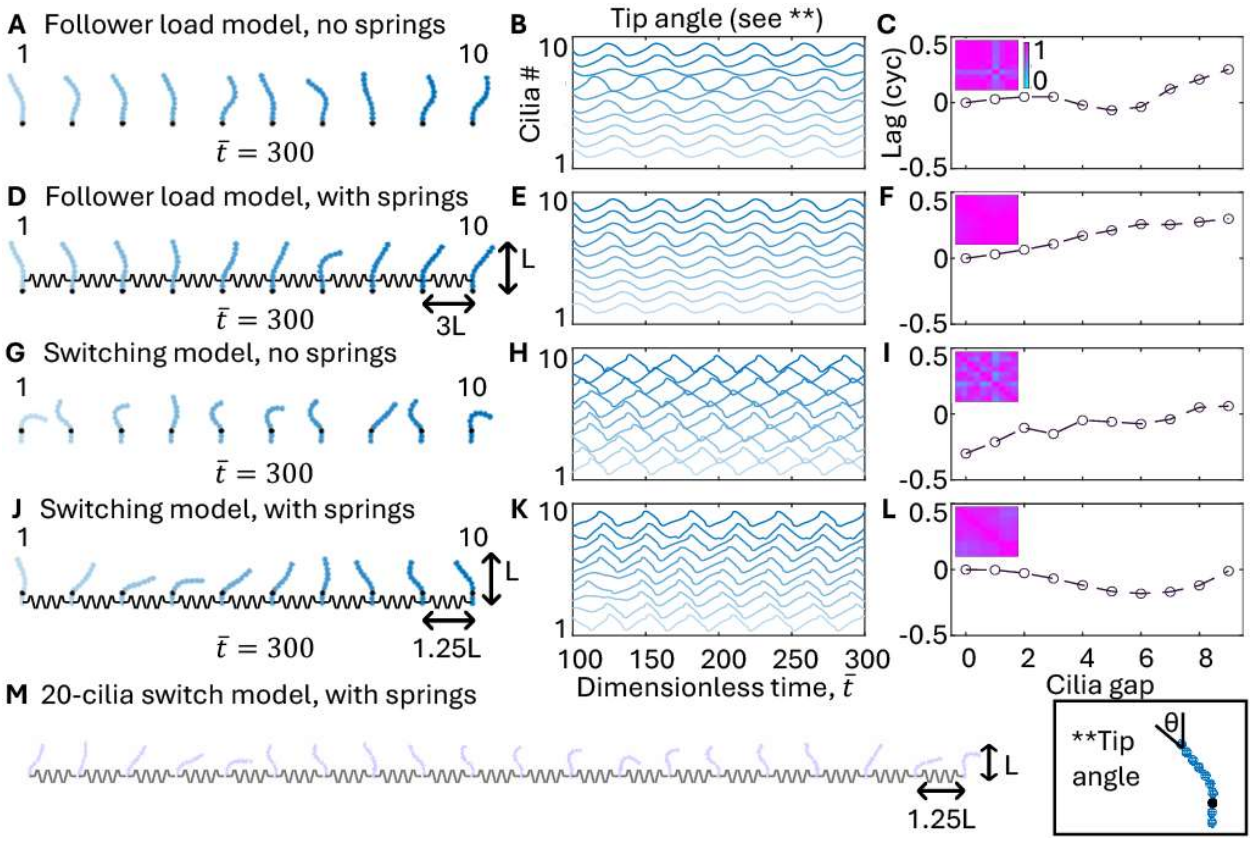
Introduction

Cilia are slender organelles which oscillate to propel surrounding fluid. Cilia arrays exhibit metachronal behavior: beating with the same frequency but a spatially varying phase. Metachronal beating enhances propulsive efficacy but the mechanism is incompletely understood; hypothesized mechanisms include hydrodynamic coupling and elastic coupling between subcortical striated fibers. This computational study explores the effects of oscillation mechanism and elastic coupling on the metachronal and synchronous behavior of cilia arrays.

Methods

Arrays of 10 autonomously beating cilia were modeled (Fig. 1A,D,G,J). Each cilium was represented as a discretized Kirchoff filament with non-local hydrodynamic coupling applied between spheres on each discretized link using Rotne-Prager-Yamakawa theory [1]. Oscillatory beating was generated by two different mechanisms: (1) a dynamic flutter instability generated by follower force (Fig. 1A-F) [2]; (2) switching between a power and recovery stroke based on base-link angle (Fig. 1G-M). The intrinsic beating frequency varied between cilia by 26%. Nonlinear elastic coupling components (torsional springs) were added between adjacent filament bases. Coordination was quantified by magnitude and lag of cross-covariance between tip angles.

Results



Filament tip angle traces from time domain simulations (Fig. 1B,E,H,K) revealed three general behaviors: unsynchronized beating (low covariance), highly synchronized beating (high covariance with small phase lag), and metachronal beating (high covariance with spatially increasing lag). For flutter-driven beating, fluid coupling alone highly synchronized cilia except when widely separated (Fig. 1C). Elastic coupling strengthened synchronization (Fig. 1F). Switching-driven cilia were unsynchronized by fluid coupling even when closely spaced (Fig. 1I), but elastic basal coupling induced graded metachrony (higher covariance

and spatial phase gradients) (Fig. 1L). Larger cilia arrays showed clearer metachronal behavior (Fig. 1M).

Discussion

Simulated cilia arrays of spontaneously beating filaments exhibited different patterns of coordination depending on the assumed beating mechanism and the type of inter-filament coupling. Fluid coupling alone may not be sufficient to produce robust metachronal cilia beating. Future work will compare model predictions to observations of cilia coordination in ciliated microorganisms (*Tetrahymena*) to clarify mechanisms of beating and coordination.

A Comprehensive Thermodynamic Eshelby-informed Model for Sarcomere Growth

Mr Thomas Hayes, Prof. Patrick McGarry, Dr. Giuseppe Zurlo, Dr. Eoin McEvoy

University of Galway, Galway, Connacht, Ireland

Introduction

Mechanical loading and active contraction play a central role in regulating skeletal muscle mass [1], but the mechanisms by which these processes drive tissue-level growth and atrophy remain unclear. We develop a thermodynamically consistent continuum framework for skeletal muscle in which cross-bridge micromechanics and sarcomere structure drive growth and force generation

Methods

Skeletal muscle generates active stress via cross-bridge kinetics, where activation alters myosin chemical potential initiating cycling and force generation [2]. We develop a novel activity-associated free energy expression that is directly informed by cross-bridge micromechanics and sarcomere structure and incorporate it into a continuum description of skeletal muscle. This continuum model is formulated in a finite-growth setting, in which the tissue is free to respond to mechanical loading and activity through growth. Imposing the Second Law of thermodynamics yields a dissipation inequality which depends on the passive Eshelby stress, arising from strain-energy, stress, and the deformation. This is compounded by an active energy contribution, associated with the fraction of force-generating cross bridges, their associated energy, a function representing sarcomere geometry. Finally, the addition of new mass counters the entropic tendency toward protein dilution in the cytoplasm. From the dissipation inequality, we derive a growth evolution law as dependent on these key energetic contributions, and we analyse sarcomere growth arising from extension and force-based loading conditions.

Results

Myosin attachment lowers their high chemical potential (Fig. 1A), and maximal attachment produces a peak in force generated (Fig. 1B). The resulting sarcomere free-energy landscape, set by actomyosin overlap drives growth (Fig. 1C). Under extension-controlled loading, the energy minimum shifts toward states with increased axial growth, whereas under force-controlled loading, it shifts toward increased radial growth (Fig. 1D,E). The axial-to-radial growth ratio varies with load and protein availability (Fig. 1F).

Discussion

This framework provides a thermodynamic basis for the phenomenology of stretch and stress driven growth processes, whereby muscle grows to maximise active force generation. Understanding this mechanism has tremendous potential for uncovering treatments for muscle-wasting diseases such as sarcopenia and ALS

Images (Optional)

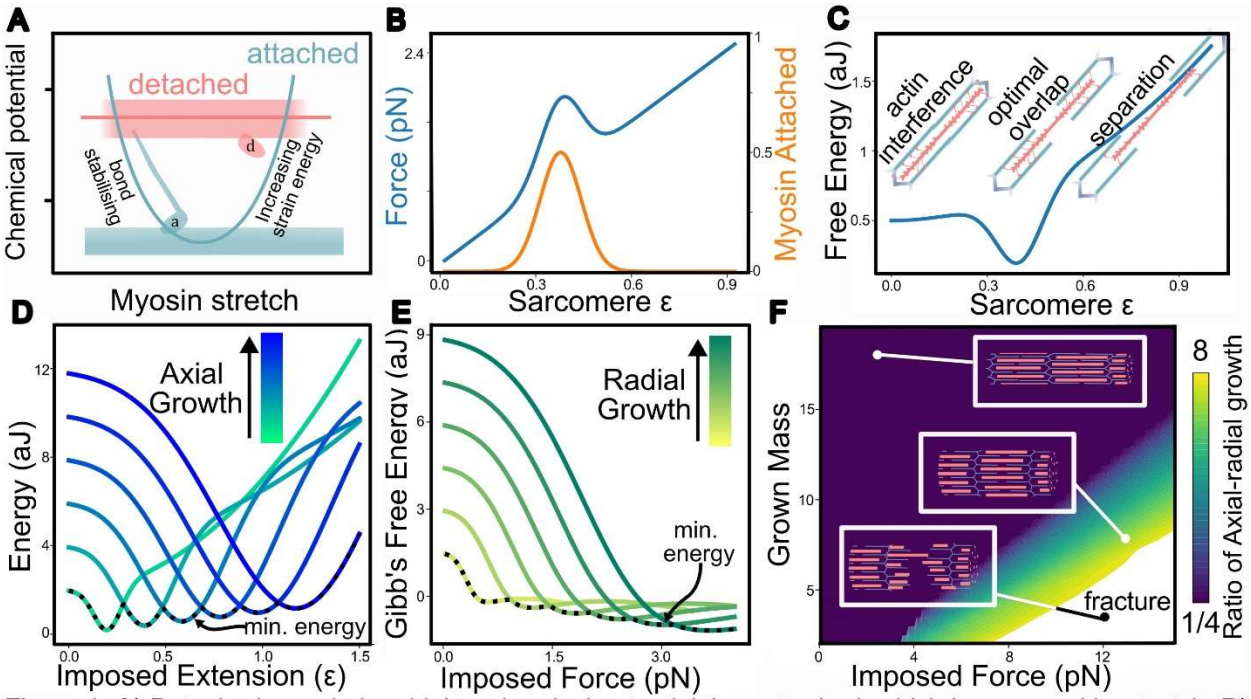

Figure 1: **A**) Detached myosin has higher chemical potential than attached, which is governed by stretch; **B**) Number of attached myosin and associated generated force, which also include passive contribution; **C**) Strain-dependent sarcomere free energy depends on actomyosin overlap; Imposed extension favours axial growth (**D**), whereas imposed force favours radial growth (**E**) by shifting energy minima; **F**) The axial-to-radial growth ratio depends on protein mass and applied load.

OA152-04

A Thermodynamic Framework to Predict Coupled Cross-Bridge Remodeling and Deformation Dynamics

Dr Ryan Coleman, Dr Patrick McGarry

University of Galway, Galway, Galway, Ireland

Introduction

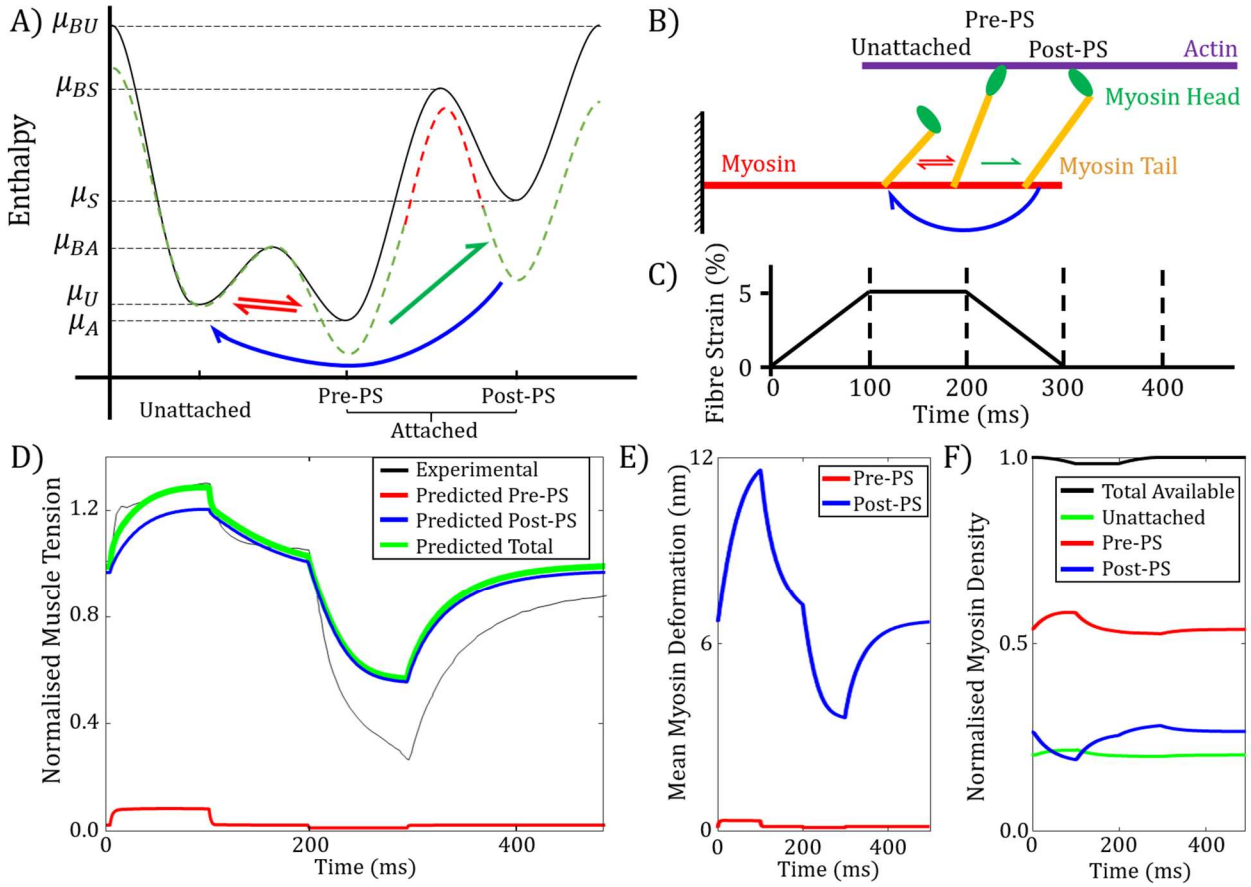
We propose a novel thermodynamic landscape to describe the mechanics of cross-bridge remodeling. This implicitly couples cross-bridge turnover with myosin tail deformation, inducing interdependent remodeling. To our knowledge this mechanism has not been described in any previous methodology and provides a novel extension to the classical Huxley-Simmons model [1]. We demonstrate that our framework provides improved prediction of experimentally measured tension generation and dynamic relaxation.

Methods

With our proposed thermodynamic landscape, we predict the rate of cross-bridge attachment, and detachment via the transition state theory (Fig.1A,B), including a bi-stable state between pre-power-stroke (pre-PS) and post-PS myosin heads reflecting tension induced via the configurational change of myosin head pivoting. Deformation rate of myosin tails is determined from dynamic force equilibrium between active tension generated by attached myosin heads with (i) externally imposed deformation, (ii) dynamic addition of new cross-bridge attachments, and (iii) loss via passive detachments.

The mechanism by which cross-bridge turnover is affected by myosin deformation is as follows. Myosin extension causes enthalpy of cross-bridges to decrease due to applied work (green dash Fig.1A). Simultaneously, extension of pre-PS myosin causes internal strain energy to increase, magnifying the barrier for pre-PS to post-PS cross-bridge transition (red dash Fig.1A).

Results



We simulate the response of muscle fibers subjected to the applied strain history shown in Fig.1C, and we compare our predictions with experimental measurements [2]. During fiber extension, tension rapidly increases and then plateaus (Fig.1D), explained by rapidly increasing deformation of the pre-PS myosin (Fig.1E). This inhibits post-PS turnover,

balancing post-PS density and deformation (Fig.1.E,F). During static stretch, tension reduces towards isometric conditions as cross-bridge concentrations self-modulate by passive turnover, regulating myosin deformation to equilibrium (Fig.1E,F). Muscle shortening reduces deformation of post-PS myosin tails (Fig.1E), facilitating tension loss.

Discussion

This framework has important implications in understanding and modelling tension dynamics in skeletal muscle, contractile smooth muscle cells, and cardiac myocytes. We will further utilize this framework to predict long term cyclic loading [3], investigating the effect of cross-bridge dynamics on sarcomere remodeling.

A Thermodynamically Consistent Biophysical Model for Stress-Dependent Cell Growth and Division

Mr Matteo Simeone[1], Mr Irish Senthilkumar[1], Dr Enda Howley[1], Dr Bart Smeets[2], Dr Eoin McEvoy[1]

[1]University of Galway, Galway, Ireland, Ireland. [2]Ku Leuven, Leuven, Belgium, Belgium

Introduction

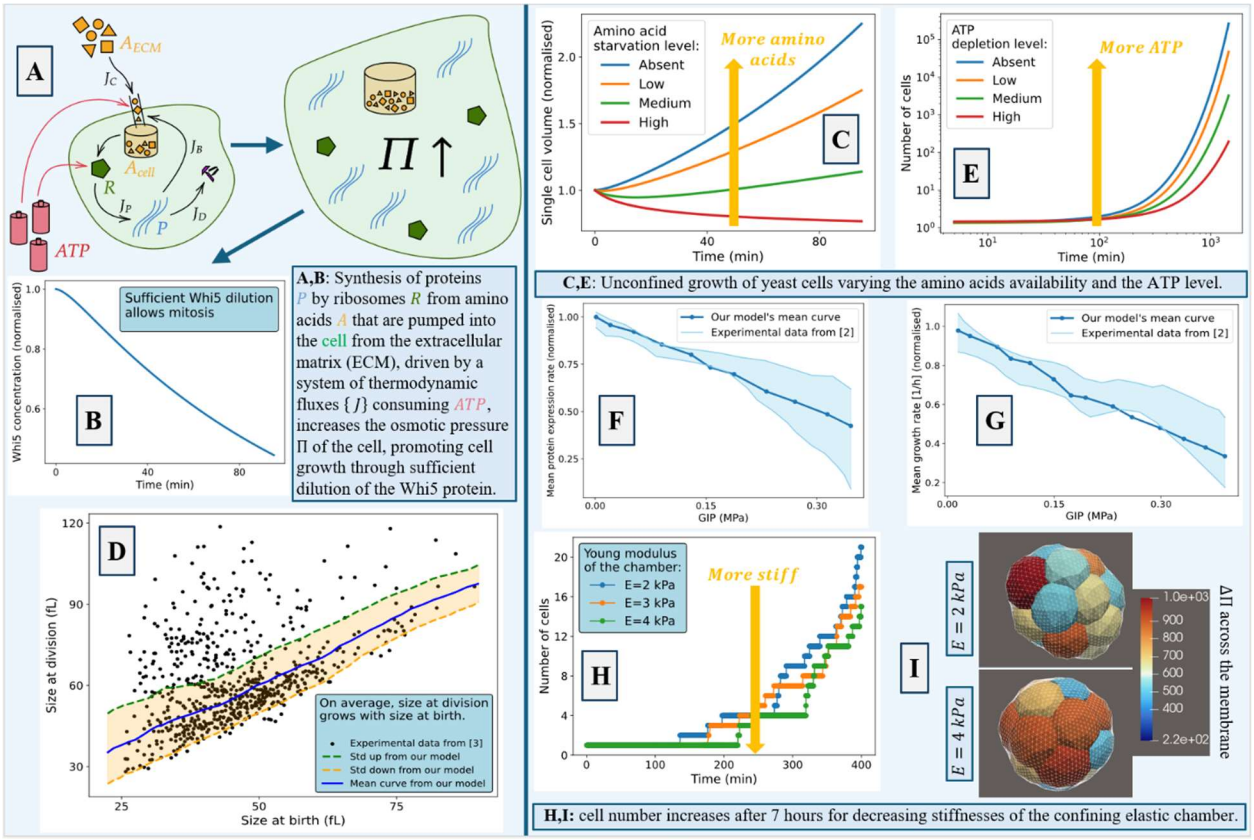
Cell proliferation within stiff or confined tissues generates growth-induced pressures (GIP), which restrict division and alter protein expression. However, the sub-cellular mechanisms underlying this mechanosensitive response remain unclear and, in particular, its dependency on biosynthesis, ATP hydrolysis, and osmotic volume control. In this work, we propose a thermodynamically consistent model for protein synthesis and amino acid turnover, which directly promotes cell cycle growth and provides new insight into stress-dependent growth.

Methods

Biophysical growth model: We consider ATP-driven protein synthesis arising from free energy differences and Boltzmann distributions. Amino acids are replenished through active uptake and protein degradation. Alongside active and passive ion exchange from the environment, these solutes govern osmotic pressure and cell cycle growth, in competition with hydrostatic fluid pressure and external loading.

Multicellular simulation: We implement our growth model with the discrete cell framework Mpacts [1] where cells are described as pressurised deformable triangulated shells with bending stiffness and active cortical tension. In analysing yeast expansion, the probability of cell division is considered to increase with dilution of Whi5 protein concentration.

Results



Our model predicts that biosynthesis drives cell growth, but ATP limitation reduces such synthesis (Fig 1E) and restriction of external amino acids drives a nutrient-limited regime (Fig 1C). The framework accurately predicts the influence on division (Fig 1D), arising from dilution of checkpoint inhibitors. Simulations of yeast growth inside a confined elastic chamber (Fig 1H,1I) reproduced key experimental observations in [2,3]: with GIP increasing over time, protein synthesis is suppressed (Fig 1F) and thus proliferation inhibited. The

relationship between growth rate and GIP showed a monotonic decrease (Fig 1G), without imposing phenomenological pressure-dependent growth laws.

Discussion

Our results indicate that GIP-driven growth arrest arises from energetic constraints on biosynthesis, osmotic regulation, and pressure generation. Impaired Whi5 dilution due to reduced cell growth under compression delays cell-cycle progression and lowers the probability of division. Cell behaviour under ATP depletion and amino acid starvation highlights distinct energy-limited versus substrate-limited regimes of pressure-dependent protein repression.

[3]University of Illinois at Chicago, Department of Biological Sciences, Chicago, Illinois, United States. [4]Rush University Medical College, Chicago, Illinois, United States

Introduction

Total knee arthroplasty (TKA) is increasingly performed in younger patients who maintain higher functional demands. Biomechanics are central to their management, yet no in vivo data exist to guide return-to-sport decisions for individuals under 60. The objective of this study was to characterize gait kinematics and kinetics in young patients (≤60 years) and older patients (>60 years) treated with TKA and to compare them with healthy controls.

Methods

Eighty-eight knees from a motion analysis database were evaluated: older TKA (n = 50), young TKA (n = 21), and healthy controls (n = 17). All TKA procedures were performed at a single institution by fellowship-trained surgeons. Gait analysis was completed using a marker-based three-dimensional motion capture system and force plates. Primary outcomes included knee joint kinematics and kinetics. Statistical non-parametric mapping was used to compare groups across the gait cycle. Post hoc pairwise SnPM t-tests with permutation inference and Bonferroni correction addressed multiple comparisons. Significance was set at $p<0.05$.

Results

Knee extension moments (%BW·ht) were substantially higher in young patients. At initial contact, young patients demonstrated 1.4 ± 1.4, which was roughly five times higher than older patients (0.2 ± 0.8) and four times higher than controls (0.3 ± 0.8, $p < 0.05$) (Fig. 1). During terminal stance, young patients showed 0.5 ± 0.6 compared with 0.2 ± 0.5 in older patients and 0.0 ± 0.3 in controls ($p < 0.05$). Young individuals also walked with greater

varus alignment throughout the gait cycle (3.2 ± 7.8°), while controls (–7.0 ± 4.3°) and older patients (–3.6 ± 5.8°) demonstrated valgus alignment. No additional significant differences in knee kinetics or kinematics were detected.

Discussion

This study provides the first in vivo gait analysis focused on young TKA recipients. These patients showed elevated knee extension moments and persistent varus alignment, both of which increase tibiofemoral loading. Such loading patterns raise concern for long-term implant durability and may influence return-to-sport decisions. Interventions that reduce excessive extension moments and varus alignment should be prioritized to support implant longevity and allow young, high-demand individuals to safely resume higher levels of activity.

Images (Optional)

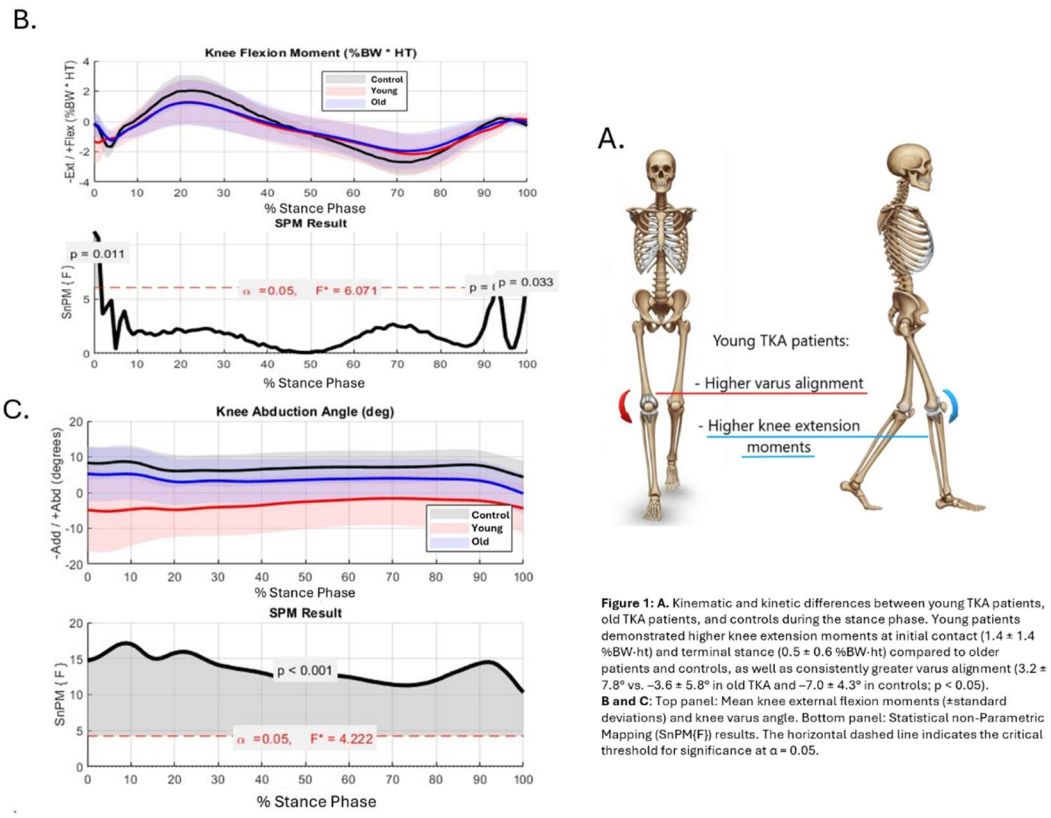

Figure 1: A. Kinematic and kinetic differences between young TKA patients, old TKA patients, and controls during the stance phase. Young patients demonstrated higher knee extension moments at initial contact (1.4 ± 1.4 %BW·ht) and terminal stance (0.5 ± 0.6 %BW·ht) compared to older patients and controls, as well as consistently greater varus alignment (3.2 ± 7.8° vs. –3.6 ± 5.8° in old TKA and –7.0 ± 4.3° in controls; $p < 0.05$). **B and C**: Top panel: Mean knee external flexion moments (±standard deviations) and knee varus angle. Bottom panel: Statistical non-Parametric Mapping (SnPM{F}) results. The horizontal dashed line indicates the critical threshold for significance at $\alpha = 0.05$.

3D Modelling Approach to Optimize Mini-Plate Configurations for High Predicted Bone Union Propensity for Mandibular Reconstruction Surgery

Ms. Cassidy Tizzard BASc, Mr. Hamidreza Aftabi PhD Candidate, Dr. John E. Lloyd, Dr. Eitan Prisman, Dr. Sidney Fels, Dr. Antony Hodgson

University of British Columbia, Vancouver, British Columbia, Canada

Introduction

Mandibular reconstruction is essential for restoring form and function of the jaw following tumor-related resection by replacing the removed segment with a donor bone graft (typically the fibula). Achieving bony union is critical; however, mechanisms affecting union rates remain poorly understood. In recent work, Aftabi et al. used a biomechanical Finite-Element simulation of the chewing cycle to demonstrate that changes in bone cut angle significantly alter predicted bone union propensity (BUP) based on strain-energy-density-based metrics (SED) [1].

Methods

We built on this proof-of-concept study by using the same 3D biomechanical modeling framework to evaluate the effect of mini-plate configuration on BUP. This study consisted of three stages: plate design, virtual reconstruction, and biomechanical simulation using the model developed by Aftabi et al. [2]. 2-hole mini-plates were designed in SolidWorks and positioned at high, middle and low placements on a body (B) defect reconstruction segment. Reconstruction was done using mandible and fibula CT segmentations which were imported into the Artisynth biomechanical modeling package to virtually reconstruct the mandible [3]. Chewing forces were applied to the reconstruction model, and bone healing was assessed using the resulting SED at each bone interface. Bone healing is likely to occur when SED exceeds a certain threshold, based on remodeling principles [1]. BUP was therefore defined as the percentage of elements with a normalized SED above this threshold.

Results

Figure 1 shows the predicted BUP for the left- and right-side mandible-fibula interfaces over one chewing cycle. Preliminary results show a ~6% difference in apposition (BUP) across the 3 configurations analyzed.

Discussion

These results demonstrate that plate placement affects predicted BUP, with results showing that lower placement configurations increase predicted BUP. We hypothesize that this approach, once generalized and validated, could be used to optimize not only plate placement, but also a broader range of surgical decisions including plate type and bone cut angle, to ultimately improve bone union outcomes in mandibular reconstruction.

Images (Optional)

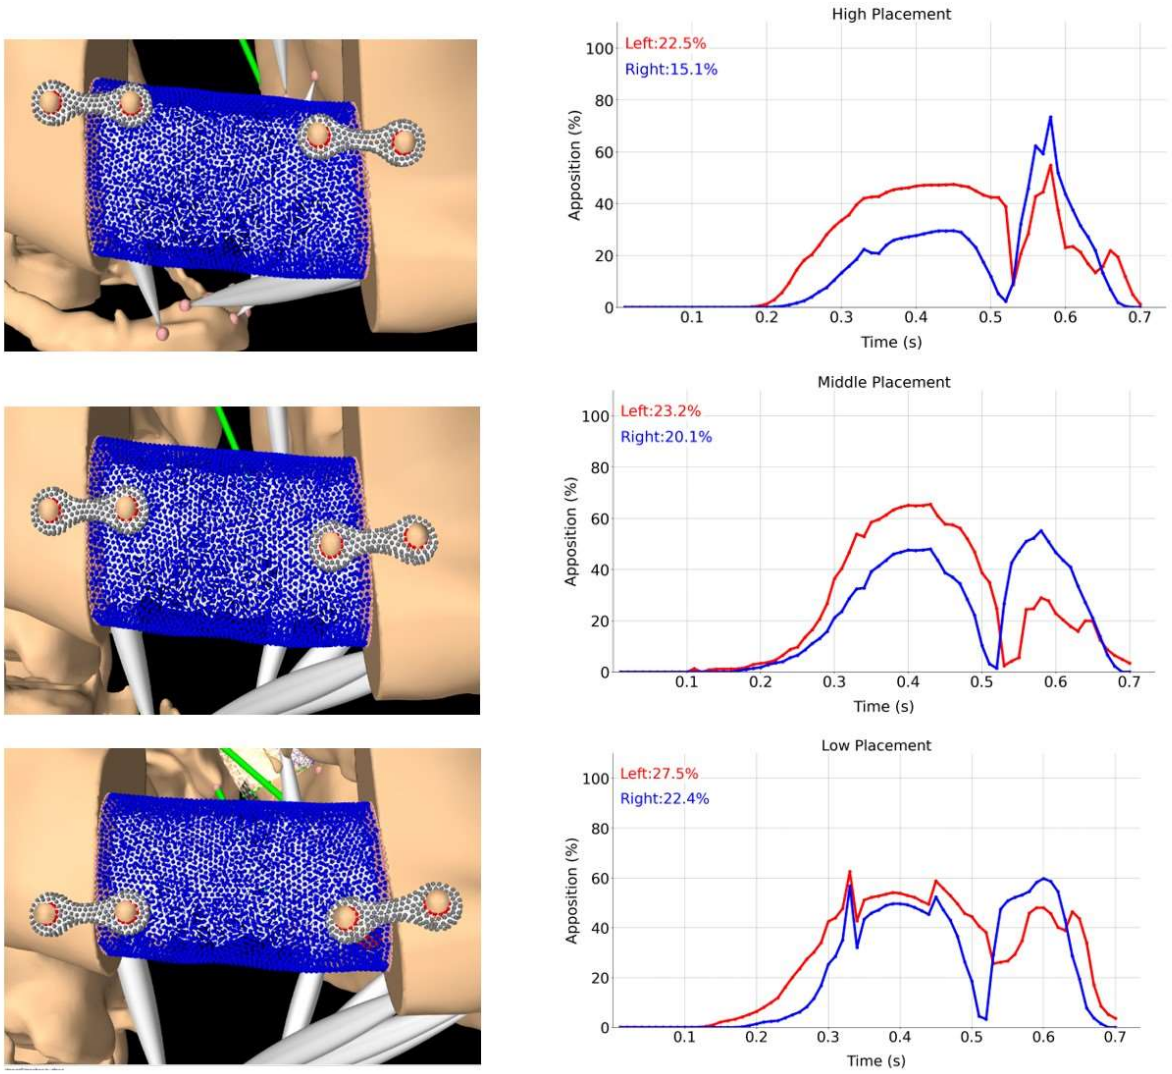

Figure 1: ***BUP Across Mini-Plate Configurations:*** *This figure shows the resulting BUP for the left and right-side mandible-fibula interfaces over one chewing cycle for high, middle, and low plate placements. The values at the top left corner of each plot are the average BUP (apposition %) for each interface.*

Biomimetic Meninges-On-a-Chip to Model Cerebrospinal Fluid Drainage and Subarachnoid Space Solute Exchange at the Temporal Bone Ear–Brain Interface in Hearing Loss and Dementia

Dr Giorgia Pistelli[1], Prof Federica Boschetti[1], Prof Claudio Conci[1], Prof Carmen Giordano[1], Prof Emanuela Jacchetti[1], Prof Manuela T Raimondi[1], Dr Diego Albani[2], Dr Simone Perottoni[1]

[1]Department of Chemistry, Materials and Chemical Engineering "Giulio Natta", Politecnico di Milano, Milan, Lombardy, Italy. [2]Department of Neuroscience, Istituto di Ricerche Farmacologiche Mario Negri IRCCS, Milan, Lombardy, Italy

Introduction

Hearing loss (HL) is a major risk factor for dementia [1]. Impaired cerebrospinal fluid (CSF) clearance of metabolic waste has been associated with both HL and cognitive impairment [2]. Although cochlear fluids communicate with CSF through narrow aqueducts in the temporal subarachnoid space (SAS), their fluid-dynamic properties and their role in solute exchange remain poorly characterized. To address this gap, the EAR2BRAIN project is developing patient-specific in silico and in vitro models of the inner-ear/brain fluidic interface. Here, we present a biomimetic meninges-on-a-chip reproducing SAS geometry, pulsatile CSF flow, intracranial pressure, and real-time molecules transport analysis in the cochlear–brain communication relevant to HL and neurodegeneration

Methods

A multi-chamber organ-on-a-chip, with a collagen-based parenchyma model, sustaining CSF-like flow and intracranial pressure (ICP)-like pulsatility was fabricated by transparent high-resolution SLA 3D printing. FITC-dextran tracers (4–500 kDa) will quantify solute transport via fluorescence microscopy and spectrofluorimetry. A cochlear aqueduct-like microchannel will be connected to the SAS channel.

Results

Collected design parameters from clinical literature led to the fabrication of the SAS–parenchyma prototype (Figure 1) enabling stable confinement of a collagen hydrogel. The system represents a simplified 1 mL flat portion of the SAS. Tracer experiments demonstrated diffusion from the hydrogel toward the SAS outlet, confirming measurable

inter-compartment transport. Anatomical data provided realistic operating ranges for CSF pressures, volumes, and flow rates.

Discussion

To date, no studies have quantitatively modeled pressure or solute exchange at the inner-ear/brain fluidic interface. While still simplified, this SAS-on-a-chip establishes the foundation for a future patient-specific biomimetic model, enabling targeted investigations of how pressure, pulsatility, and molecular size shape solute transport, to clarify fluid communication in the temporal bone under conditions characteristic of HL, impaired CSF drainage, and neurodegeneration.

Lower Extremity Joint Loading During Squatting Differs Across Hemophilic Arthropathy Severity in Persons with Hemophilia

Dr. Danielle Siegel PhD[1], Mr. Caden Robertson MS[1], Dr. Joanna Roybal PT, DPT[1], Mr. Joseph Mah[1], Dr. Laura Singer-Fox PT, DPT[1], Ms. Niamh Mah[1], Dr. Sharon Funk PT, DPT[1], Dr. Marilyn Manco-Johnson MD[1], Dr. James Carollo PhD[2], Dr. Brecca Gaffney PhD[1,3], Dr. Beth B. Warren MD[1,2]

[1]University of Colorado Anshutz, Aurora, Colorado, United States. [2]Children's Hospital Colorado, Aurora, Colorado, United States. [3]University of Colorado Denver, Dever, Colorado, United States

Introduction

Persons with hemophilia (PwH) experience recurrent joint bleeding that can lead to progressive hemophilic arthropathy (HA), which shares characteristics with both osteoarthritis and inflammatory joint disease. While previous work has identified altered joint mechanics in the general PwH population compared to healthy individuals, it remains unclear how joint loading changes across HA severity. Characterizing these differences may reveal biomechanical adaptations associated with disease progression. Therefore, this study aimed to determine how hip, knee, and ankle joint loading during bilateral squatting differs across HA severity in PwH compared to healthy individuals.

Methods

Motion capture data were collected from eighteen PwH with mild (6M, age: 30.3±7.0y), moderate (5M/2F, age: 38.1±16.4y), and severe (5M, age: 30.2±7.3y) HA and seven healthy controls (6M/1F, age: 23.7±5.4y) during a bilateral squat to a self-selected depth. Joint reaction forces (JRF) at the hip, knee, and ankle were estimated in OpenSim and the JRF impulse was calculated to represent the total joint load for each limb over the squatting task. HA severity was classified using the Hemophilia Joint Health Score (HJHS), a validated physical exam where higher scores indicate greater impairment. For PwH, the JRF impulse from the more affected limb (determined by HJHS) were compared to the mean of both limbs in controls. Group differences were evaluated using Cohen’s d effect size.

Results

Knee and hip JRF impulse decreased with increasing HA severity, while no differences in ankle JRF impulse were observed (Figure 1).

Discussion

PwH exhibited reduced knee and hip joint loading during squatting with increasing HA severity. These differences highlight that HA severity-specific adaptations emerge with disease progression, reinforcing the importance of studying PwH in subgroups rather than aggregating the population, as important biomechanical differences may be obscured. Monitoring joint loading across HA severity may help identify when offloading begins to accelerate functional decline and increases bleeding risk. Additionally, squatting is a knee-dominant task, likely explaining why differences were most pronounced at the knee and hip, while ankle loading remained unchanged. Future work should examine more ankle-dominant tasks given the ankle's high incidence of bleeding events, to further understand joint loading across HA severity.

Images (Optional)

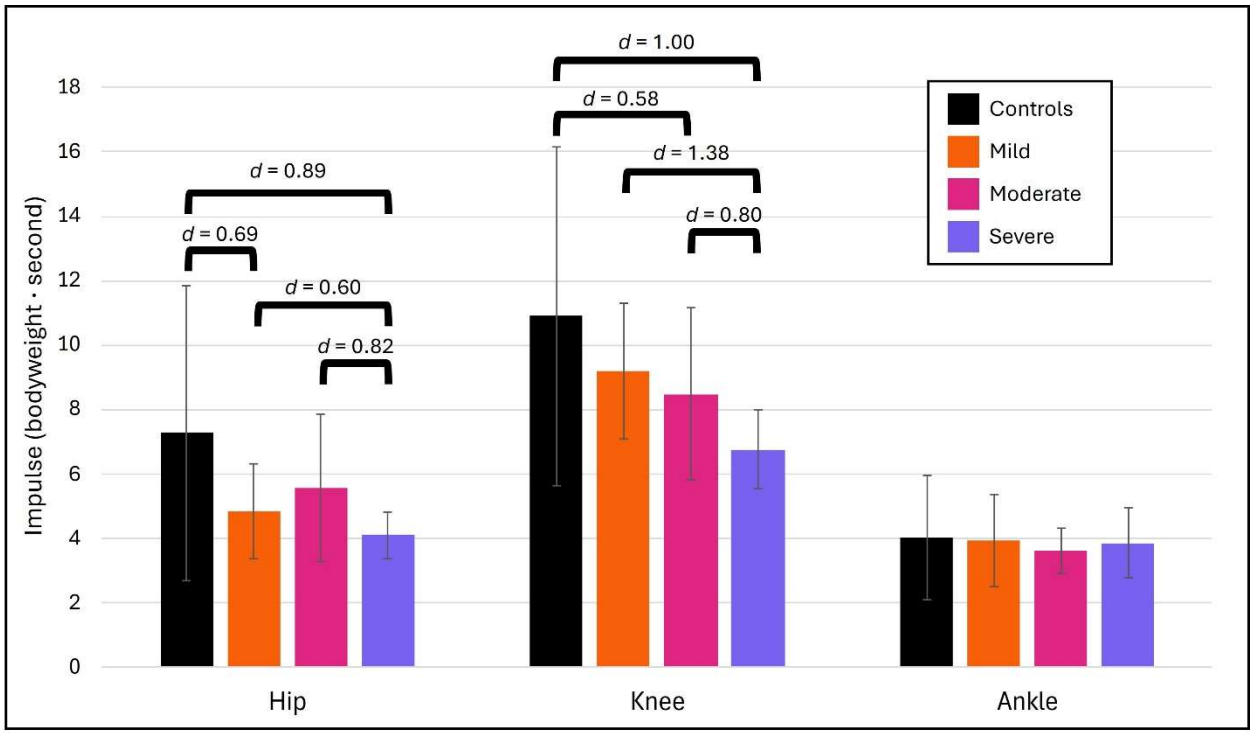

Figure 1: Impulse of the joint reaction forces (mean and standard deviation) at the hip, knee, and ankle representing the total load over time during a bilateral squatting activity for healthy controls compared to persons with hemophilia with mild, moderate, and severe hemophilic arthropathy. Cohen's d effect size is indicated for comparisons with a medium ($0.5 \geq d < 0.8$) and large ($d \geq 0.8$) difference.

Sweep-Frequency Impedance (SFI) for Middle-Ear Pathology Classification With Machine Learning

Dr. Michio Murakoshi[1], Dr. Teruki Toya[2], Dr. Di Zhou[1], Dr. Manabu Inaba MD[3], Dr Hisashi Sugimoto MD[3]

[1]Kanazawa University, Kanazawa, Ishikawa, Japan. [2]University of Yamanashi, Kofu, Yamanashi, Japan. [3]Kanazawa University Hospital, Kanazawa, Ishikawa, Japan

Introduction

Tympanometry is widely used to assess conductive hearing loss although its diagnostic accuracy is limited. Our group has developed a sweep frequency impedance (SFI) meter that measures middle-ear dynamic characteristics with a swept-frequency stimulus and demonstrated its clinical utility [1]. However, the required 10-second stimulus posed challenges for older adults and infants. This study aimed to implement a shorter stimulus and evaluate a machine-learning approach for classifying middle-ear pathologies [2,3].

Methods

Data were collected from 42 ears of 25 normal-hearing adults, 18 ears of 14 patients with ossicular fixation and 10 ears of 10 patients with ossicular separation. A 2-second chirp stimulus was delivered and recorded sound pressure at the ear canal was Fourier-transformed to obtain a sound-pressure-level (SPL) curve (Fig. 1). From this curve, RF (resonance frequency) and ΔSPL (related to tympanic membrane vibration amplitude) were extracted and plotted in two dimensions. Probabilistic distances from class-specific distribution centers were used to compute P_F (fixation index) and P_S (separation index), enabling classification of middle-ear status (Fig. 2).

Results

Tympanometry was evaluated using static compliance (SC), while SFI classification used P_F and P_S. For tympanometry, sensitivity, specificity and AUC for fixation were 0.61, 0.41 and 0.50; for separation, 0.88, 0.92, and 0.88 (Fig. 3). For SFI, fixation values were 0.64, 0.88, and 0.86, and separation values were 1.0, 1.0, and 1.0. These findings show that SFI outperformed tympanometry in identifying middle-ear disorders (Fig. 4).

Discussion

SFI provided more accurate classification than tympanometry, particularly for fixation. Previous wideband tympanometry (WBT) studies reported AUCs of 0.95 and 0.88 under different pressure conditions [4], and 0.81 in another study [5]. Despite measurements being made at ambient pressure, SFI achieved comparable performance using only two features, RF and ΔSPL. The reduced 2-second stimulus and machine-learning framework enabled efficient and accurate assessment of middle-ear conditions, demonstrating diagnostic capability similar to WBT.

A 3D Goal Equivalent Manifold Approach to Detecting Season-Long Post-Concussion Motor Deficits in Female Soccer Players

Dr. Xiong Zhao, Mr. Reza Rahimi, Dr. Allison Clouthier, Dr. Janie Cournoyer, Dr. Ryan Graham

University of Ottawa, Ottawa, Ontario, Canada

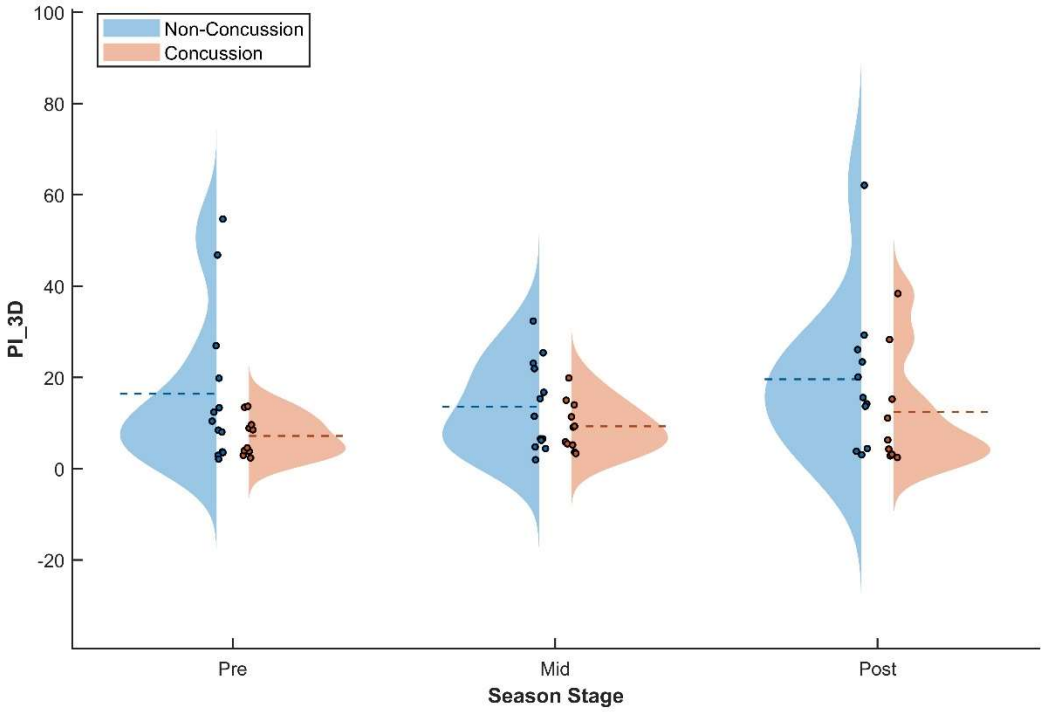
Introduction

Athletes with a history of concussion often display lingering motor control alterations that are not captured by conventional clinical evaluations. Studies show that these athletes are at a higher risk of sustaining musculoskeletal injuries. However, the mechanisms underlying these persistent deficits remain unclear. Traditional biomechanical analyses typically examine joint angles or peak forces, overlooking how variability is structured. The Goal-Equivalent Manifold (GEM) framework decomposes variability into goal-relevant and goal-equivalent components, but most applications are two-dimensional and exclude timing error, a key component of rhythmic tasks. This study extends GEM into three dimensions, displacement, velocity and timing error, to evaluate whether a 3D approach can capture motor control differences between athletes with and without concussion history.

Methods

Twenty-five female varsity soccer players (11 with history of concussion) performed 35 metronome-paced squats during pre-, mid-, and post-season sessions. Whole-body kinematics were captured using markerless motion capture. The center of mass served as the primary execution variable. In 2D GEM, the goal was represented as $f(D,V) = D/V - T_{target} = 0$. To incorporate temporal precision, the 3D goal was defined as $f(D,V,T_{err}) = D/V - (T_{target} + T_{err}) = 0$. A task-consistent operating point was calculated for each athlete, and variability was decomposed into goal-relevant (delta_P) and goal-equivalent components (delta_T1, delta_T2). A 3D performance index (PI_3D) was computed as $sqrt(std(deltaT1)^2 + std(delta_T2)^2) / std(delta_P)$. Group × Time effects were evaluated using Generalized Estimating Equations.

Results



Timing error contributed 12.2% of total variability across the season. No significant group differences were detected in 2D metrics. In contrast, athletes with concussion history exhibited consistently lower PI_3D as shown in Figure 1 (pre: 7.17 vs 16.40; mid: 9.28 vs

13.59; post: 12.44 vs 19.60), with a significant main effect of concussion (p = 0.017). These findings align with prior evidence of persistent neuromuscular and sensorimotor deficits following concussion.

Discussion

The 3D GEM framework demonstrated its sensitivity for identifying subtle, persistent motor control alterations. Incorporating spatio-temporal variability into athlete monitoring may enhance return-to-play decisions and guide targeted neuromuscular rehabilitation.

Introduction

Adults rarely adopt unilateral skipping, yet astronauts spontaneously adopted this gait on the Moon, reportedly due to improved stability [1, 2]. Future space missions will require mobility preservation in lower gravity [3], raising the question of why hypogravity enables otherwise latent gait solutions. Gravity affects mechanical loading and sensory input. Of the various sensory systems, proprioception – which provides information regarding limb position, movement and load – is a promising candidate for the control of gait modes. Here, we combined simulated hypogravity experiments in humans and transgenic mice to investigate whether proprioception is necessary for the emergence of gravity-dependent gait modes.

Methods

Twelve adults performed treadmill walking, skipping, and running at 1.00 g and under simulated Mars (0.38 g) and Moon (0.17 g) gravity using an elastic unloading system [3]. Muscle synergies, composed of time-dependent muscle activation patterns and time-invariant muscle weights, were extracted from twelve lower limb muscles using non-negative matrix factorisation [4]. Eight adult transgenic mice [5] were tested with a similar setup at 1.00 g and 0.17 g; four underwent selective ablation of muscle spindles and Golgi tendon organs. Locomotion was recorded with high-speed videography and analysed using markerless motion capture and principal component analysis. All analyses employed linear mixed-effects models.

Results

In each human gait mode, reduced gravity affected the muscle synergy temporal activation patterns, whereas the time-invariant muscle weights remained largely unchanged. Skipping and running showed similar activation patterns, but different order of otherwise similar muscle weights. Control mice exhibited a consistent hindpaw-unloading strategy at 0.17 g, forming a distinct state-space cluster that, following proprioceptive ablation, was absent.

Discussion

Our findings suggest that the nervous system possesses latent gait strategies that emerge when gravitational loading changes. The data indicate that proprioception acts as a gateway to awaken latent gait modes. As we venture into environments with reduced gravity, it will be fundamental to understand how sensory feedback unlocks these hidden strategies to predict how locomotion adapts far from Earth.

Muscle Activation During Hypogravity Running

Ms. Lina Yu BN, RN, Ms. Hannah G. Yesuf BN, RN, Mr. Dawson S. Sheehan BN, RN, Dr. Jared R. Fletcher PhD

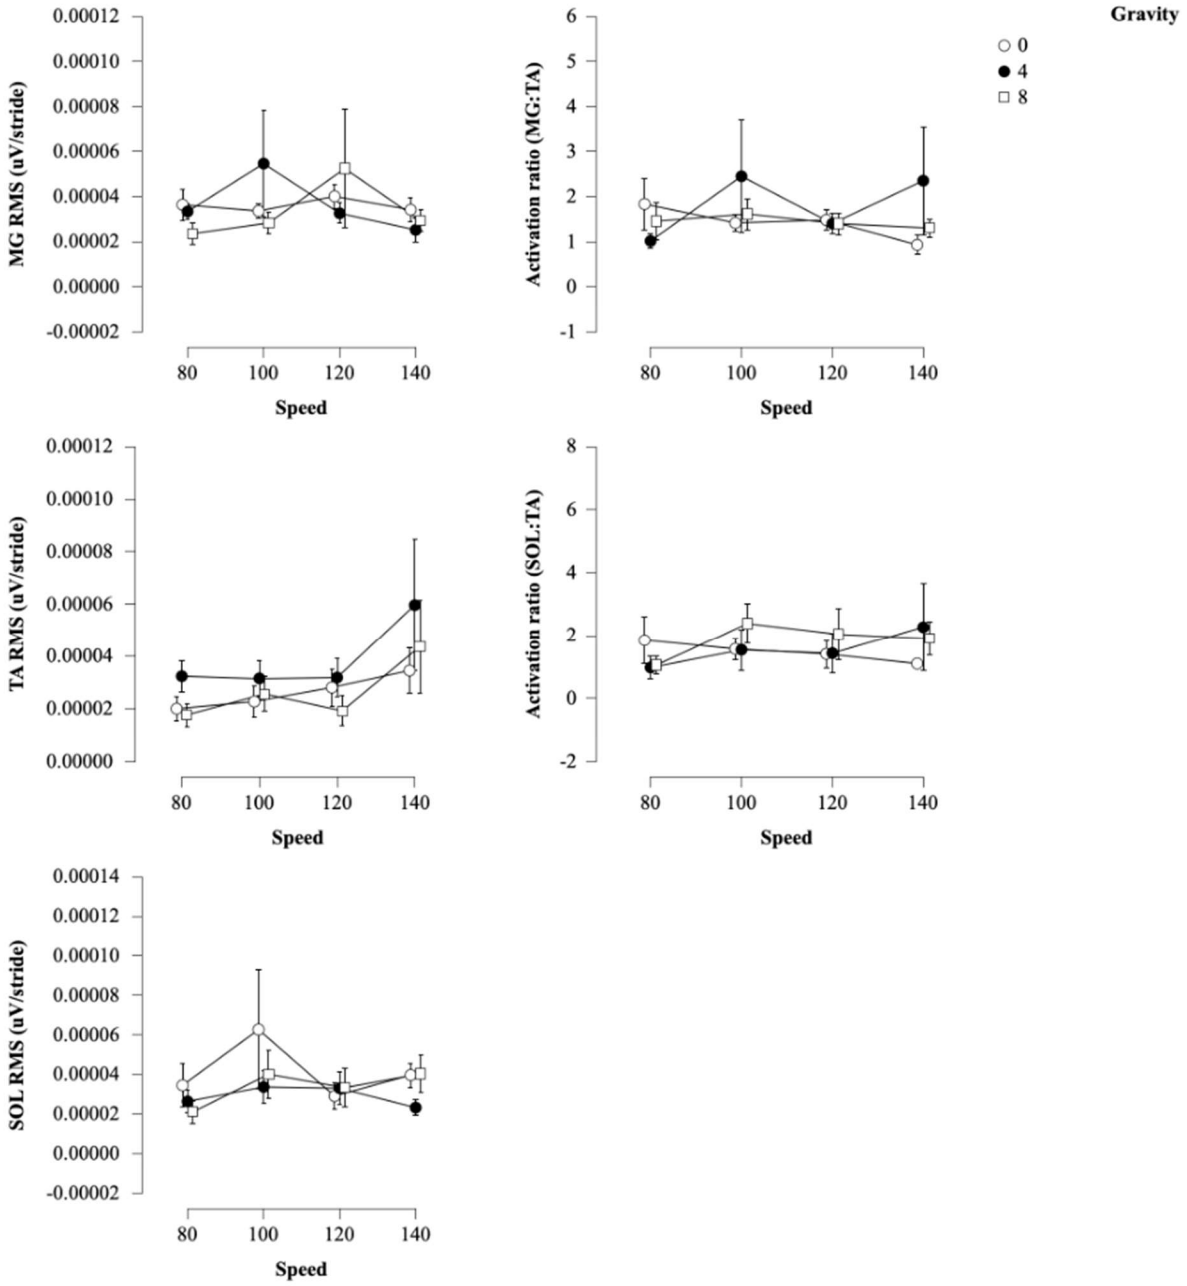
Mount Royal University, Calgary, Alberta, Canada

Introduction

Running in hypogravity reduces lower limb muscle activity because less force is required to support and propel the reduced body weight [1]. The energy cost of running (E_{run}) is also reduced, together or independent of changes in joint kinematics and lower-limb muscle (co)activations. This study therefore examined the relationship between E_{run} and muscle (co)activation as a function of running speed and body weight unloading.

Methods

Sixteen healthy adults ran at 80%, 100%, 120%, and 140% of their preferred running speed under three simulated gravity levels (100%, 86%, and 82% body weight) using a *Lever Up* harness system. Ultrasound imaging of the gastrocnemius medialis (GM) was used to quantify MG shortening, while surface EMG recorded and quantified average integrated EMG per stride (iEMG/stride) from the MG, soleus, tibialis anterior, and fibularis longus.



Results

CoT decreased significantly with increasing running speed ($p< 0.001$) and was further reduced with greater unloading. Across all muscles, iEMG/stride was similar across all speeds and gravity levels (all $p>0.09$, Figure 1). MG:TA coactivation also showed no significant effects of speed ($p=0.697$; gravity: $p=0.540$; speed x gravity: $p=0.425$), and SOL:TA coactivation similarly demonstrated no significant interactions ($p= 0.25$) nor main effects (speed: $p=0.122$; gravity: $p=0.638$).

Discussion

Despite significant reductions in E_{run} with speed and unloading, lower limb muscle activation and co-activation remained unchanged. suggesting changes in active muscle volume of the lower limbs is not a primary factor in an elevated metabolic cost. Rather, neuromuscular control is preserved during unloaded running which may help guide exercise countermeasures by emphasizing mechanical rather than neural factors when targeting energy expenditure during prolonged space flight.

Do Astronauts Need to Run Faster? Achilles Tendon Loading Across Running Speeds and Simulated Reduced Gravity

Ms. Hannah G. Yesuf BN, RN, Mr. Dawson S. Sheehan BN, RN, Ms. Lina Yu BN, RN, Dr. Jared R. Fletcher PhD

Mount Royal University, Calgary, Alberta, Canada

Introduction

Exercise is used to limit rapid musculoskeletal and tendon deconditioning during prolonged space flights [1]. The Achilles tendon (AT) stores and returns elastic energy during running, contributing to a low metabolic cost, but elastic energy storage incurs a metabolic cost [2]. It remains to be seen how AT elastic energy storage and the accompanying muscle metabolic cost are affected by unloading. Our objective was to estimate AT elastic energy storage in relation to muscle metabolic cost across running speeds and gravities.

Methods

16 participants (5 male, 11 female) completed running trials on a *Lever Up* unloading system under three simulated gravity levels (100%, ~86%, and ~82% body weight), and four speeds (80%, 100%, 120%, and 140% of preferred running speed). AT force during stance was estimated from vertical ground reaction forces and location using a force-instrumented insole [3]. AT elastic energy was calculated from AT force and a fixed AT stiffness [4]. Metabolic cost was measured via indirect calorimetry, and medial gastrocnemius (MG) positive muscle work (W^+) and power (P^+) was calculated from muscle force estimates and MG fascicle shortening (ΔL_f) using ultrasonography, respectively.

Results

Peak AT force (and thus AT elastic energy storage) increased significantly with running speed ($p < 0.001$) and decreased with increased body weight unloading ($p = 0.043$). MG ΔLf and W^+ were not altered by speed ($p>0.48$) or gravity ($p>0.18$) whereas P^+ was significantly lower during intermediate unloading ($p<0.05$).

Discussion

These findings support that running speed is the primary stimulus for Achilles tendon loading. Thus, faster running speeds are required to achieve similar unloaded AT forces and maintain tendon health in reduced gravity. In contrast, the MG muscle is placed under similar mechanical demands across hypogravity levels. The nonlinear pattern across

unloading levels may reflect different neuromuscular strategies as effective body weight decreases.

[10]University of Exeter, Exeter, England, United Kingdom

Introduction

Humans typically walk or run, but occasionally employ unilateral skipping, an asymmetric gait combining double-support and aerial phases. Adults rarely skip on Earth, yet astronauts frequently did it on the Moon. Why do humans avoid skipping on Earth whereas readily adopt it in hypogravity? Skipping may reduce lower-limb muscle activation [1] and improve stability [2], but such benefits appear offset on Earth by its high metabolic cost [3]. In hypogravity, the metabolic cost of skipping decreases – even without wearing spacesuits [3] – making it more favourable. Thus, we tested the hypothesis that hypogravity alone reduces joint- and limb-level mechanical work during skipping, and compared these effects to those during walking and running.

Methods

Five adults (3 females; 31.2±6.2 years; 61.4±5.1 kg) skipped at 1.39, 1.94, and 2.50 m/s, walked at 1.39 m/s and ran at 2.50 m/s on an instrumented treadmill. Participants ambulated at Earth (1.00g), Mars (0.38g) and Moon (0.17g) gravities simulated via body-weight suspension [3], while 24 cameras tracked 68 bilateral markers. Inverse kinematics and dynamics were computed in OpenSim 4.4 using a scaled Rajagopal 2016 model. Instantaneous joint power was calculated from joint moments and angular velocities; stride-averaged positive hip, knee, and ankle powers were summed to obtain total power.

To allow comparisons across gaits and speeds, mass- and distance-normalised work (W_{mech}) was calculated from total limb power divided by speed.

Results

Gravity modulated the magnitude and between-limb distribution of W_{mech}. At Earth gravity, skipping's W_{mech} was greater than walking; although smaller than running, W_{mech} was asymmetrical between skipping limbs. As gravity decreased, W_{mech} declined more in skipping and running than walking, and work was evenly generated between skipping limbs (Fig.1).

Discussion

As gravity decreases, the mechanical demands of skipping approach those of walking and running. On Earth, skipping's benefits are offset by its high work demands. However, at Moon gravity, generated work converged across gaits and between skipping limbs, allowing humans to exploit skipping's biomechanical advantages without energetic penalties.

Cost of Transport in Reduced Gravity: Optimizing Astronaut Exercise Prescriptions

Mr. Dawson Sheehan BN, Ms. Lina Yu, Ms. Hannah Yesuf, Dr. Jared Fletcher PhD

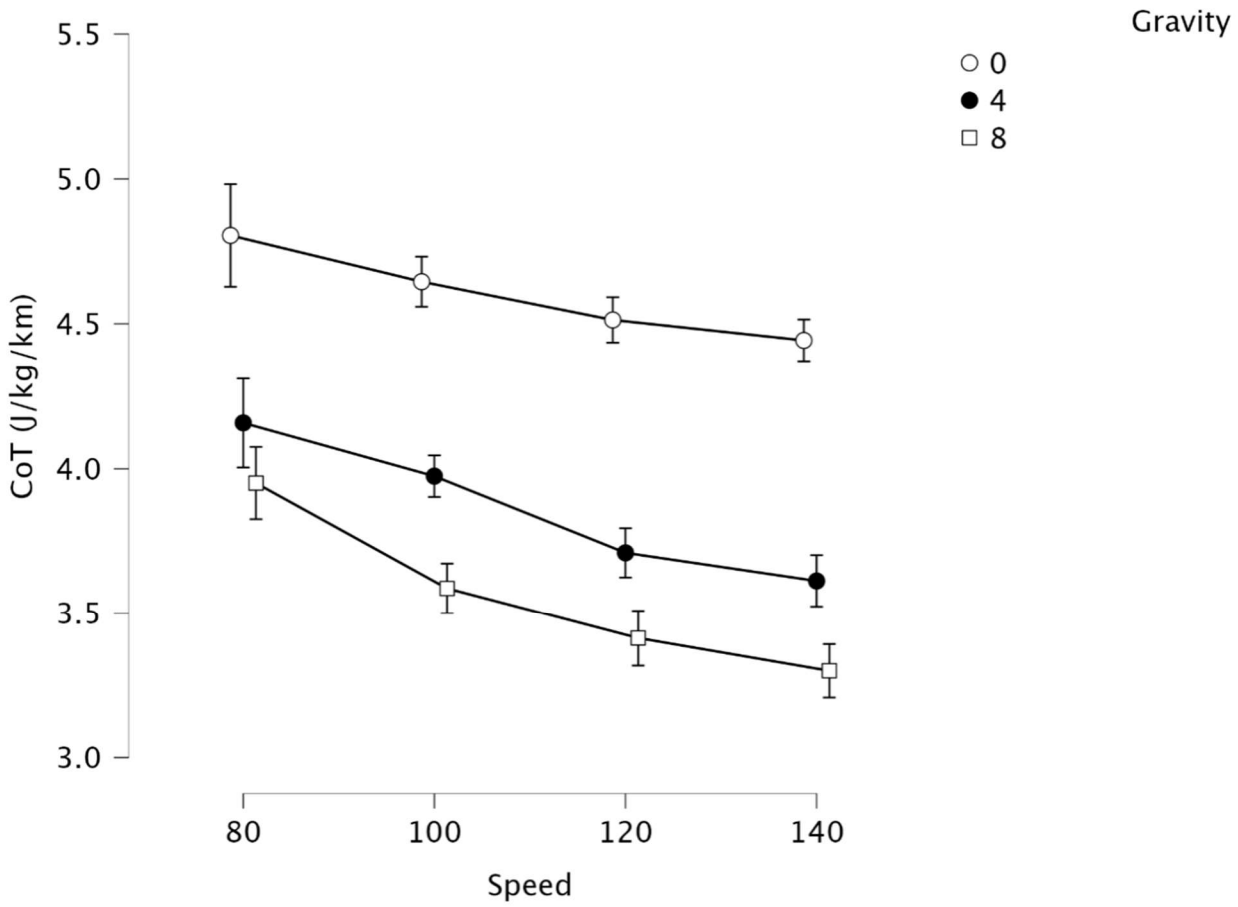
Mount Royal University, Calgary, Alberta, Canada

Introduction

There is a curvilinear relationship between cost of transport (CoT) and running speed [1]. In simulated microgravity, unloading reduces CoT, because the cost to support body weight is reduced [2]. Thus, in reduced gravity, a higher than optimal running speed is required to induce a similar CoT as on Earth. The energetics and mechanics of running at faster speeds in simulated microgravity has not yet been explored.

Methods

16 trained runners ran at 80%, 100%, 120%, and 140% of their self-selected (preferred) running speed under three simulated gravity levels (100%, ~86%, and ~82% body weight) using a series of pulleys to reduce body weight (Lever Up, Lever Movement, Boulder CO, USA) . Each condition consisted of a 6-minute run with 2-minute rest. CoT was calculated during the steady-state via indirect calorimetry. Gait kinematics and kinetics were calculated from in-shoe force sensors (LoadSol, Novel GmbH, Munich, DEU).



Results

CoT decreased significantly with increasing running speed ($p < 0.001$) and was further reduced with greater unloading ($p < 0.001$ Figure 1). Stance time increased with speed ($p < 0.001$) but decreased with unloading ($p < 0.001$); stride frequency increased with speed ($p < .001$) and decreased with unloading ($p < 0.001$); and duty cycle (%) increased with both speed and unloading ($p < 0.001$). Impulse per stride decreased significantly as unloading increased ($p < 0.001$).

Discussion

CoT decreased with increasing running speed and greater unloading, making locomotion more economical in simulated hypogravity. A lower CoT may reduce the metabolic stimulus needed to maintain aerobic capacity and cardiorespiratory fitness during spaceflight. A lower CoT is largely attributed by the reduced cost of generating force against body weight in simulated hypogravity.

IMU-Based Measures of Trunk Movement Variability Are Not Sensitive to Fatigue in Female, Varsity Rowers During a 2000m Rowing Time-Trial

Dr Matthew Slopecki[1], Mr Paul Lucas Spagnuolo[1], Dr Julie N. Côté[2]

[1]McGill University, Montreal, Quebec, Canada. [2]University of Ottawa, Ottawa, Ontario, Canada

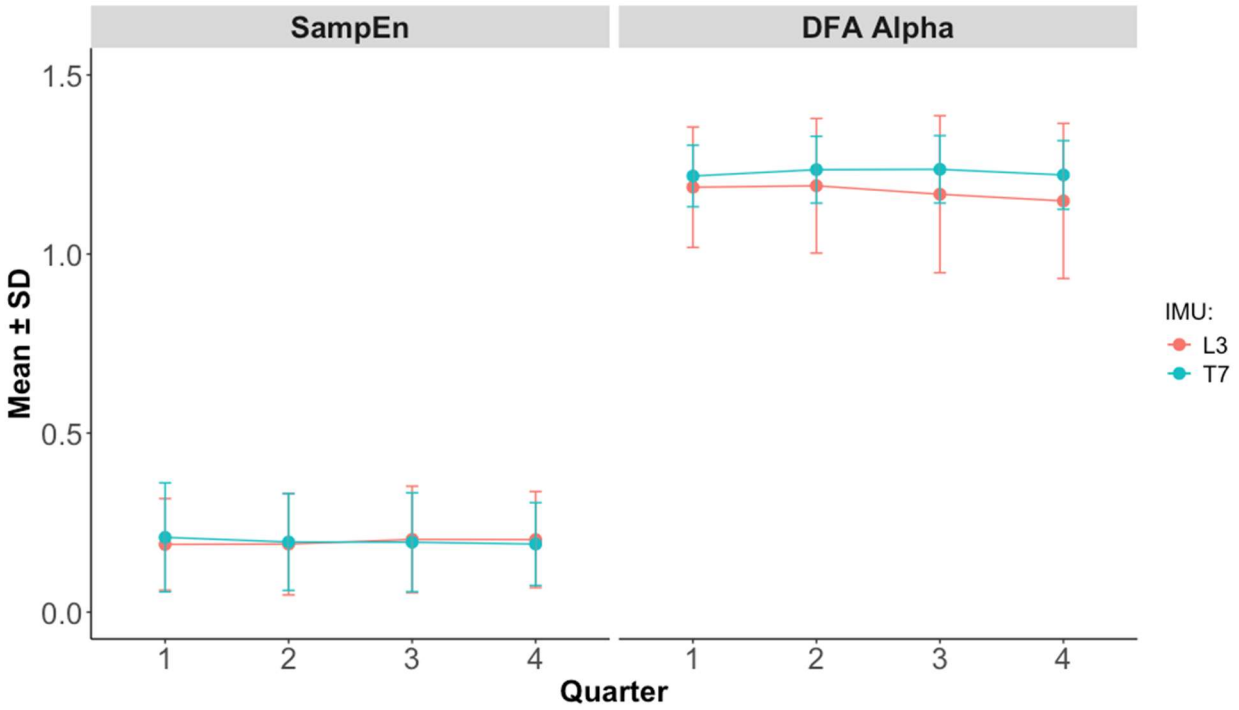
Introduction

Female rowers experience high lifetime incidence rates of back pain [1]. Furthermore, females have been shown to have greater electromyographical indices of fatigue during a 2000m rowing ergometer time trial (2kTT) at the thoracic and lumbar erector spinae muscles [2]. However, it is unclear if this leads to measurable effects on trunk movement patterns. Increases in cycle-to-cycle movement variability, using Sample Entropy (SampEn), are common compensatory strategies to maintain cyclical movement performance when fatigued [3]. Furthermore, detrended fluctuation analysis (DFA) can quantify long-term power correlations, or coordinated kinematic patterns. If these indices are sensitive to fatigue, affordable wearable systems could detect the onset of fatigue-related trunk kinematics. The aim of this study was to determine if changes in SampEn and DFA were observed in trunk kinematics during a 2kTT in competitive female rowers.

Methods

6 female collegiate (U-Sports) rowers completed a 2kTT. Inertial measurement units (Xsens Dot; 120 Hz) were placed on T7 and L3 vertebrae. Tri-axial angular velocity data were collected. SampEn and DFA were applied to raw angular velocity signals in the sagittal plane at each quarter of the 2kTT. Two ANOVAs compared differences in 1) SampEn and 2) DFA Alpha between each quarter of the 2kTT. Bonferroni corrected significance was set to $P < 0.025$.

Results



Mean (± SD) SampEn and DFA Alpha values at T7 and L3 are presented in Figure 1. No main effects of Quarter were observed at T7 or L3 vertebrae for SampEn or DFA Alpha.

Discussion

Both thoracic- and lumbar-spine kinematic patterns showed low irregularity (SampEn) or high levels of long-term power correlations (DFA Alpha) in angular velocity patterns. No differences were detected across the 2kTT, including in the later phases where muscle fatigue has been observed [2]. As such, these variables were not sensitive indicators of

trunk-muscle fatigue during the 2kTT. Future work should explore alternative kinematic measures that better capture fatigue-related changes and identify injury-risk predictors.

Assessing Symmetry in Sweep Rowers: Comparison of Muscle Activation in Port, Starboard, and Bisweptual Female Collegiate Rowers on the Ergometer

Miss Madeleine Enns, Dr. Hunter Bennett

Old Dominion University, Norfolk, Virginia, United States

Introduction

Sweep rowing is an inherently asymmetrical activity. Research on sweep rowers' (a)symmetry on the ergometer is limited: one study among elite sweep rowers found asymmetric leg activation to be correlated to rowing side [1], while another found asymmetric back activation to be uncorrelated to side [2]. Symmetry on the ergometer among female collegiate rowers has not been assessed. Thus, the purpose of this preliminary investigation was to compare the muscle activation of port, starboard, and bisweptual female collegiate rowers on the ergometer.

Methods

Nine female collegiate rowers participated in this study: three port rowers, three starboard rowers, and three bisweptual rowers (with side allocation defined as greater than 75% of practice time on that side in the past two years). Each subject performed a 1000m-ergometer piece at 30 strokes per minute. Muscle activation was collected bilaterally via electromyographic (EMG) sensors on the rectus abdominis, external obliques, transverse abdominis, erector spinae, latissimus dorsi, and rectus femoris. Inertial measurement units (IMUs) were placed on upper extremities to visualize stroke phase. EMG signals were linear enveloped and normalized to the peak value recorded during warmup. Maximum voluntary contraction (MVC) was calculated during the stroke phase. Bilateral symmetry (right / left EMG) were compared using nonparametric t-tests ($alpha<0.05$).

Results

Bilateral asymmetry mean and standard deviation data are in Table 1. Despite rowing predominately on different sides, groups did not differ on symmetry index (all $p>0.05$) within this preliminary investigation. However, port rowers displayed greater left-side activation in the eternal obliques, transverse abdominis, erector spinae, and latissimus dorsi. Bisweptual and starboard rowers had a greater mix of asymmetry towards both right and left sides.

Discussion

This preliminary study did not find statistically significant differences in symmetry indexes in relation to rower's side. Nevertheless, asymmetry among all groups warrants further research with larger sample sizes, and investigating how to address female collegiate rower's muscle imbalances. Future studies should also consider repeating the data collection process on the water and analyzing symmetry in regards to a rower's years of experience.

Assessing the Effect of Inter-Athlete Spatiotemporal Coordination on Pairs Rowing Performance Times

Mr. Ian Doctor BSc (Honors), Mr. Daniel Brickman MSc, Miss Aurora Battis MSc, Mrs. Katie Bruggeling-Lavoie MEd, Dr. Shawn Beaudette PhD

Brock University, St. Catherines, Ontario, Canada

Mr. Ian Doctor

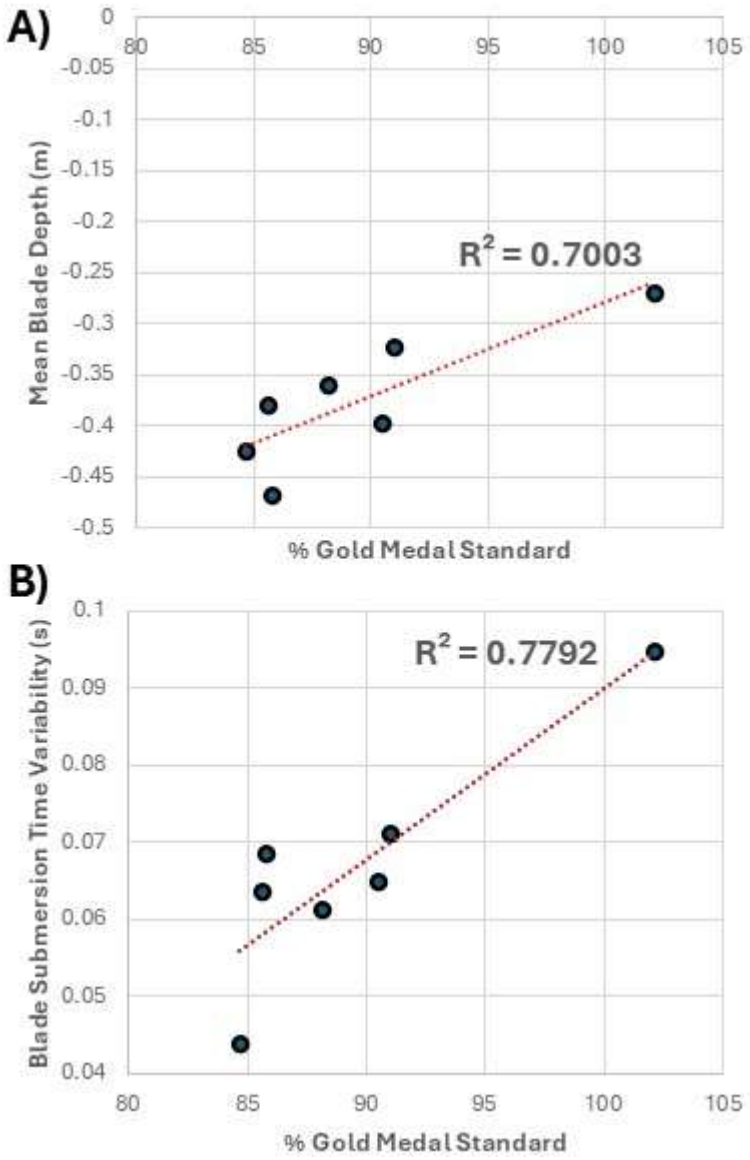
Introduction

Biomechanical analysis to maximize multi-athlete crew performance has been limited to use of force measurement devices with high potential error and poor reliability in intra-athlete contexts [1]. Prior research on inter-athlete coordination has utilized relative oar angles and subjective perception of coordination from athletes [2]. With the advent of 3D markerless motion capture, it is now feasible to analyze multiple athletes to assess the effect of inter-athlete spatiotemporal coordination on pair rowing performance times.

Methods

14 competitive rowers have so far been recruited (10M/4F); all are same-sex pairs with documented 2-kilometer race times on the Henley Rowing Course (Port Dalhousie, CAN). Pairs completed a 1-minute indoor rowing tank trial at race pace in matching pair combinations to the race data. Eight Miqus (Qualisys AB, SE) cameras captured concurrent video data for the duration of the trial. Post-processing utilized THEIA3D (Theia Markerless inc.), Visual3D (V3D LLC.), and MATLAB (v. R2025a MathWorks Inc.) to model and analyze the variability of oar kinematics and athlete center of mass, lower (ankle, knee, hip), and upper (shoulder, elbow, wrist) extremity joint and lumbar spine kinematics. 3D kinematics and movement timing variability were compared with on-water time trial data of 2-kilometer race segments for each athlete pair.

Results



Bivariate linear regression analysis compared on-water times with kinematic outcomes. Results were precented absolute and normalized to % Gold Medal Standard (%GMS) time for age, sex, and weight class. Significant results for normalized data were Mean Blade

Depth (MBD) (R^2=0.7003, p=0.004) [Fig1a] and Blade Submersion Time Variability (BSTV) (R^2=0.7792, p=0.008) [Fig1b].

Discussion

An increase in MBD is correlated with an increase in %GMS, alluding to full blade contact and engagement with the surface of the water being a strong indicator of performance. The significant relationship of BSTV to %GMS indicates potential presence of enhanced response to changes in stroke dynamics (i.e. ratio between drive and recovery phases), where faster pairs might adapt to tempo changes at critical stroke stages (blade entry to water, early drive phase) [1] within the sampled data more effectively than slower pairs.

Recognition of Front-Crawl Stroke Phases Using an Inertial Measurement Unit and Deep Learning

Master's Student Mathilde MONTEL[1,2], Assistant Professor Antoine BOUVET[1]

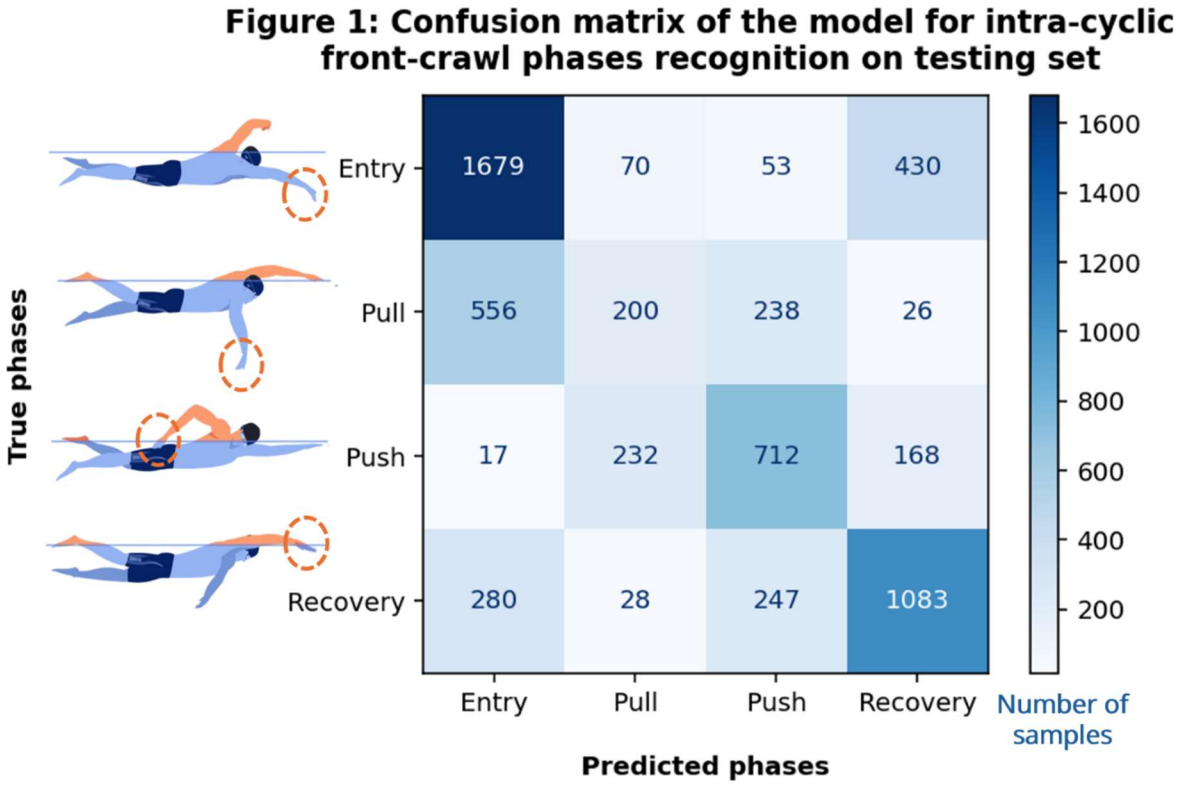
[1]M2S Laboratory (ENS Rennes/University of Rennes), Rennes, Bretagne, France. [2]ENS Rennes Sports Sciences & Physical Education Department, Rennes, Bretagne, France

Introduction

Monitoring intra-cyclic kinematics during daily training is crucial to support swimming performance. Gold-standard methods (i.e., manual video analysis) are time-consuming and impractical for coaches, making the use of Inertial Measurement Units (IMUs) to automate sports monitoring promising. However, intra-individual (e.g., speed, fatigue) and inter-individual (e.g., technique, expertise) kinematic variability restrict the validity and reliability of traditional IMU-based classification algorithms in ecological conditions. Thus, a generalizable human activity recognition method is needed for practical swimming phase monitoring. This study presents a deep learning model for intra-cyclic front-crawl analysis using a wrist-mounted IMU.

Methods

IMU and video data were collected at 60 Hz from 10 regional-to-national swimmers (5 male, 5 female) swimming 800 m of front-crawl at varying intensities, from warm-up to sprint. The video data were manually labeled with four phases (entry, pull, push, recovery) and used to train, validate, and test a Bi-LSTM neural network based on acceleration and angular acceleration, using a hold-out subject validation. After probabilistic post-processing of the model's predictions using a sliding window, classification performance was assessed using precision, recall and F1-score. Phase durations were also computed for user-friendly intra-cyclic monitoring.



Results

The model achieved an average F1-score of 0.62 for phase recognition on the testing set: 0.69 (entry), 0.26 (pull), 0.60 (push) and 0.65 (recovery). Most errors occurred between adjacent phases (see Figure 1). The difference in duration between the predicted and true phases was 3.2% (entry), 25% (pull), 2.4% (push), and 7.6% (recovery).

Discussion

Predictions were more accurate for entry and recovery, but weaker for the pull phase, likely because it is the dataset's shortest and the one with the highest inter-individual variability. Adding more swimmers with distinct techniques and exploring hybrid architectures (e.g., CNN-Bi-LSTM) could help the model generalize and reduce errors. The model can nonetheless estimate overall time spent in each phase with low uncertainty, offering performance monitoring insights. As a preliminary study, this work is a first step toward developing a powerful training assistant to automatically analyze swimmers' intra-cyclic kinematics across skill levels during in-situ training monitoring.

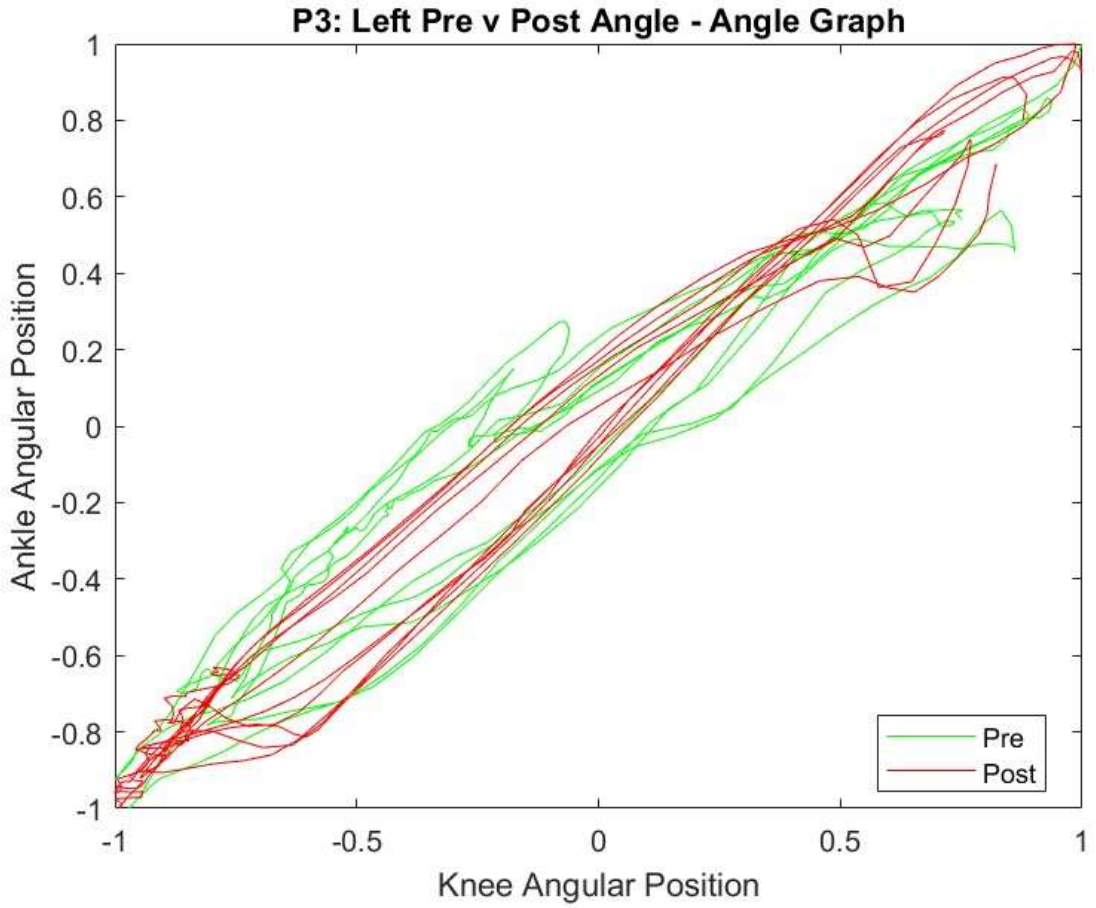
[4]Rehabilitation Research Program, Centre for Aging SMART, Vancouver Coastal Health Research Institute, Vancouver, BC, Canada. [5]Research Institute, BC Children's Hospital, Vancouver, BC, Canada. [6]Department of Orthopedics, Faculty of Medicine, UBC, Vancouver, BC, Canada

Introduction

Rowing has been observed to improve function for adolescents with cerebral palsy (CP). Quantifying changes in range of motion (ROM) may not sufficiently describe motor skill acquisition during rowing for adolescents with CP. Coordination, a primary motor impairment of CP, has been suggested to provide a better understanding of biomechanics of movement. Recently, nonlinear analysis methods such as vector coding have been applied to rowing kinematics, providing further detail regarding coordination patterns and variability between joints. This analysis may provide an opportunity for increased understanding of potential changes in lower extremity coordination in adolescents with CP. This study investigates changes in lower extremity kinematics during the rowing stroke in adolescents with CP following a 3-month rowing program.

Methods

Participants were identified during routine clinical appointments at BC Children's Hospital. Training included 3-months of on-water rowing (90mins/session, 1-2 sessions/week). Rowing kinematics were collected pre- and post- learn-to-row program (12-camera Qualisys marker-based system, modified Helen Hayes marker set). The indoor rowing machine was instrumented with a load cell (4448N, Omega Engineering), measuring force at the handle. Participants rowed for 500m; five consecutive rowing cycles where consistent force was generated were extracted for analysis. Hip, knee, and ankle ROM was calculated. Coordination was evaluated through vector coding, comparing proximal to distal instantaneous joint positions (hip-to-knee, knee-to-ankle, hip-to-ankle) through calculating a coupling angle. Data is presented using descriptive statistics.



Results

Thirteen participants (ages 12-18yrs, females=4; hemiplegia=5, diplegia=7, quadriplegia=1; gross motor function classification scale, I=4, II=6, III=3). Stroke performance measures showed increased peak force development (mean:155N, range:38-510N) and stroke-rate (1.2, 5.8-0.3strokes/min). Changes in mean ROM were more variable- hip; increase 2.5degs, range:-15.5-24.5, knee; increase 3.5degs, range:-24-72, and ankle; increase 0.5degs, range:-17.5-13.5. Due to the variable changes in ROM, the vector coding technique may present a metric able to describe changes in motor performance. Vector coding analysis completed for 3/13 participants. (Fig1) shows smoother trajectory of movement post-training, with less alternating between ankle and knee dominancy.

Discussion

Vector coding applied to rowing kinematics may provide further detail regarding skill acquisition and coordination patterns between lower extremity joints, associated with improvements in motor performance in adolescents with CP.

Effects of Pool Depth on Swimming Performance: Application to the 200-m Freestyle

Mr. Junsik Oh M.S.Student[1], Mr. Beomsu Jang[2], Professor Jooeun Ahn Ph.D[1], Professor Keunhwan Park Ph.D[2]

[1]Seoul National University, Seoul, Seoul, Korea, Republic of. [2]Gachon University, Seongnam, Gyeonggi, Korea, Republic of

Introduction

Wave drag, accounting for 3–50% of total resistance in freestyle swimming, is an important determinant of performance [1]. Given the depth dependence of wave drag, performance should vary accordingly, but this relationship has not been quantified. To quantify this depth effect, we developed a simplified depth-scaling model of hydrodynamic resistance and applied it to race results from the 2024 Paris Olympic Games (pool depth: 2.15 m) to assess its relevance in elite competition.

Methods

The model estimates total drag—including friction, form, and wave drag—as a function of depth (H) and the wave-drag fraction (α) [2]. Using the official World Aquatics database, we obtained the final race results of the men's 200-m freestyle at the 2024 Paris Olympic Games. From each athlete's race time, we calculated the mean swimming velocity, and, assuming constant mechanical power output, used our model to estimate their predicted performance if the pool depth had been 3 m [3,4].

Results

Under average race-speed conditions (V = 1.90 m/s) and α = 0.4, previously reported measurements within V ± 0.05 m/s fell within the model's prediction bounds [3,4]. Based on these conditions and assuming constant power output, the model estimates a 1.38–1.59% reduction in race time when pool depth increases from H = 2.15 m to H = 3 m.

Discussion

Our findings provide quantitative evidence that pool depth can influence freestyle performance and confirm the relevance of this effect in elite competition. However, the present model has been evaluated primarily near a race speed of 1.90 m/s, and its behavior at other velocities will be addressed in future work. Overall, these results suggest that pool depth should be considered in both training and competition planning.

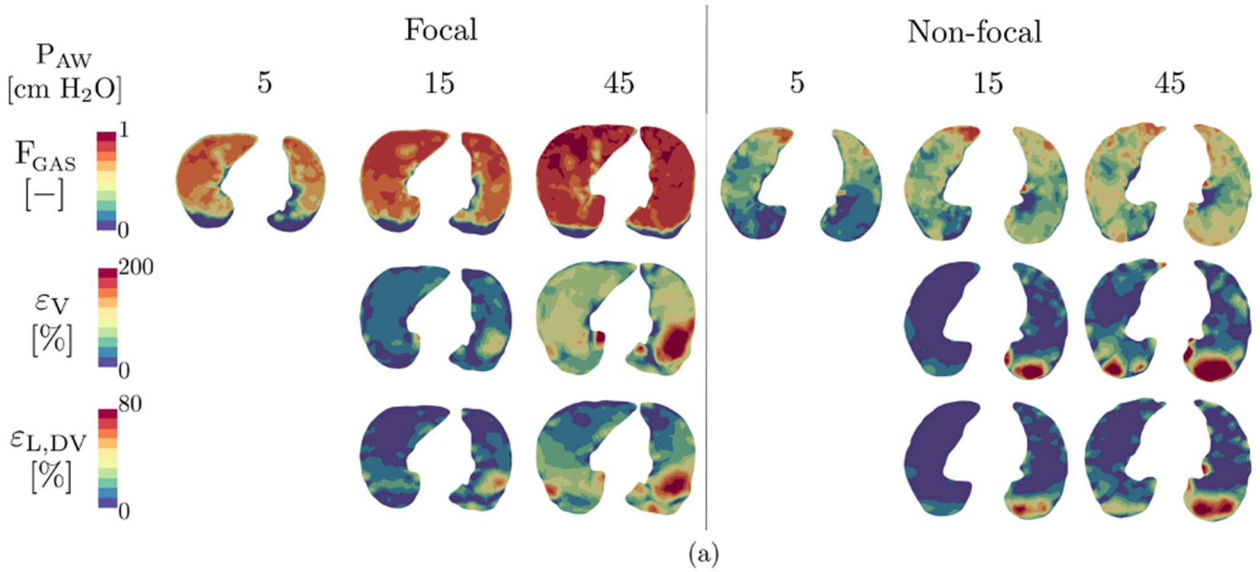
[6]Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, MA, United States. [7]Center of Acute Respiratory Critical Illness (ARCI), Santiago, RM, Chile

Introduction

Acute respiratory distress syndrome (ARDS) exhibits morphological heterogeneity, which may influence regional mechanical behavior during recruitment maneuvers (RMs). Although focal and non-focal phenotypes show distinct radiological patterns, quantitative in-vivo evidence of their differential regional deformation remains limited. We aimed to characterize and compare regional volumetric-strain and dorsoventral linear-strain in human focal and non-focal ARDS during RMs using image-based biomechanical analysis.

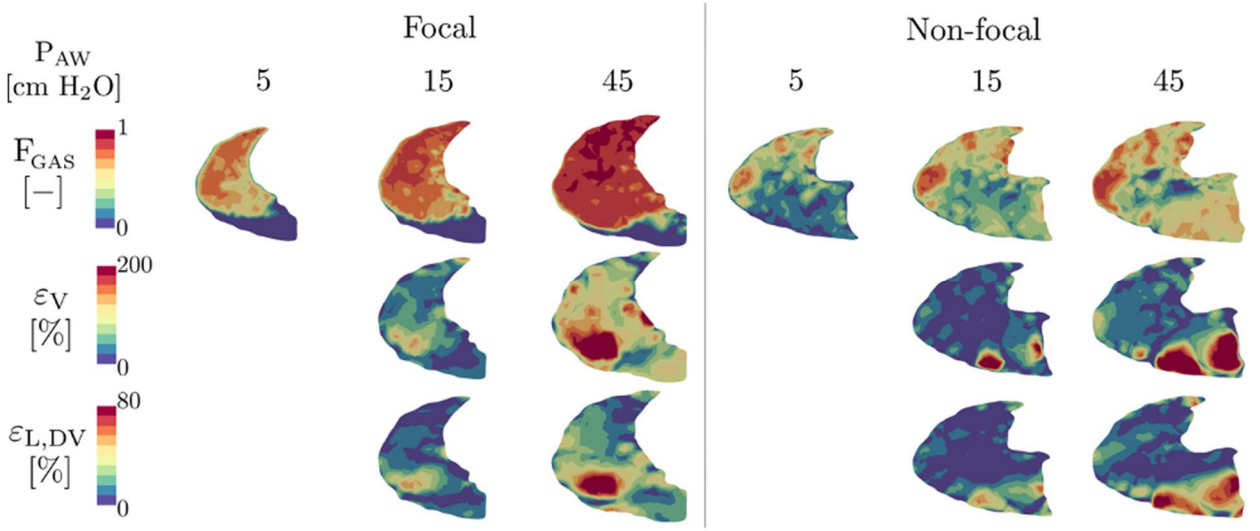
Methods

We retrospectively analyzed CT scans from 11 adults with moderate-to-severe ARDS. Breath-hold CT images were acquired at airway pressures of 5, 15, and 45 cmH_2O. Lungs were segmented and meshed, and image registration (NiftyReg) was used to compute regional deformation relative to 5 cmH_2O. Gas fraction (FGAS) and aeration compartments were quantified at each pressure. Volumetric-strain and dorsoventral linear-strain were computed on tetrahedral finite element meshes, and regional values were analyzed across four gravitational regions (ventral, mid-ventral, mid-dorsal, dorsal) for focal (n=4) and non-focal (n=7) phenotypes.



Results

Strain distributions were heterogeneous in both phenotypes but exhibited distinct spatial patterns. In focal ARDS, the initially normally aerated mid-ventral and mid-dorsal regions, the anatomical location of the “baby lung”,showed the highest deformation during RMs. At 45 cmH_2O, volumetric-strain in these regions exceeded 150–200%, with a peak of dorsoventral linear-strain in the mid-dorsal region. These high-strain zones occurred adjacent to persistently collapsed dorsal tissue. In contrast, non-focal ARDS demonstrated strain elevations predominantly in dorsal regions, corresponding to recruitment of previously poorly or non-aerated tissue. Ventral and mid-ventral strain remained significantly lower than in focal ARDS



Discussion

This study provides the first quantitative in-vivo evidence that focal and non-focal ARDS exhibit different patterns of regional mechanical deformation during recruitment. In focal ARDS, the baby lung is exposed to disproportionately high volumetric and linear strain, particularly at interfaces between aerated and collapsed regions, mechanistic “stress raisers” consistent with interdependence theory. These findings offer a biomechanical explanation for the poor response and higher risk of overdistension previously reported in focal ARDS during RMs and high PEEP. Conversely, in non-focal ARDS, elevations in strain largely reflect beneficial recruitment rather than injurious deformation of already aerated tissue. These results support morphology-based personalization of ventilation strategies

Exploring V/Q Distribution in Children With MRI-Informed Personalised Computational Lung Models

Ms Megan Soo, Prof Merryn Tawhai, Dr Ho-Fung Chan

Auckland Bioengineering Institute, University of Auckland, Auckland, Auckland, New Zealand

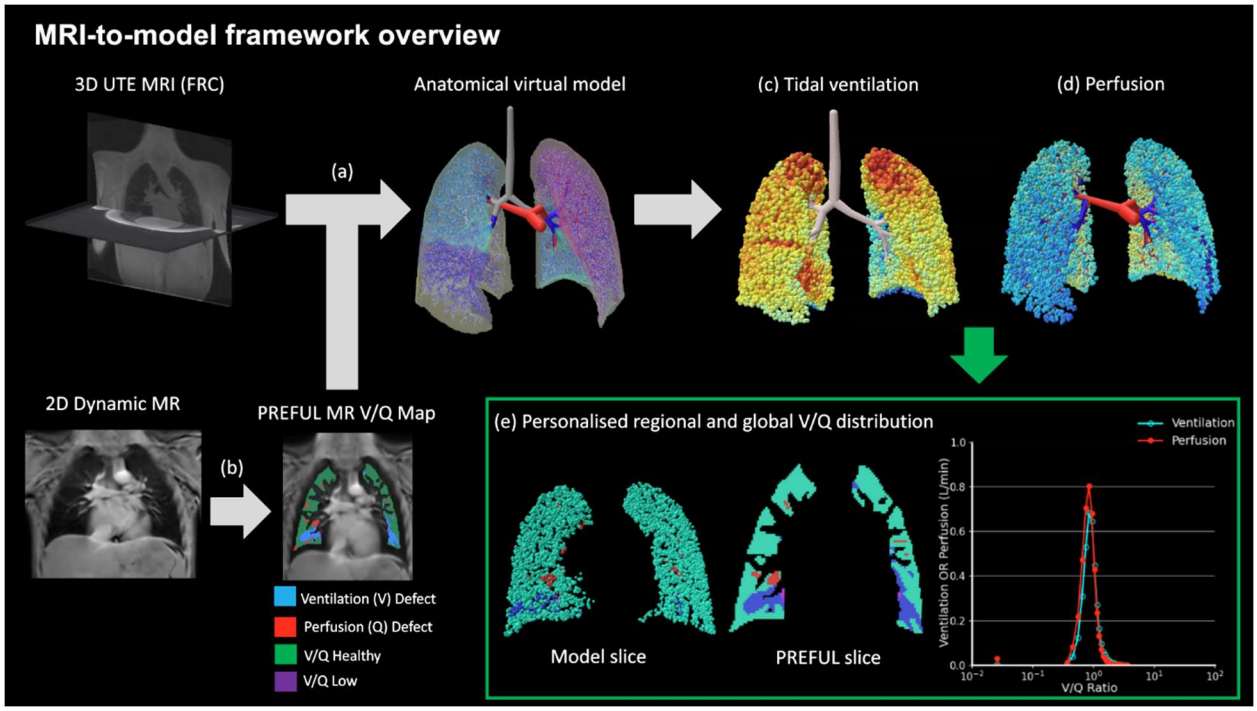
Introduction

Novel lung MRI techniques are promising clinical tools for guiding paediatric lung disease management and can provide regional structure-function lung biomarkers to inform computational physiology lung models. Here, we developed an MRI-to-model framework that integrates novel MRI biomarkers to generate personalised lung models of ventilation and perfusion in healthy children. The predicted ventilation/perfusion (V/Q) distributions could potentially facilitate new strategies for managing respiratory conditions.

Methods

Three healthy children were imaged with a novel structure and function lung MRI protocol. Personalised anatomical lung models were generated using 3D ultra short echo-time (UTE) MRI [1] (Fig 1a). To account for gravitational tissue deformation, acinar tissue units were spatially and volumetrically distributed across both lungs based on MRI-derived approximate tissue density distribution at functional residual capacity (FRC). Phase resolved function lung imaging (PREFUL) MRI [2] maps of ventilation and perfusion from 2D dynamic MRI were used to identify acinar tissue units with ventilation/perfusion defects (Fig 1b). A ventilation model simulated tidal flow via pressure-driven expansion/contraction of tissue units (Fig 1c). A perfusion model simulated blood flow across extra- and intra-acinar tissue units at FRC (Fig 1d).

Results



Simulated global ventilation and perfusion measurements, lung compliance (101±13 mL/cmH_2O), specific compliance (72.3±7.2 mL/cmH_2O/L-FRC), work per litre (0.53±0.02 J/L), and mean pulmonary artery pressure (15.8±0.2 mmHg), were within the normal reported range for healthy children. Simulated regional ventilation and perfusion defects in the lung models demonstrate good spatial agreement with corresponding PREFUL ventilation and perfusion maps (Fig 1e). Furthermore, the simulated VQ ratio plot, across

all acinar tissue units, was homogenous and centred around one, indicative of healthy gas exchange and VQ matching.

Discussion

MRI-informed computational lung models can provide simulations of regional ventilation/perfusion matching distribution that could facilitate novel personalised insights into gas exchange efficiency. This novel MRI-to-model framework will be further implemented in a larger cohort of healthy children, and in future work, the framework will be applied to children with asthma who have ventilation heterogeneity.

Effects of Respiratory Heart Rate Variability on Cardiac Biomechanics: Experiment and Modelling Investigations

Mr Chamal Kohombakadawala[1], Dr Toan Pham[1,2], Dr Kenneth Tran[1], Prof Andrew Taberner[1,2], Dr June-Chiew Han[1]

[1]Auckland Bioengineering Institute, University of Auckland, Auckland, Auckland, New Zealand. [2]Department of Engineering Science and Biomedical Engineering, University of Auckland, Auckland, Auckland, New Zealand

Introduction

Heart rate variability (HRV), a naturally occurring phenomenon in healthy individuals, is closely synchronised with respiration. Inhalation and exhalation, respectively, inhibit and restore vagal outflows, leading to increased and decreased heart rates within each breathing cycle. This cardiopulmonary phenomenon, termed 'respiratory heart rate variability' (RespHRV), has recently been shown to improve cardiac output when externally reinstated via a pacemaker. This finding led to the hypothesis that RespHRV pacing increases cardiac work and, also energy expenditure.

Methods

We tested the hypothesis experimentally using left-ventricular muscles (n = 10) isolated from the rats and studied using the work-loop calorimeter. Simultaneous measurements of mechanics (force, length, work) and energetics (heat) were made across wide ranges of preloads and afterloads. Each muscle was paced with and without RespHRV. We also tested the hypothesis using a six-compartment computational model of human pulmonary and systemic circulations (PMID: 8238596) to simulate RespHRV effects on cardiac pressure-volume dynamics. RespHRV was modelled by alternating inter-beat intervals (two beats at 100.8 beats per minute, four beats at 63 beats per minute), compared with fixed pacing at 72 beats per minute.

Results

Experimentally, average muscle force, work, heat, and mechanical efficiency were not different between the two pacing protocols. However, RespHRV pacing elicited twitch-by-twitch variations in force magnitude and shortening, which was absent without RespHRV. Model simulations across varying cardiovascular loads, including elevated peripheral resistance and blood pressure, cardiac pressure-volume work did not differ between RespHRV and fixed pacing. Similar results were obtained when contractility was modelled as heart-rate dependent.

Discussion

In conclusion, both experimental and computational findings reject the hypothesis that RespHRV pacing alone directly augments cardiac work or efficiency under acute conditions. We speculate that chronic adaptations or additional mechanisms such as changes in cellular ionic activity, protein expression, and/or structural remodelling may underlie the improved cardiac output observed with external RespHRV pacing. Chronic experiments and models integrating excitation-contraction and subcellular remodelling are warranted to fully test the hypothesis.

Applying Adaptive Boundary Conditions to Improve Biomechanical Modeling of the Pulmonary Vasculature Post Lung Transplantation

Mr. Jonathan Ibinson[1], Mr. Alexander Barr MS[1], Dr. Jorge Mallea MD[2], Dr. Jason Szafron PhD[1]

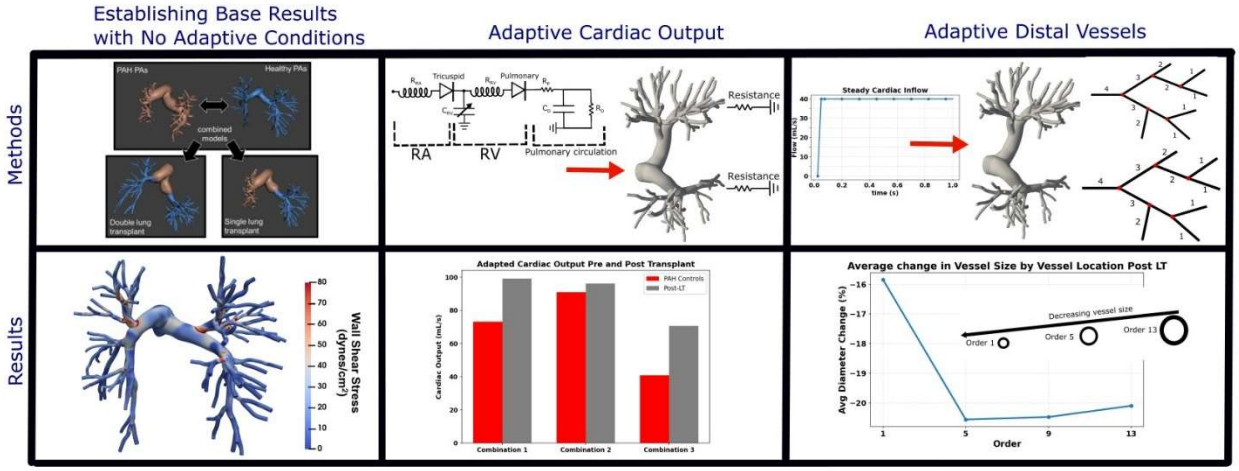
[1]Carnegie Mellon University, Pittsburgh, PA, United States. [2]Mayo Clinic, Jacksonville, Florida, United States

Introduction

Optimal lung transplantation (LT) outcomes remain limited by inflammatory pathways with a mechanobiological component [1] . After transplant, hemodynamics change with the combined cardiopulmonary system of the donor and recipient. In LTs, two main shifts occur: decreased afterload in the recipient right-heart from removing diseased, often narrowed pulmonary vessels and changed flow through the donor vessels with a heart potentially adapted to high pressures. We aim to build a LT simulation pipeline that accounts for these mechanical shifts to improve predictions of post-LT vascular remodeling.

Methods

We created post-LT 3D CFD simulations using SimVascular [2]. Donor and recipient pulmonary vasculatures were joined for in silico representations of LT. We paired morphometric trees with vessels of varying sizes to outlets for detailed simulations of the distal vasculature. A 0D right heart model was created for both the donor and recipient that included the right-heart chambers, valves, and the pulmonary system. We simulated a 0D LT to get the new cardiac input, using the heart from the diseased patient and the pulmonary system parameters from the healthy patient. We simulated adaptive distal pulmonary vessels by adjusting order diameters to minimize differences from order-averaged healthy wall shear stress (WSS) [3].



Results

We modeled a healthy donor with three different PAH vasculature combinations, simulating donor organ procurement. The PAH heart post-LT saw an average increase of 20.3 mL/s in cardiac output. When exposed to decreased flow, distal vessels saw constriction of the vessels, example shown normalized to the size of the distal vessel in the bottom right figure panel.

Discussion

Both adaptive results matched expectations of system behavior with cardiac output increasing from reduced afterload and distal resistance increasing to restore WSS towards the pre-operative level in the healthy patient. These shifts change the long-term mechanobiological stimuli experienced by donor lungs, which drive vascular remodeling and immune cell infiltration. Future work will focus on iterative coupling until both cardiac output and distal resistance reach a steady state to reflect joint feedback from both mechanisms.

Quantifying Microvascular Topology of the Myocardium with Synchrotron X-ray Phase Contrast Micro-tomography to Investigate Microthrombi Occlusions

Mr. Ross Straughan MSc[1], Dr. Anne Bonnin PhD[2], Dr. Nikola Cesarovic Med. Vet, PhD[3], Prof. Dominik Obrist PhD[1]

[1]ARTORG Center for Biomedical Engineering Research, University of Bern, Bern, Bern, Switzerland. [2]Swiss Light Source, Paul Scherrer Institute, Villigen, Aargau, Switzerland. [3]Department of Health Sciences and Technology, ETH Zurich, Zurich, Zurich, Switzerland

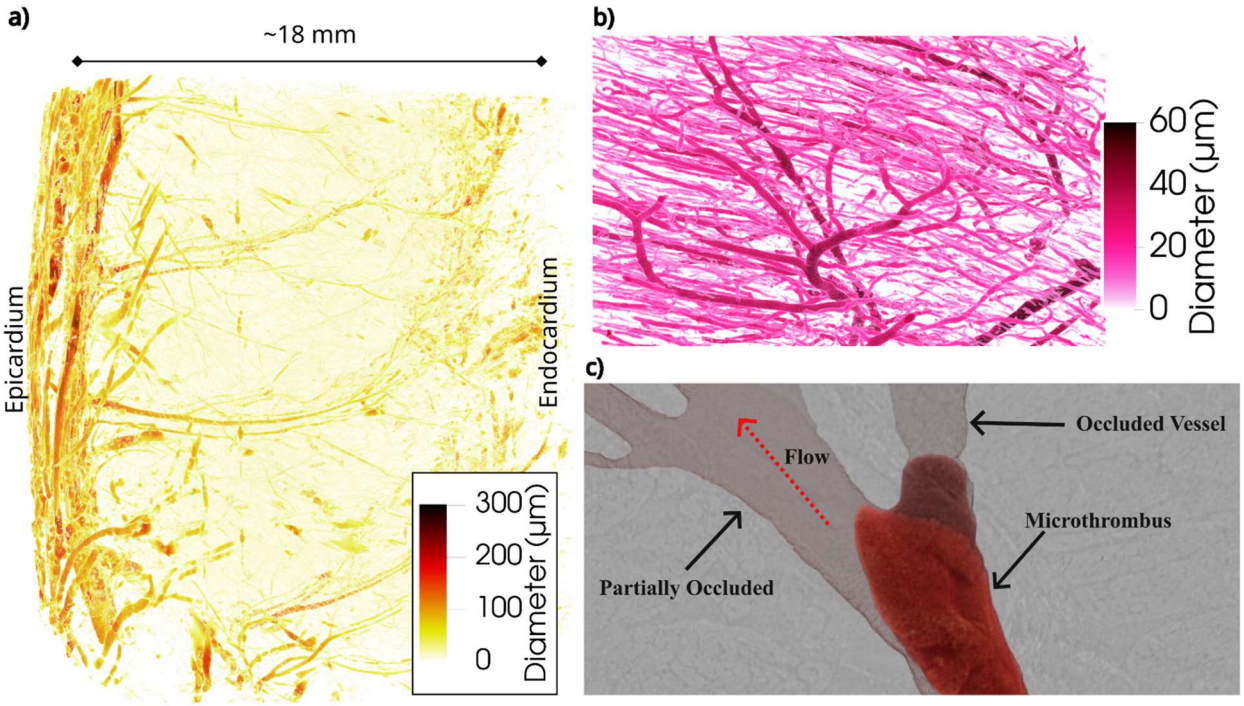
Introduction

Approximately half of patients that receive percutaneous coronary intervention to treat myocardial infarction suffer from Microvascular Obstruction (MVO) [1]. In cases of MVO, large thrombi are believed to be broken up, flow downstream and occlude small vessels (< 200μm diameter) of the coronary microcirculation, preventing sufficient reperfusion [2].

Despite its frequent occurrence, there is a lack of adequate diagnosis and treatment of MVO, which significantly worsens the clinical outcome after myocardial infarction. Improving diagnosis and treatment requires a better understanding of the microvascular architecture of the myocardium including the location of occluding microthrombi (MT).

Methods

A porcine model was adapted to mimic clinically observed MVO by the infusion of MT directly into the coronary circulation [2]. Six samples from six pigs were extracted and imaged with Synchrotron X-ray Phase Contrast micro-tomography with a voxel resolution of 1.625 μm. Deep-learning tools were utilized to segment myocardial layers, microvasculature and microthrombi.



Results

Preliminary topological analysis of the segmented microvascular architecture reveals large vessels (>50μm) transversing the myocardium (figure a) and smaller vessels (<50μm) aligning circumferentially and orientated anisotropically (figure b) alongside myocytes. Collateral vessels, which may provide an important role in mitigating the impact of MVO, have also been observed. MT segmentations reveal their hierarchical location within the microvascular network, allowing for a better understanding of MVO pathology mechanisms.

Discussion

To our knowledge, these are the first three-dimensional segmentations of the myocardial microvasculature approaching the capillary level (~10 μm in diameter) for the entire thickness of the myocardium. Future efforts will be spent quantifying how MT-specific occlusions (such as in figure c) reduce or maintain the mass transfer of blood within the myocardium. By improving our understanding of these mechanisms, we hope to improve the development of targeted therapies and validate emerging diagnostic technologies.

Real-Time Risk Stratification for Coronary Artery Thrombosis using Machine Learning

Mr. Kyle Tennison[1], Dr. Aurele Goetz PhD[2], Dr. Pablo Jeken Rico PhD[2], Dr. Kirsten Dummer MD[3], Dr. Jane Burns MD[3], Dr. Alison Marsden PhD[4], Dr. Elie Hachem PhD[2], Dr. Karthik Menon PhD[1]

[1]Georgia Institute of Technology, Atlanta, GA, United States. [2]Mines Paris - PSL, Paris, Paris, France. [3]UC San Diego School of Medicine, San Diego, CA, United States. [4]Stanford University, Stanford, CA, United States

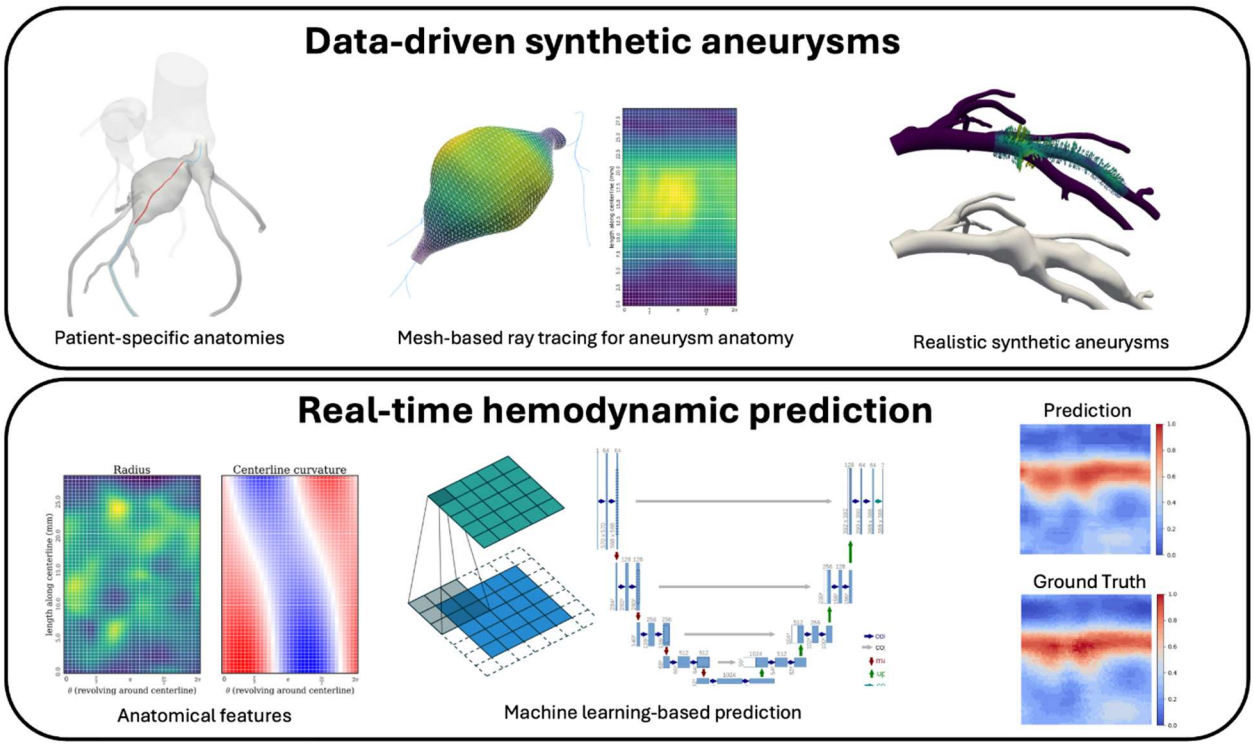
Introduction

Kawasaki Disease (KD) is an acute vasculitis that predominantly affects children under 5 years of age. Without timely treatment, 25% of patients will develop coronary artery aneurysms (CAAs) that may cause thrombosis and subsequent myocardial infarction. Current treatments are purely guided by CAA diameter normalized for body surface area [1]. While previous work has shown that hemodynamics potentially predicts risk better than CAA diameter [2], hemodynamics cannot be measured using standard clinical tools. Computational models can quantify hemodynamics but are expensive and not feasible in clinical settings. Moreover, machine learning methods are hampered by the lack of large datasets for this relatively rare disease.

Methods

We develop a combined computational modeling and machine learning pipeline for real-time non-invasive risk stratification. Using data from patient-specific imaging, we develop techniques for learning features of real aneurysms to create a library of anatomically realistic synthetic aneurysms. We use computational fluid dynamics to compute thrombosis risk in the dataset of real and synthetic aneurysms, and build convolutional neural networks (CNN) for real-time predictions of thrombosis risk.

Results



The creation of synthetic aneurysms consists of identifying local coordinate systems along aneurysm centerlines, ray-tracing for creating 2D feature maps of aneurysms, and registration to implant synthetic aneurysms on healthy vasculature. The pipeline has been tested with clinicians using a dataset of real and synthetic aneurysms. The rates of identifying real and synthetic aneurysms as real aneurysms were roughly equal, indicating the pipeline generates realistic anatomies.

The prediction of hemodynamics was performed on 810 vascular samples using a U-Net architecture. The inputs were vessel radius, curvature, distance from coronary ostium, and location of branches. The proof-of-concept was performed on predicting spatial distributions of time-averaged wall shear stress (TAWSS). The results show we are successfully able to predict patient-specific TAWSS distributions using CNNs.

Discussion

We are developing a framework for real-time and non-invasive prediction of thrombosis risk for KD patients that can be performed in clinically-realistic timeframes. The results are promising, both in terms of learning anatomical features of aneurysms, and predicting hemodynamics.

Cannula-Driven Hemodynamics and Embolic Transport During Cardiopulmonary Bypass Using Validated Patient-Specific CFD-LPT Modeling

Dr. Nafis Arefin PhD, Dr. Bryan Good PhD

University of Tennessee, Knoxville, Tennessee, United States

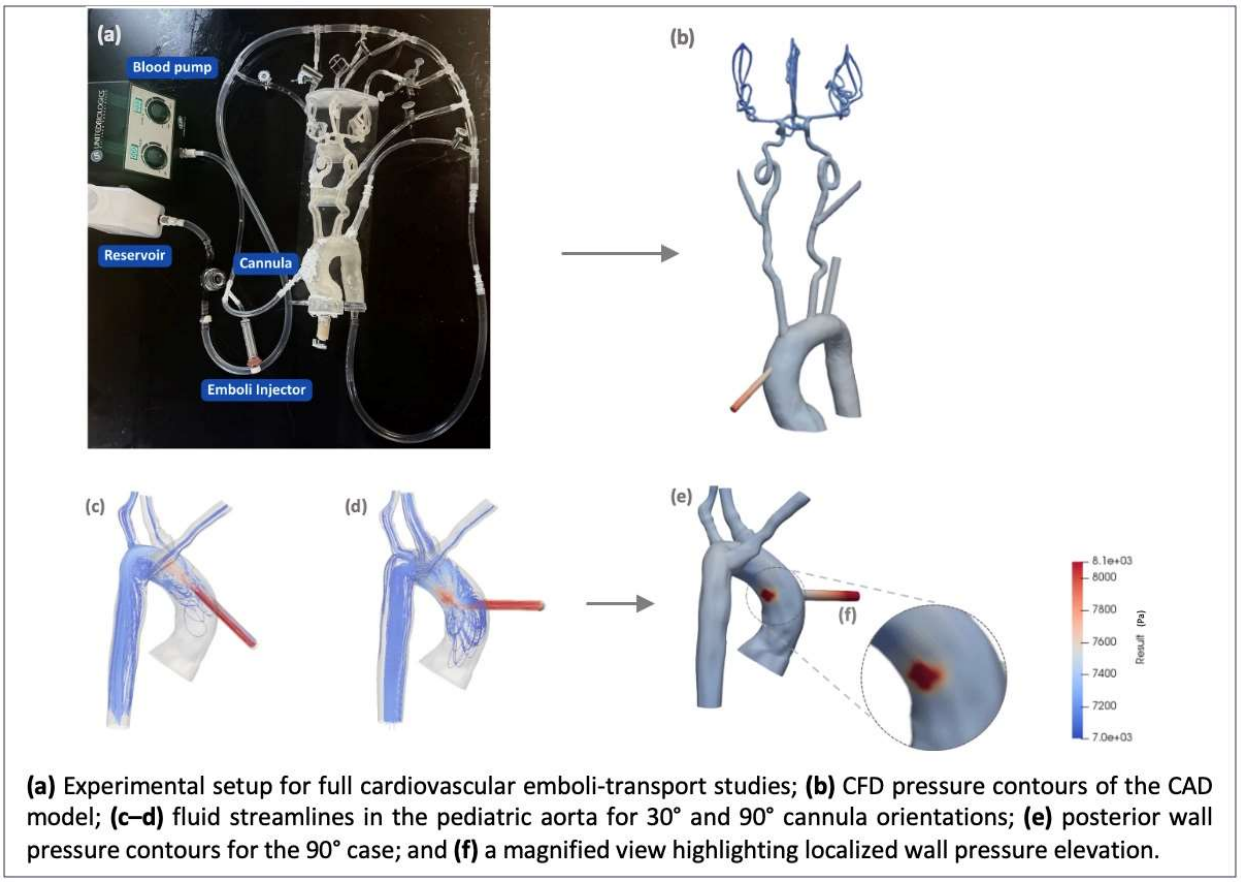
Dr. Nafis Arefin

Introduction

Cardiopulmonary bypass (CPB) enables life-saving cardiac surgeries, but the high-velocity jet from the aortic cannula disrupts native hemodynamics, dislodges plaques, and affects emboli transport, elevating the risk of stroke, renal, and hepatic complications. While cannula angle has been studied to some extent, prior work did not quantify how cannula orientation, age-dependent anatomy, and CPB parameters collectively dictate embolic pathways. This study addresses these gaps using validated CFD coupled with Lagrangian Particle Tracking (LPT) across patient-specific aortic anatomies representing multiple age groups. We quantitatively assessed how cannulation strategy and CPB operating conditions influence embolic transport into the full aortic and cerebrovascular anatomy, with the hypothesis that these parameters would significantly modulate embolic trajectories.

Methods

In-vitro validation used silicone-based mock circulatory loops replicating CPB cannulation and perfusion conditions. Four patient-specific aortic geometries were simulated with two cannula orientations (30° and 90°) and six CPB conditions (μ = 1.5, 2.5, 3.5 cP; Q = 3, 5 LPM). Physiological outlet boundary conditions were manually implemented in *OpenFOAM,* and embolic transport quantified using LPT, tracking 1000 collision-free emboli (0.5–2.5 mm) per simulation. Post-processing was performed in *ParaView*.



Results

Notably, the 30° angled cannula consistently reduced emboli escape by 36% on average, while decreasing posterior wall pressure by 24%. Increasing flowrate from 3 to 5 LPM raised cerebral and renal emboli by 45% and 27%. At low viscosity (1.5 cP), emboli exit into the external carotid and hepatic arteries increased by 35-55%.

Discussion

This study presents the first validated, patient-specific, multi-age embolic transport model spanning the full cardiovascular system. Angled cannulation reduced embolic transport, whereas perpendicular jets increased turbulence, elevated wall stress, and promoted embolus formation and dispersion. Higher flow rates and lower viscosity intensified turbulence, driving emboli toward slow-moving near-wall regions and increasing branch exit. Age-specific geometric differences, particularly sharper arch curvature and smaller diameters in the pediatric model, further shaped transport pathways. Limitations include rigid walls and spherical emboli, and future work will incorporate compliant walls with more realistic embolus properties. Overall, these findings provide a quantitative foundation for optimizing cannulation strategies and CPB management, enabling safer perfusion approaches that minimize stroke and organ-injury risk.

Lysis Of Microthrombi in a Multi-Scale In-Vitro Model of Coronary Microvascular Obstruction

Dr. Yannick Rösch[1], Dr. Anastasia Milusev[2], Ms. Petra Wolint[3], Dr. Sabrina Frey[2], PD Dr. Nikola Cesarovic[3], Prof. Dr. Dominik Obrist[1]

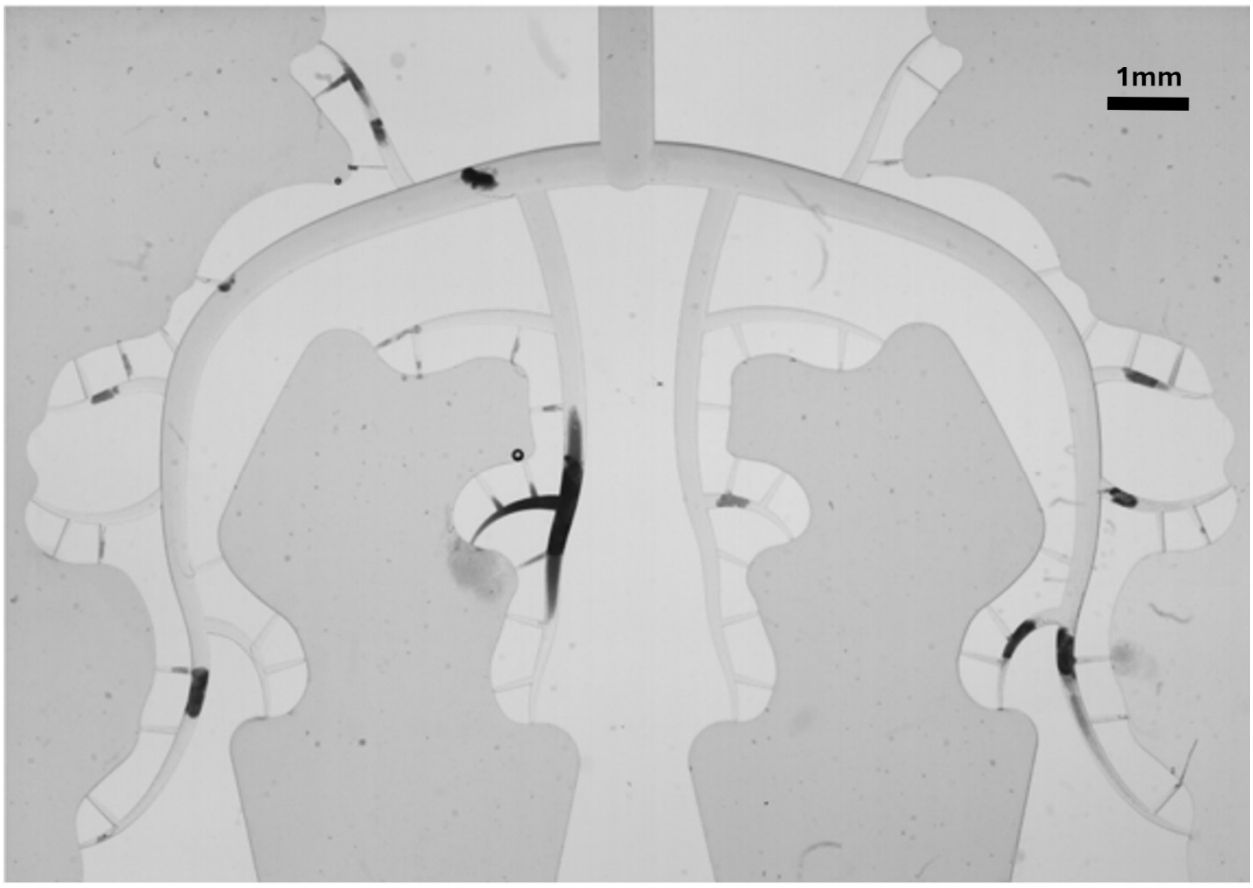
[1]University of Bern, Bern, BE, Switzerland. [2]CorFlow Therapeutics AG, Bern, BE, Switzerland. [3]ETH Zurich, Zurich, ZH, Switzerland

Introduction

Coronary microvascular obstruction (MVO) affects more than 50% of all patients after successful percutaneous treatment of ST-elevation myocardial infarction (STEMI) [1]. MVO leads to impaired perfusion of the myocardium and may be caused by microthrombi (MT) obstructing vessels with a diameter of 200µm or smaller. Today, there exists no effective therapy for MVO. In this study, we test a novel therapeutic approach in which thrombolytic drugs are directly infused into the coronary vessels via catheter while the local perfusion is temporarily interrupted by a balloon.

Methods

We developed a multi-scale in-vitro model comprising a left-heart mock loop (macro), a coronary phantom (meso), and a chip modeling the microvasculature (micro) [2]. This setup reproduces physiological flow in the microchip, including effects of pulsating arterial pressure and the intramyocardial pumping effect due to myocardial contraction. The infusion of MTs into the microfluidic chips leads to an obstruction of the smaller vessels. A microdose (1.5mg) of alteplase (rtPA) is then infused into the coronary phantom and the microchip while the coronary circulation is blocked by balloon occlusion for 90 seconds. For the following 15.5 minutes, the chip is perfused with human plasma while the position and lysis of the MTs are captured by a camera with LED-backlight illumination.



Results

Alteplase infusion resulted in a 3.5x (on average) faster reduction of the thrombus burden compared to control experiments without alteplase. Some MTs remained unchanged throughout the experiment because they were located in vessels that could not be reached by alteplase due to the absence of local flow, while others were mobilized after partial lysis and were transported to smaller vessels, resulting in new obstructions. Finally, a significant number of MTs were completely dissolved during the experiment.

Discussion

The results show that the novel therapeutic approach leads to a significant and enhanced reduction of the thrombus burden. This is remarkable as the total dose of infused alteplase was 60x lower than the recommended dose for intravenous drug infusion [3].

Evaluating Posterior Boundary Conditions in Patient-Specific Finite Element Models of the Optic Nerve Head

Ms. Patricia M. Sabin MS[1], Dr. Brandon K. Zimmerman PhD[1], Ms. Kelly A. Clingo BS[1], Dr. Cameron A. Czerpak PhD[1], Dr. Manuel Lucas Sampaio de Oliveira PhD[1], Dr. Harry A. Quigley MD[2], Dr. Thao D. Nguyen PhD[1,2]

[1]Johns Hopkins University, Baltimore, MD, United States. [2]Johns Hopkins School of Medicine, Baltimore, MD, United States

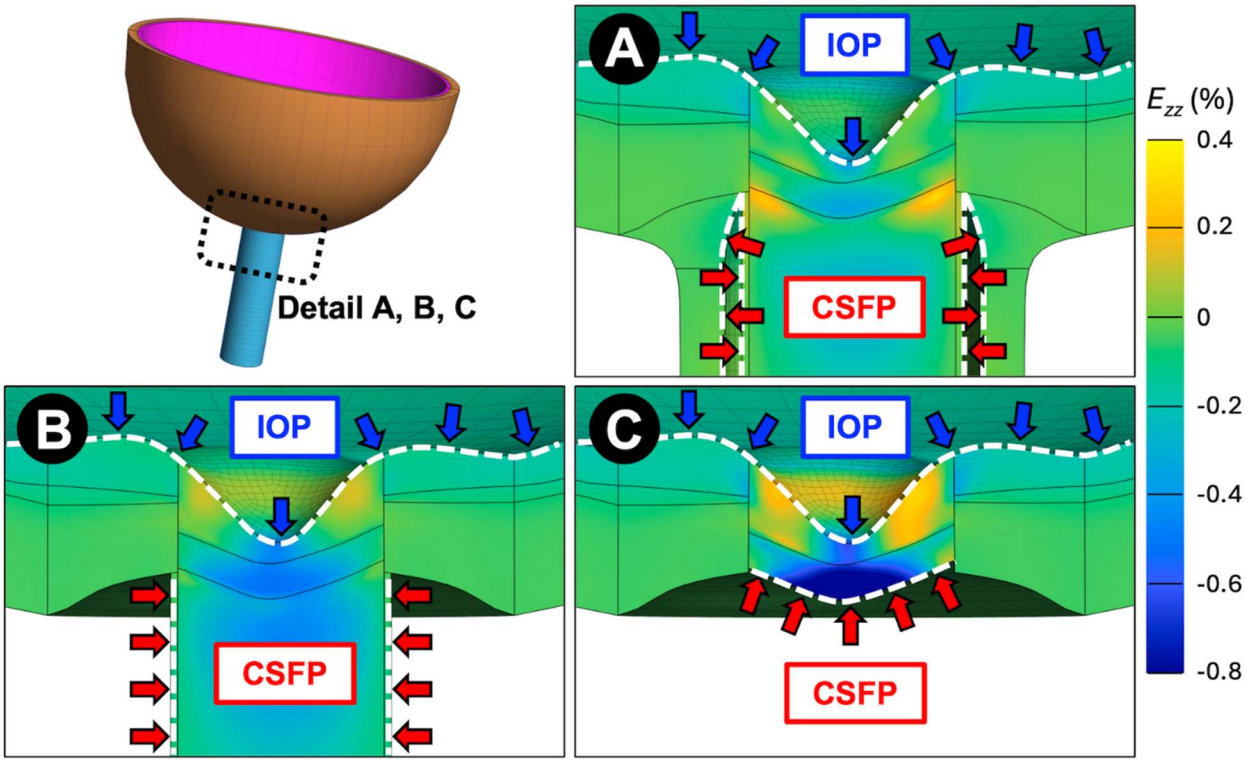
Introduction

Eye-specific modeling of optic nerve head (ONH) biomechanics is important for understanding individualized glaucoma risk factors. A major limitation is the inability to directly measure the retrolaminar tissue pressure (RTP) acting on the posterior boundaries of the ONH. Recently, we employed digital volume correlation (DVC) of optical coherence tomography (OCT) to map the ONH deformation response in patients with normal pressure hydrocephalus (NPH) undergoing extended cerebrospinal fluid (CSF) drainage [1]. Intraocular pressure (IOP) and CSF pressure (CSFP) were measured before and after treatment. We seek to apply this unique dataset to assess approaches for using CSFP to model RTP boundary conditions.

Methods

Three eyes from 3 NPH patients (45-81 years) were imaged by spectral domain OCT. The retina, choroid, sclera, and lamina cribrosa (LC) were segmented using an automated algorithm and reviewed by a trained observer. Parameterized posterior shells with optic nerve and sheath were generated, and segmented volumes were converted into eye-specific ONH geometries and embedded within the shells. For each eye, we investigated three models for applying CSFP to the posterior tissues (Fig. 1) to evaluate the sensitivity of the deformation field to the posterior boundary conditions. A 12.3 mmHg CSFP decrease and 2 mmHg IOP increase were assumed for all eyes to compare the effect of geometry across models. Material properties were chosen from the literature.

Results



Applying CSFP in the subarachnoid space (Fig. 1A) produced less compressive LC axial strain (E_{zz} = -0.10 ± 0.01%) and smaller maximum principal strain (E_{max} = 0.28 ± 0.03%) than applying only on the pia mater (Fig. 1B; E_{zz} = -0.23 ± 0.04%, E_{max} = 0.30 ± 0.03%). Strains

from applying CSFP directly on the LC were varied (Fig. 1C; E_{zz} = -0.11 ± 0.21%, E_{max} = 0.60 ± 0.15%).

Discussion

Preliminary results indicate that LC strain predictions are sensitive to CSFP loading configuration, and incorporating the full optic nerve sheath may be important for modeling despite added computational cost. Future work will extend the dataset to 7 eyes and leverage known IOP/CSFP changes and DVC-derived strain fields to further evaluate posterior boundary conditions and refine ONH material properties.

Mechanical Softening of the Lamina Cribrosa Drives a Pro-Inflammatory Astrocyte Activation and Retinal Ganglion Cells Loss in a Rat Model of Chronic High Intraocular Pressure

Prof Xiuqing QIAN[1,2], Ms Yuqing WANG[1], Ms Jingxi ZHANG[3], Ms Zihan XI[1], Ms Dong MA[1], Ms Xinmiao HAN[1]

[1]Capital Medical University, Beijing, Beijing, China. [2]Beijing Key Laboratory of Intelligent Diagnosis Technology and Equipment for Optic Nerve-Related Eye Diseases, Beijing, Beijing, China. [3]Beijing Friendship Hospital, Beijing, Beijing, China

Prof Xiuqing QIAN

Introduction

In glaucoma, microstructure and mechanical properties alterations in the lamina cribrosa (LC) are primary drivers of optic neuropathy. However, the precise cascade linking altered tissue mechanics in the LC to astrocyte activation and subsequent retinal ganglion cells (RGC) loss remains incompletely defined. This study aims to investigate the relationship between biomechanical changes in the LC, activation of LC astrocytes, and structural/functional damage to the optic nerve.

Methods

A rat model with chronic high intraocular pressure (IOP) was established, maintaining high IOP for1, 4, 8weeks(n=6). We used a method combining atomic force microscopy (AFM) with image processing to segment and determine the mechanical properties of the LC and optic nerve. Optic nerve injury was comprehensively assessed via in vivo optical coherence tomography (OCT), axonal staining, immunofluorescence staining for RGCs, and rhodamine-based axonal transport assays. The activation of LC astrocytes was evaluated by detecting glial fibrillary acidic protein (GFAP) via immunofluorescence and its corresponding mRNA expression levels via qPCR. Expression of key inflammatory factors was quantified by qPCR, and their causal role in RGC injury was investigated.

Results

With duration of elevated IOP, the elastic modulus of the LC and optic nerve significantly decreased, indicating tissue softening. This mechanical degradation coincided with severe

structural and functional impairments: OCT revealed retinal nerve fiber layer thinning, axonal staining showed profound disorganization and loss, and axonal transport was significantly blocked. Immunofluorescence and qPCR confirmed activation of astrocytes, evidenced by upregulated GFAP. Crucially, this activation was coupled with marked upregulation of neuroinflammatory factors (IL-1α, TNF-α, C1q), whose presence was spatiotemporally associated with significant RGC apoptosis.

Discussion

Chronic high IOP causes LC softening and reduced load-bearing capacity. This altered mechanical microenvironment effectively triggers astrocyte activation, leading to a destructive neuroinflammatory response characterized by release of IL-1α, TNF-α, and C1q. This study reveals that LC astrocytes-driven neuroinflammation constitutes a critical intermediary step in the glaucomatous pathology, acting to amplify RGC damage after the initial biomechanical injury. Therefore, modulating the mechano-inflammatory axis linking tissue softening and astrocyte activation represents a potential strategy for mitigating secondary neurodegeneration.

Scleral Collagen Uncrimping Amplifies Nuclear Strain Relative to Fiber Strain

Dr. Xuehuan He[1], Mr. Qi Tian[1,2], Ms. Hannah Schilpp[1], Ms. Annika Oberdorfer[1,2], Dr. Xinyue Wang[1], Dr. Po-Yi Lee[1,3], Ms. Yingzhe Han[1,2], Dr. Yuankai Lu[1], Dr. Ian A. Sigal[1,2]

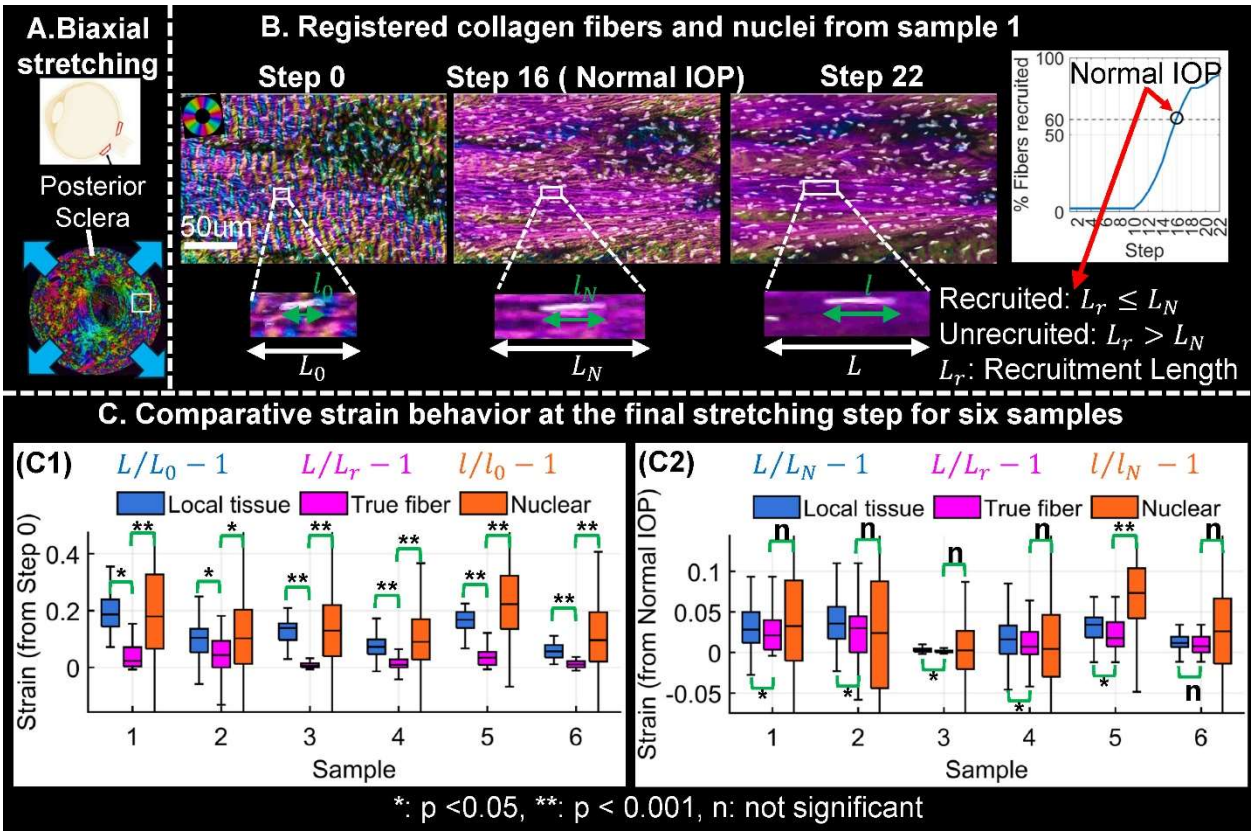
Introduction

Tissue mechanical behavior varies across scales. To understand how cells (predominantly fibroblasts) respond and drive scleral remodeling under abnormal intraocular pressure (IOP), it is important to examine mechanics not only at the tissue level but also at the collagen fiber and nuclear levels. Collagen fiber uncrimping and recruitment are established drivers of nonlinear tissue mechanics, but their effects at these smaller structural levels remain unclear. We quantified tissue, fiber, and nuclear strains under biaxial loading to determine how uncrimping and recruitment influence nuclear deformation within the scleral microenvironment.

Methods

Coronal sections (16 μm) from six sheep optic nerve heads were mounted on a custom biaxial stretcher and imaged at each stretch step with instant polarized light microscopy for collagen orientation and DAPI fluorescence for nuclei (Fig. 1A–B). Using previously reported methods we measured collagen fiber bundle length and waviness [1]. From these, we determined % fiber recruitment, and the stretch step corresponding to normal IOP (earliest step with 60% or higher fiber recruitment) (Fig. 1B). Nuclei were segmented and tracked using Cellpose [2]. Three measures of strain were computed at the final stretching step: local tissue strain (fiber bundle length changes), true fiber strain (post recruitment strain of the same bundle), and nuclear strain (nuclear major axis length changes). Each measure was calculated relative to both Step 0 and Normal IOP (Fig. 1C). We used the Wilcoxon signed rank test to compare tissue and fiber strains, and the Wilcoxon rank sum test to compare fiber and nuclear strains.



Results

Using Step 0 as reference, tissue and nuclear strains exceeded fiber strain in all samples (Fig. 1C1). When Normal IOP was used as reference, a configuration in which 60% or more fibers are already recruited, nuclear and fiber strains did not differ significantly in five samples (Fig. 1C2).

Discussion

These results suggest that nuclear strain amplification arises during collagen uncrimping at lower IOP and disappears after fiber recruitment. Thus, fiber recruitment emerges as a key regulator of the nuclear mechanical environment, with implications for scleral remodeling and glaucoma progression.

Early Post-Injury Gait Deviations Predict Long-Term Hindlimb Kinematic Impairment After Medial Meniscal Transection in Rats

Dr. Seyed Mohammadali Rahmati PhD[1], Dr. Jarred M. Kaiser PhD[2,3], N/A Morgan Daly BS[4], N/A Kaylee Lowe BS[4], N/A Austin Moyer BS[4], Dr. Liang-Ching Tsai PhD[4], Dr. Young-Hui Chang PhD[1]

Introduction

Altered knee biomechanics after injury increase osteoarthritis (OA) risk, suggesting that gait deviations may reflect pathways to degeneration and provide prognostic information. The ability to predict late-stage gait deviations based on early post-injury changes may enable targeted interventions to reduce long-term impairments. To characterize the temporal relationships among gait deviations, we quantified bilateral 3D joint angles in rats with medial meniscal transection (MMT) at Pre-surgery and at 2-, 4-, 6-, and 8-weeks (W) post-surgery. The MMT model induces detectable early-stage OA by 3W post-injury and progresses to moderate-to-late-stage OA by 8W. We hypothesized early kinematic changes predict 8W deviations, with differing strengths among stages. We also hypothesized a nonlinear recurrent neural network (RNN) would enable earlier and more accurate predictions than linear regression.

Methods

Thirty-one rats underwent MMT of the left hindlimb, with 26 used to train linear regression and RNN models and 5 held out for RNN evaluation. Biplanar X-ray fluoroscopy was processed with deep-learning key point detection and singular-value-decomposition–based bone registration to reconstruct joint kinematics (Figs. 1(a),(b)). Linear regression and the RNN used identical inputs and outputs, mapping Δ2W-Pre, Δ4W–Pre, or Δ6W-Pre joint-angle deviations to Δ8W-Pre.

Results

Experimental joint kinematics diverged markedly from Pre-surgery patterns at 2W, showed partial recovery at 4W, and diverged again at 6W. By 8W, deviations were pronounced and similar across rats, reflecting a characteristic OA gait. Consistent with the first hypothesis, the predictive strength of early post-surgery deviations for 8W gait deviations varied across stages. For linear regression, 6W inputs produced the strongest correlations with 8W

outcomes (Fig. 1(c)), whereas the RNN achieved lowest errors with 4W inputs (Figs. 1(d),(e)).

Discussion

Our data reveals that the non-linear structure of RNN can predict moderate-to-late stage OA gait by 4W post-injury in the MMT model, which is earlier than linear regression that was most predictive at 6W. Our preclinical approach enabled a repeatable model for measuring gait progression during post-traumatic OA in a controlled, accelerated timeline, but suggests that a similar approach could be adapted to provide early clinical prognosis to enable effective management through rehabilitation.

Kneeformatics: Deriving Knee-Specific Motion Signature from Static Medical Imaging

Dr. Ahmet Erdemir PhD, Ms. Snehal Chokhandre MS

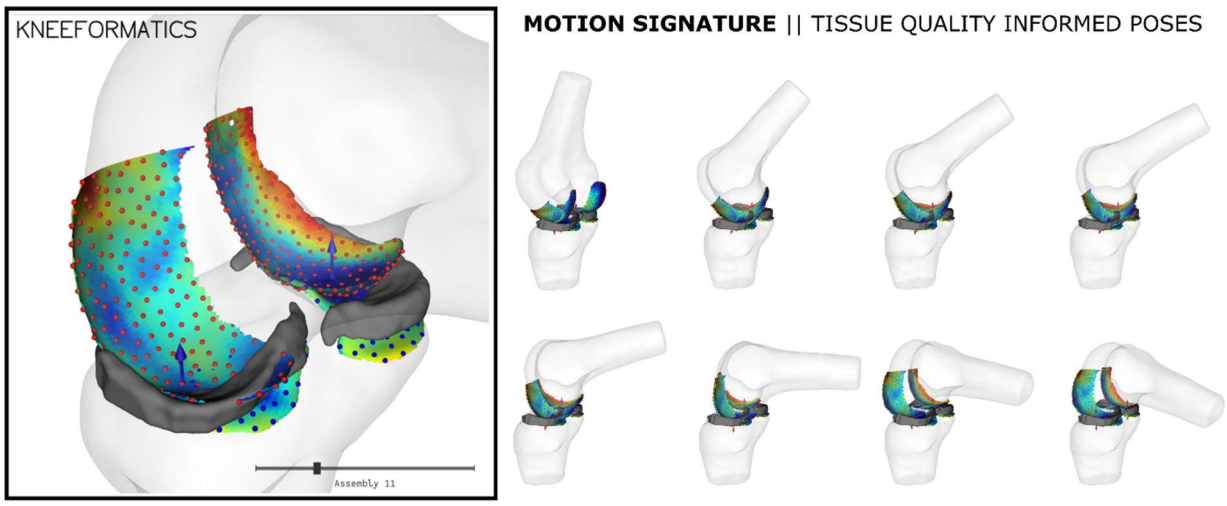
Cleveland Clinic Research, Cleveland, Ohio, United States

Introduction

Knee injuries and disorders are significant burdens on quality of life. Since each knee has unique mechanics that affect mobility, pathology and recovery, it is imperative that individualized movement patterns of the knee are taken into consideration for diagnosis, risk assessment, and planning of interventions. However, determination of movement metrics is mostly a research endeavor that requires sophisticated biomechanical experimentation or physics-based computational modeling that are neither comprehensive nor clinically proven. Recently, we have developed Kneeformatics to deliver knee-specific movement qualities directly by processing static clinical imaging data such as MRI or CT [1]. In this study, we will demonstrate how we use Kneeformatics to determine the knee-specific motion signature.

Methods

Kneeformatics leverages bone, cartilage and meniscus geometries obtained from clinical imaging. A combinatorial contact location sampling pairs points on medial and lateral articulations of tibia against those of the femur. For each point set, optimization aligns contact locations to calculate tibiofemoral translations and rotations. Resulting kinematic configurations are further reduced by removing poses with non-physiological penetration of articulating surfaces (including menisci). Bone quality is also mapped on each point on the articular surfaces by determining the average of image intensity across a kernel volume attached to the articular surface point and oriented towards the subchondral region. High bone quality regions are indicators of frequent and high mechanical loading and thus their alignment across opposing articular contact surfaces denote frequented joint kinematic configurations where joint loads are transmitted, i.e., motion signature.



Results

Determination of motion signature was demonstrated by using data from Open Knee(s) [2]. A sample set of poses are shown for oks003, that were determined by filtering and ranking poses that align high intensity locations of femoral and tibial contact (e.g., blue areas).

Discussion

Knee-specific motion signature can be useful for individualized assessment of injury risk or disease progression. It can support personalization of implant surgery and rehabilitation. This advancement provides a pathway for comprehensive characterization of knee biomechanics compatible with existing clinical workflows where imaging is readily collected.

Adaptation to Repeated Slip-Like and Trip-Like Perturbations During Walking in Older Adults With Mild Cognitive Impairment

Ms. Jessica Pitts, Dr. Tanvi Bhatt

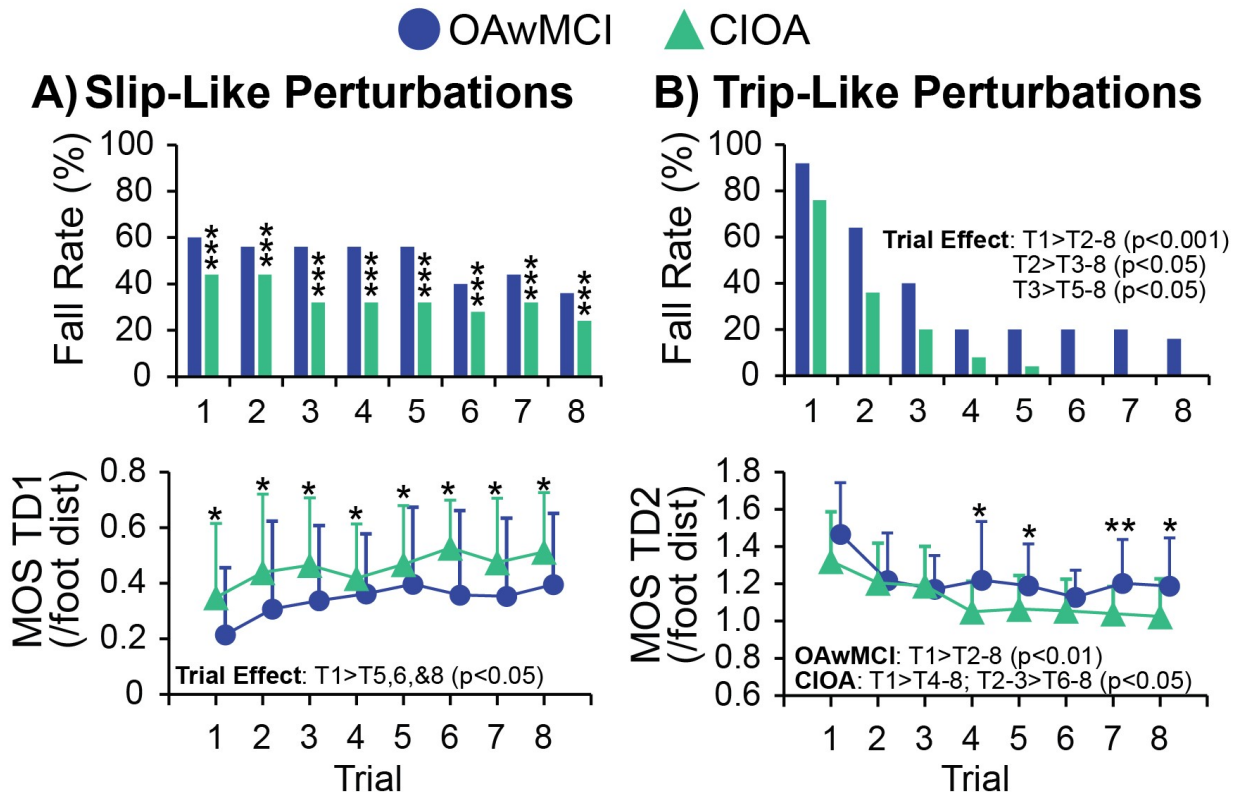
University of Illinois at Chicago, Chicago, IL, United States

Introduction

Older adults with mild cognitive impairment (OAwMCI) show impaired reactive balance control and 2x higher fall risk compared to cognitively intact older adults (CIOA). In CIOA, repeated perturbation exposure induces rapid, trial-by-trial motor adaptations that improve reactive balance responses. However, it is unknown if OAwMCI can acquire similar adaptations due to pathological deficits in sensorimotor integration/motor learning. Therefore, this study examined trial-by-trial adaptations to slip-like and trip-like perturbations in OAwMCI vs. CIOA.

Methods

25 OAwMCI (Montreal Cognitive Assessment (MoCA): 18-25) and 25 CIOA (MoCA: 26-30) experienced 8 slip-like (S1-8) and 8 trip-like perturbations (T1-8) during treadmill walking. Slips and trips were induced by sudden belt deceleration (-6 m/s^2) or acceleration (5 m/s^2) to induce a backward or forward loss of balance (respectively). An overhead load cell detected falls (>30% body weight), and 2x8 GLMs examined the effects of group (OAwMCI, CIOA) and trial (1-8) on fall rate. Similar 2x8 ANOVAs assessed margin of stability (MOS), recovery step length, hip height, and trunk angle at first and second recovery touchdowns (TD1, TD2).



Results

For slips, fall rate was higher in OAwMCI vs. CIOA ($p<0.001$), although did not significantly change across trials ($p>0.05$). MOS at TD1 was more stable on S5-8 vs. S1 in both groups ($p<0.05$), although lower overall in OAwMCI ($p=0.018$). Step length at TD1 was longer in both groups on S5-6 vs. S1 ($p<0.05$). For trips, fall rate showed no group differences, although decreased significantly across T1-5 ($p<0.001$). MOS at TD2, step length at TD1, and trunk angle at TD2 had significant group*trial interactions ($p<0.05$), with CIOA showing greater improvements than OAwMCI (improved stability, longer step length, less trunk flexion).

Discussion

Both groups acquired adaptive improvements which improved reactive COM stability and/or reduced fall rate, including longer recovery step length (backward for slips, forward for trips) and decreased trunk flexion (for trips). However, OAwMCI improved less than CIOA and could not reach the same performance level, which could be attributed to issues updating/accessing the internal model (plans for future responses based on prior sensorimotor feedback). Thus, reactive balance training for OAwMCI may benefit from tailored dosages/adjunct approaches.

Older Adults Demonstrate Altered Biomechanical Control of Their Lateral Center of Mass Trajectory in Response to Weighted Vest Walking

Ms. Nancy Nguyen[1], Dr. Carrie Earthman[1], Dr. Jocelyn Hafer[1], Dr. John Jeka[1], Dr. Noah Rosenblatt[2], Dr. Jeremy Crenshaw[1]

[1]University of Delaware, Newark, DE, United States. [2]Rosalind Franklin University of Medicine and Science, North Chicago, IL, United States

Introduction

Individuals with obesity have altered frontal-plane gait mechanics and impaired walking balance. We have developed methods to quantify how lead- and trail-limb mechanics contribute to the changes in the lateral center of mass (COM) velocity during gait. In our previous cross-sectional study, increased body size was associated with increased trail-limb contributions. It is unknown if this relationship was due to greater non-muscular mass or other concomitant factors associated with obesity. The purpose of this study was to determine the effects of added mass alone on lead- and trail-limb contributions to lateral COM motion.

Methods

Fifteen adults with healthy-weight (8F/7M; Age: 63.6 (3.1) years; BMI: 23.4 (2.3) kg/m^2) walked on an instrumented treadmill (speed=1.12 (0.3) m/s) with and without a weighted vest (15% body weight) at the same speed in each condition. The weighted vest was placed around the torso, with mediolateral symmetry prioritized as weight was added. We implemented a novel, force-plate-only approach to calculate lead- and trail-limb contributions to the lateral COM acceleration, based on the vertical projection of the COM and center of pressure (COP) positions and the vertical ground reaction force (GRF) (see Figure 1). To account for gait phase duration, acceleration curves were integrated over time to estimate a change in velocity for each limb contribution phase. Between-condition comparisons of these contributions were assessed with paired t-tests.

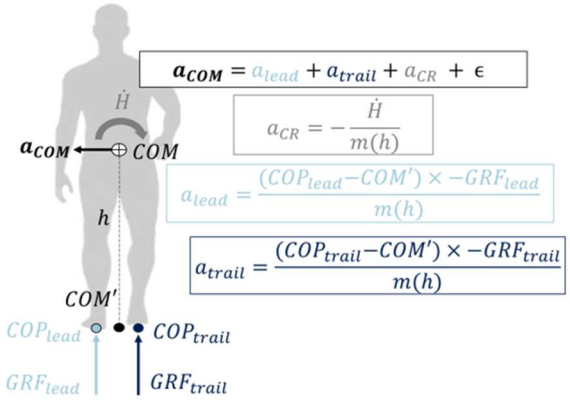
Results

Compared with unweighted walking, during weighted walking participants increased trail-limb contributions ($p=0.04$, $d=0.57$, Figure 1) by increasing relative GRF ($p<0.01$, $d=1.01$) and prolonging double support time ($p<0.001$, $d=1.12$). Additionally, participants decreased lead-limb contributions ($p=0.001$, $d=-1.07$, Figure 1) due to smaller relative GRF ($p=0.04$, $d=-0.59$) and smaller lateral distance between the COM and COP ($p=0.001$, $d=-1.04$).

Discussion

During weighted walking, individuals demonstrated altered biomechanical control of their lateral COM trajectory. The results for trail-limb contributions align with what we observed in our cross-sectional study of those with and without obesity. However, in our cross-sectional study, we observed no relationship between lead-limb contributions and body size. Therefore, we cannot rule out the influence of concomitant factors associated with obesity such as thigh circumference, musculoskeletal diseases, or proprioception deficits on lead-limb mechanics.

Images (Optional)



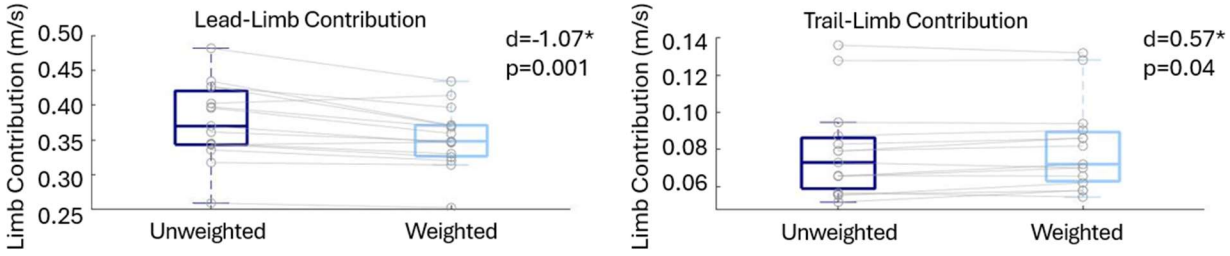


Figure 1. Representation of limb contributions to center of mass acceleration. Limb- and phase-specific contributions to lateral COM trajectory was assessed through lead- (light blue) and trail- (dark blue) limb contributions to mediolateral (ML) center of mass acceleration (a_{COM}), based on center of pressure location ($COP_{lead/trail}$), mediolateral COM position (COM'), vertical ground reaction force ($GRF_{lead/trail}$), body mass (m), and COM height (h). All measures were derived from force-plate recordings.

Not All Movements Are Equal: Balance Recovery Across Daily Movements in Older Adults

Ms Nikita Sharma MSc Biomedical Engineer[1], Dr. Marko Ackermann[2], Prof. Dr. Simon Steib[1], Dr. Lizeth H. Sloot[3]

[1]University of Heidelberg, Heidelberg, Baden-Württemberg, Germany. [2]Karlsruhe Institute of Technology, Karlsruhe, Baden-Württemberg, Germany. [3]Newcastle University, Newcastle, North East England, United Kingdom

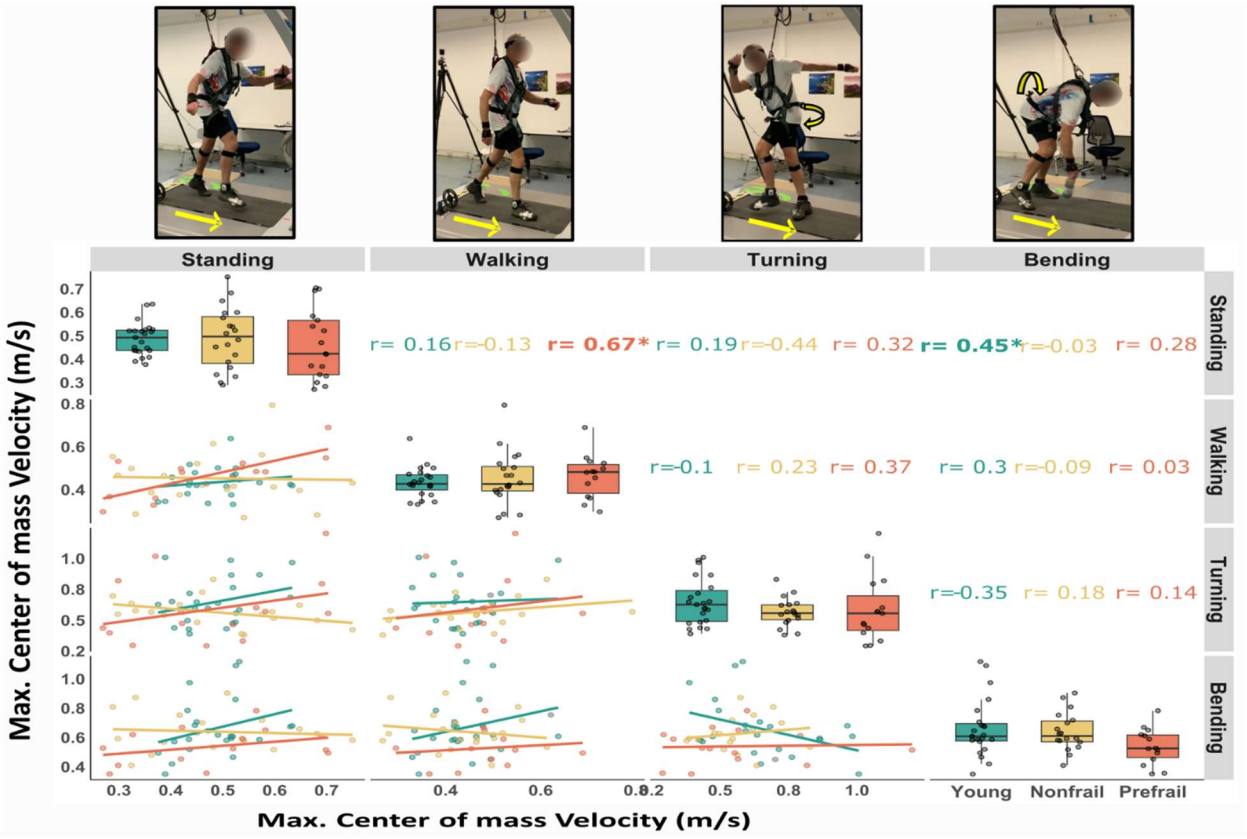
Introduction

Older adults fall during different daily movements [1]. These movements impose different balance challenges – e.g. turning requires more lateral than forward control in walking, potentially affecting someone's ability to recover balance after a destabilizing perturbation. However, balance is mostly assessed during steady-state walking, and not at someone's maximum recovery ability. This study evaluated whether an individual's maximum balance recovery ability depends on movements and age.

Methods

Twenty non-frail (72±5 yrs), 15 pre-frail (84±5 yrs; basis fried frailty scale, [2]) older and 23 younger adults (25±3yrs) underwent unexpected treadmill belt accelerations of increasing magnitude (until >3 recovery steps or stop requested) during standing, walking, in-place turning, and bending forward. An IMU suit recorded full-body kinematics. Balance recovery was quantified as the peak centre of mass velocity excursion during the highest magnitude perturbation window and compared between movements (relative within the group) using Spearman's rank-order correlations, which were compared between groups using Fisher's r-to-z transformation.

Results



As expected, pre frail reached lower magnitudes for each movement compared to non-frail ($p_{friedman}<0.0001$) and young ($p_{friedman}<0.0001$), but still had comparable COMvel excursions ($p_{Kruskal\text{-}Wallis} \geq 0.1$). Individual balance recovery ability was not correlated between movements (each group, all movements: $r<0.5$, $p>0.5$; Fig 1), except turning and bending ($r=0.45$, $p<0.05$) in young and standing versus walking ($r=0.67$, $p\leq0.01$) in the pre-frail. This correlation did not differ between groups except for a stronger standing-walking

association in prefrail adults versus young (z=2.12, p<0.05) and non-frail (z=2.19, p<0.05) adults.

Discussion

Our unique approach exploring balance recovery at an individual's limit and across daily movements revealed that balance recovery is movement-specific, with balance issues in one movement (eg. walking) not predicting issues in another (eg. turning). We found movement-specificity for both young and older adults, although we didn't measure frail older adults. Next, we will analyse balance recovery strategies underlying these differences between movements using angular momentum. These results indicate we need to rethink our focus on balance recovery during gait and tailor balance training to an individual's movement-specific balance deficits.

Advanced Age Alters Joint-Level Planning for and Response to Walking Perturbations

Dr. Emily Eichenlaub[1], Dr. Jessica Allen PhD[2], Dr. Vicki Mercer PT, PhD[3], Dr. Jeremy Crenshaw PhD[4], Dr. Jason Franz PhD[1]

[1]University of North Carolina at Chapel Hill and North Carolina State University, Chapel Hill, NC, United States. [2]University of Florida, Gainesville, FL, United States. [3]University of North Carolina Chapel Hill, Chapel Hill, NC, United States. [4]University of Delawar, Newark, DE, United States

Introduction

When preparing for and responding to a walking balance challenge, lower extremity joint moments are used to regulate angular momentum to mitigate instability and prevent a fall [1]. Age-related deficits in motor planning and execution may elicit altered joint angular impulse control strategies to mitigate that instability, potentially increasing the risk of falling. Compounded by diminished muscle strength and power, we would further suspect that these age-related differences are disproportionately larger following unanticipated perturbations. This study investigated age- and anticipation-related differences in lower extremity joint-level proactive and reactive balance strategies via joint angular impulses. We hypothesized that older adults would exhibit greater reactive responses to balance challenges than younger adults, particularly when unanticipated.

Methods

15 younger adults (10F; age: 22.3±3.3 years; walking speed: 1.41±0.14 m/s) and 15 older adults (9F; age: 73.6±5.5 years; walking speed: 1.28±0.20 m/s) responded to treadmill belt perturbations delivered at the instant of heel-strike in which the belt accelerated or decelerated over 200 ms at 6 m/s^2 delivered either unexpectedly (i.e., unanticipated) or at the end of a 3-s verbal countdown (i.e., anticipated) in a randomized order. We calculated hip, knee, and ankle joint angular impulses during the preceding, perturbed, and recovery strides and compared between groups, focusing here on age × anticipation interaction effects.

Results

We found no age × anticipation interaction effects during the preceding stride for either perturbation direction (p-values>0.05). Compared to anticipated accelerations, unanticipated accelerations elicited larger (older adults) and smaller (younger adults) ankle dorsiflexion angular impulses during the perturbed stride (interaction, p=0.038) (**Fig. 1A**). Compared to anticipated decelerations, unanticipated decelerations elicited larger

(older adults) and smaller (younger adults) knee extension angular impulses during the recovery stride (interaction, $p<0.001$) (**Fig. 1B**).

Discussion

Anticipation-related difference in proactive lower-extremity angular impulses did not differ with age. The same is not true for reactive responses, which are fundamentally altered compared to younger adults. These findings elucidate aging effects on dynamic strategies to plan for and respond to walking balance challenges, which may inform roadmaps for prioritizing targeted interventions to decrease older adults' risk of falling.

Dynamic Compression Moderates Rate Dependent Tensile Mechanics in the Annulus Fibrosus

Mr Craig Almeida, Dr. Jill Middendorf, Ms Victoria Allen, Mr Shunyu Tan

Johns Hopkins University, Baltimore, MD, United States

Introduction

The annulus fibrosus (AF) experiences multiaxial loading. Thus, constitutive models that accurately predict multiaxial mechanics are important for understanding disc degeneration. Prior biaxial experiments showed that constant high-magnitude axial compression alters AF tensile mechanics, but AF mechanics under a more physiological dynamic low-magnitude compression with simultaneous tension remain unknown[1]. This loading is clinically relevant, especially as degeneration shifts compressive load from the nucleus pulposus to the AF[2]. This study examines how increasing dynamic axial compression influences circumferential tensile mechanics in the AF and how this loading alters parameters from existing constitutive models.

Methods

Rectangular porcine AF samples were prepared (Fig.1a,N=3). Control data consisted of three uniaxial tensile tests in the circumferential direction at 0.02%/s, 0.01%/s, and 0.0067%/s up to 10% strain magnitude. Biaxial tests added simultaneous axial compression of 10%, 20%, or 30%. Compression was applied at 0.02%/s, while tensile rate was adjusted to match total loading time. Percent changes in toe modulus, linear modulus, and peak stress relative to the 0.02%/s uniaxial case quantified differences between uniaxial and biaxial loading. Material parameter differences were obtained by fitting all data to a fiber-matrix-interaction constitutive model[3].

Results

Reducing the tensile loading rate from 0.02%/s to 0.0067%/s reduced the toe modulus, linear modulus and peak stress across all samples (Fig1:b-d). During simultaneous biaxial loading, the percent decreases in tensile properties (toe modulus, linear modulus and peak stress were smaller than those observed under rate-controlled tension alone, indicating that a simultaneous axial compression reduces the influence of tensile loading rate (Fig1:b-d). Increasing compression further reduces this influence. Constitutive modelling revealed that parameters fit to rate-controlled data do not fit well to the biaxial data (Fig1:e-g).

Discussion

Unlike prior work showing reduced tensile stress under constant high compressive preload, the low-magnitude dynamic compression used here did not reduce tensile stress. Although the mechanism is unclear, the authors believe poro-viscoelastic effects to reduce the influence of tensile loading rate during simultaneous compression. However, uniaxial coefficients still failed to predict multiaxial behavior, underscoring the need for multiaxial experiments to improve AF mechanical models and enhance predictions of spinal degeneration.

Images (Optional)

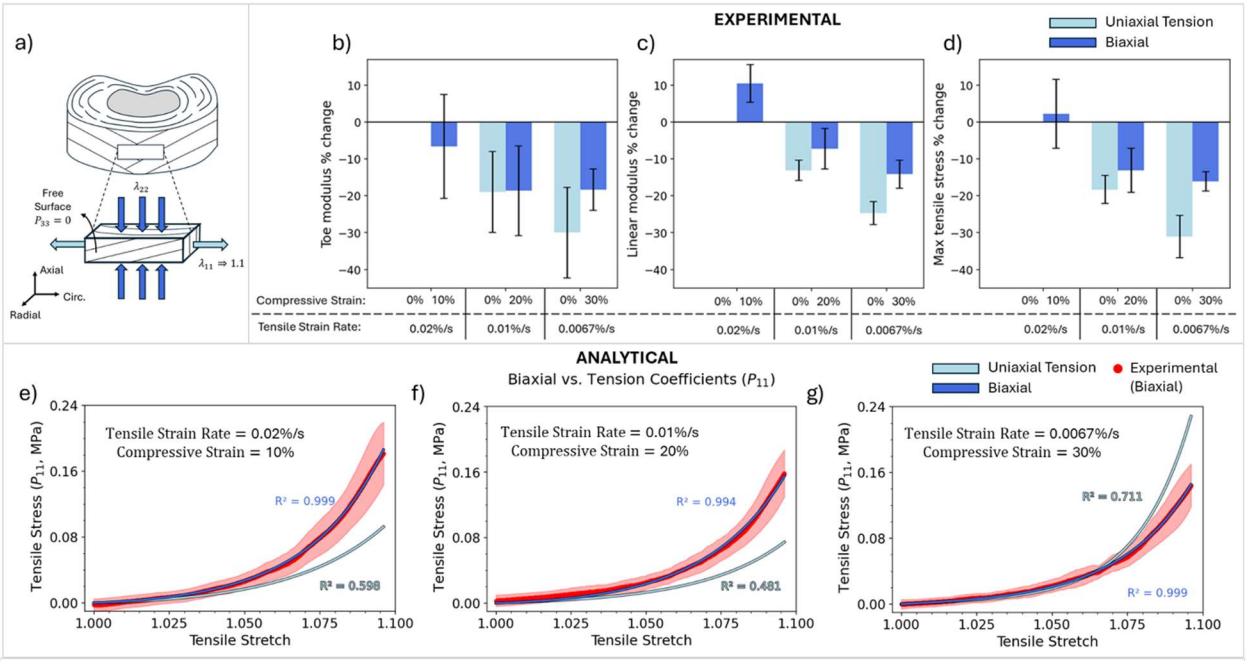

Fig.1: Schematic shows sample preparation and boundary conditions (a). Simultaneous compressive load reduces the influence of tensile strain rate on the tensile subfailure mechanics (b-d). Coefficients fit to biaxial experimental data fit well. However, those fit to the uniaxial tensile data do not fit well to the biaxial data (e-g).

Quantitative Magnetic Resonance Imaging of Age-Related Adaptations to Glenoid Labrum Health

Ms. Colleen Vogel[1], Dr. Kwan-Jin Jung PhD[1], Ms. Denali Hutzelmann[1], Dr. Heath Henninger PhD[2], Dr. Caleb Cordes PhD[3], Dr. Matthew Hanks PhD[1], Dr. Joshua Leonardis PhD[3]

[1]University of Illinois at Urbana-Champaign, Urbana, IL, United States. [2]University of Utah, Salt Lake City, UT, United States. [3]The Ohio State University, Columbus, OH, United States

Introduction

The glenoid labrum is a fibrocartilaginous structure essential for shoulder stability, yet it is prone to degeneration and injury over the lifespan. Age-related collagen loss may influence labral integrity, but quantitative *in vivo* assessments remain limited. Ultrashort echo time magnetic resonance imaging (MRI) with magnetization transfer (UTE-MT) enables measurement of macromolecular fraction (MMF), a biomarker for collagen content [1], offering a novel approach to evaluate labral health. This study quantified the effects of age, sex, and arm dominance on glenoid labrum MMF using UTE-MT.

Methods

Forty-five healthy adults (25 females, 20 males; mean age 45.3 ± 16.9 years) underwent bilateral shoulder MRI on a 3T scanner using double echo steady state (DESS) and custom UTE-MT sequences. Labral segmentation was performed in 3D Slicer using DESS images, and voxel-wise MMF was computed in MATLAB from UTE-MT images (Figure 1A). Linear models tested the primary hypothesis that MMF decreases with age and differs by sex, and the secondary hypothesis that arm dominance affects MMF.

Results

Males exhibited significantly higher mean MMF than females (40.4 ± 7.3% vs. 39.6 ± 7.2%; $p = 0.031$) (Figure 1B). Age alone did not significantly impact MMF ($p = 0.759$), but a sex-by-age interaction was observed ($p = 0.033$), with males showing a steeper decline across the lifespan (Figure 1C). Dominant arms demonstrated greater MMF than non-dominant arms (41.1 ± 7.6% vs. 38.8 ± 6.9%; $p = 0.008$), independent of sex (Figure 1D).

Discussion

UTE-MT imaging revealed sex-specific and arm dominance-related differences in labral collagen content, with males exhibiting higher MMF and greater age-related decline. This

may be driven by known sex- and age-related differences in sex hormones like estrogen, which play important roles in musculoskeletal tissue health and integrity [2]. Dominant arms demonstrated greater MMF, perhaps reflecting an adaptive response to repetitive use. These findings highlight UTE-MT as a promising tool for the early detection of labral degeneration and for understanding normative and pathological adaptations across the lifespan, supporting its potential role in preventive care and the personalized management of shoulder health.

Trunk Tissue Asymmetry and Its Association with Aging, Disc Degeneration, and Physical Activity in Asymptomatic Adults

Dr. Soumyadip Sen, Dr. Orod Gharibi, Dr. Lichun Lu, Dr. Robert Pignolo, Dr. Asghar Rezaei

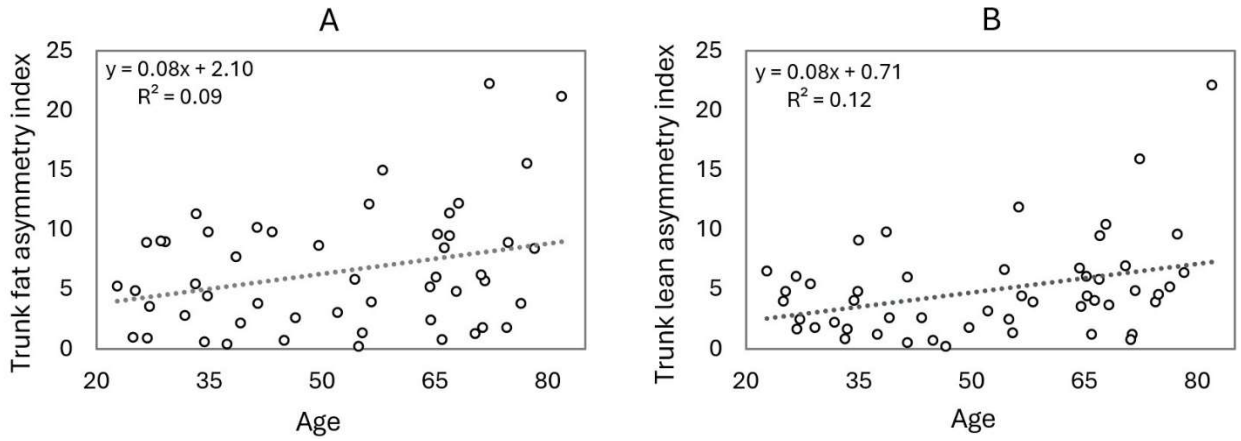
mayo Clinic, Rochester, MN, United States

Introduction

Aging is linked to the loss of muscle mass, increased fatty infiltration, and asymmetries in body composition, which collectively contribute to functional decline and disc degeneration (DD). These asymmetries arise from habitual daily activities and are evident in various domains, including muscle strength and movement patterns. Such asymmetries hold significant clinical relevance. Nevertheless, asymmetrical patterns of lean and fat mass within the trunk remain insufficiently investigated. This study seeks to examine the associations among mass asymmetry, age, DD, and physical activity levels in individuals without symptoms.

Methods

Clinically asymptomatic adults who had undergone magnetic resonance imaging (MRI) of the lumbosacral spine within the preceding three years were enrolled in the study. Participants underwent whole-body DXA scans to assess body composition, including lean mass, fat mass, and bone density. Degenerative disc disease (DD) was evaluated using the modified Pfirrmann grading system. Physical activity levels were measured using the International Physical Activity Questionnaire (IPAQ) short form. Subjects were stratified into two age groups—those younger than 55 years and those aged 55 years and older—to facilitate comparison of asymmetry between the groups.



Results

A study of 51 adults (19 men, 32 women; mean age 52.3 years) found significant left-sided dominance in trunk lean and fat tissue ($p<0.0001$), while legs were mostly symmetrical except for lean mass in those over 55 ($p=0.0094$). Trunk tissue asymmetry increased with age (Figure 1), but leg asymmetry did not. Mean DD grade correlated with age ($R^2=0.48$, $p<<0.0001$), but not with tissue asymmetry. In younger adults, combined models showed only age was significant. No link was found between patient-reported physical activity level and asymmetry, but trunk fat mass index varied between medium and high activity groups ($p=0.0251$).

Discussion

Trunk asymmetry is present in asymptomatic individuals across all age groups and becomes more pronounced with aging, but leg asymmetry appears only in older adults. Physical activity influences the amount of trunk fat but does not have any association with asymmetry. These findings highlight the need for early preventive strategies to maintain musculoskeletal balance and spinal health.

Labral Mechanics After Femoroacetabular Impingement (FAI) Related Surgery: An Integrated In Vitro Imaging Study

Mr. Mohammadreza (Hooman) Kheshti[1,2], Dr. Luke Beaton[1], Mr. Minh Khoi Doan[1], Dr. Matthew G. Teeter[1,2], Dr. Louis Ferreira[1], Dr. Ryan M. Degen[1], Dr. K.C. Geoffrey Ng[1,2]

[1]Western University, London, Ontario, Canada. [2]Robarts Research Institute, London, Ontario, Canada

Introduction

Cam-type femoroacetabular impingement (FAI) is a major cause of labral and cartilage injury and may progress to early osteoarthritis. Because the acetabular labrum plays a central role in joint stability, force distribution, and the suction seal, understanding how hip preservation procedures influence its deformation is critical. This study quantified labral strain across key surgical stages for FAI using a CT-integrated testing system, and imaging across multiple joint positions.

Methods

Twenty paired cadaveric hips (age 61 ± 9 years; 10 male, 10 female) without prior pathology were mounted on a CT-compatible positioning rig after removal of soft tissues. Each hip was CT imaged (Canon Aquilion ONE) in nine combined positions of flexion (0°, 60°, 90°)and axial rotation (neutral, internal, external rotation). Following capsulotomy, eight 0.8 mm titanium beads (4 labral, 4 acetabular) were placed in a curvilinear pattern. Paired hips were randomized to two surgical sequences: Protocol A**:** cam over-resection, labral tear, repair, and reconstruction with posterior tibial tendon; Protocol B**:** labral tear, repair, reconstruction, and cam over-resection, where the capsule was repaired after each stage. A custom MATLAB workflow extracted bead coordinates and calculated radial strain at each stage, where statistical analyses were assessed with Friedman tests and post-hoc Wilcoxon comparisons ($\alpha = 0.05$).

Results

In Protocol A, labral reconstruction consistently produced greater radial strain than the native and repaired states in all positions ($P < 0.01$; Figure 1.B1). In Protocol B, reconstruction with an open capsule increased strain at 90° flexion in internal rotation compared with native ($P = 0.03$; Figure 1.B2). With capsular closure at 0° flexion in external

rotation, reconstruction also generated higher strain than both the native and repaired labrum ($P < 0.05$).

Discussion

Labral reconstruction showed the highest strain, whereas cam over-resection and labral tears did not substantially change deformation compared to native hip. These findings also suggest the native labrum can keep the strain low after tissue changes. This work advances our understanding of how specific surgical steps alter labral mechanics and helps clarify whether increases or decreases in labral strain may place the hip joint at risk.

Images (Optional)

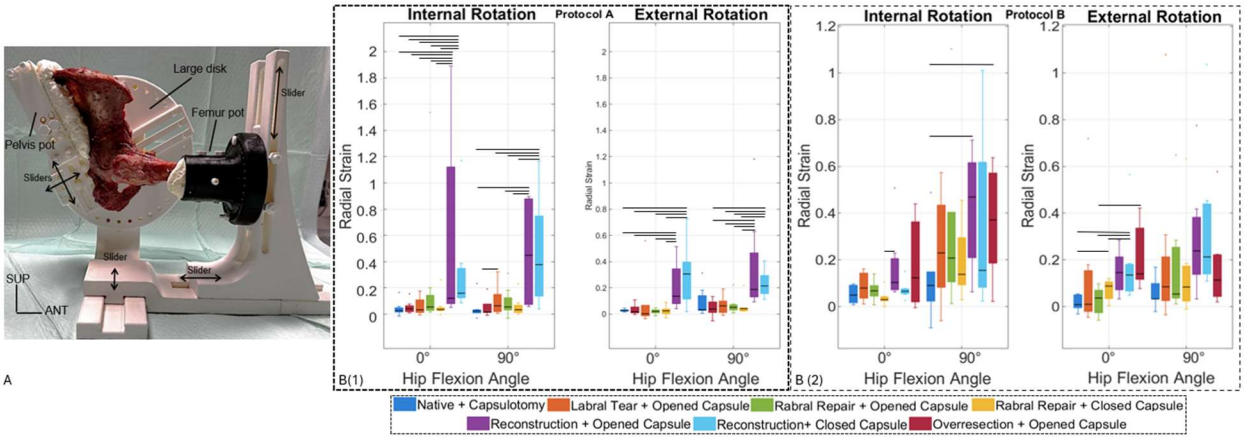

Fig 1. (A) Testing device compatible with clinical imaging with mounted cadaveric hip specimen in sagittal view (60° flexion and neutral rotation). (B) Box-and-whisker plots of radial strain under external rotation (ER) at 0°, 60°, and 90° flexion for Protocol A (B(1)) and Protocol B (B(2)). Different colors represent the tested conditions. Significant differences are denoted by asterisks: Protocol A with 2 asterisks ($P < .01$) and Protocol B with 1 asterisk ($P < .05$).

OA162-01

Sex-Differences in Vertical and Cross-Axis Vibration Transmissibility to the Sacrum and Head During Seated Whole-Body Vibration Exposure

Mr. Ian Scagnetti PhD (Candidate), Ms. Eliza Cazzola MASc., Dr. Megan Govers PhD, Dr. Michele Oliver PhD, PEng

University of Guelph, Guelph, ON, Canada

Introduction

Seated whole-body vibration (WBV) exposure is associated with musculoskeletal injuries (MSKI), including low-back and neck pain. Women are at increased risk during WBV exposure, but research to understand underlying factors is limited. Risk can be estimated by measuring vibration transmissibility (TR) where higher TR to the spine may indicate higher compression and/or shear forces. The objective of this work was to quantify sex-differences in vertical and cross-axis vibration transmissibility at the head and sacrum for eight discrete frequencies and two accelerations.

Methods

17 males (28 ± 6 yrs) and 22 females (26 ± 6 yrs) were exposed to 3 trials of seated vertical WBV including 16 combinations of acceleration (0.25 or 0.5 m/s2 RMS) and frequency (1,3,5,7,9,11,13, or 15Hz). Exclusion criteria included: back and/or pelvis injury and/or current pregnancy. Exposure orders were counterbalanced. Vertical acceleration was measured at the input, and triaxial accelerations were measured at the sacrum and head using ICP accelerometers. Accelerations were corrected to the basicentric coordinate system defined in ISO 2631-1 using motion-capture. Adjusted vertical and cross-axis TR were calculated using the RMS method (ISO 2631-1). Vertical and cross-axis TR were compared between participants using a repeated-measures MFANOVA including within-subject effects of acceleration and frequency, and a between-subject effect of sex. When appropriate, differences between means were assessed using Bonferroni-corrected pairwise comparisons.

Results

Females had significantly greater ($p<0.05$) vertical TR than males at the sacrum (7 Hz) and head (3, 13, 15 Hz). Approaching statistical significance, females had greater cross-axis TR than males in the fore-aft ($p = 0.066$) and lateral ($p = 0.057$) directions at the sacrum (7 Hz), and fore-aft direction at the head (5 Hz, $p = 0.053$).

Discussion

Females experience greater vertical and cross-axis TR than males at the sacrum and head, which may indicate increased compression and/or shear forces in the spine. Intervertebral joints have lower tolerance for shear forces associated with fore-aft and lateral TR, which may be contributing to increased injury risk for females. Sex-differences in regional body composition may contribute to TR sex-differences due to differing tissue properties and should be further investigated.

Predicting Sex Differences in Seated Whole-Body Vibration Transmissibility Using Body Composition and Anthropometric Measures

Mr. Ian Scagnetti PhD (Candidate), Ms. Eliza Cazzola MASc., Dr. Megan Govers PhD, Dr. Michele Oliver PhD, PEng

University of Guelph, Guelph, ON, Canada

Introduction

Mobile machine operators are exposed to whole-body vibration (WBV) which is associated with back and neck injuries, with women at increased risk. WBV risk can be estimated by quantifying vibration transmissibility (TR). TR characterizes how vibration travels through the body where increased TR may indicate higher spine compression and/or shear forces. Work investigating sex-differences in WBV exposure risk is limited; however, understanding sex-specific TR may help inform vibration mitigation strategies. Exposing participants to vertical vibration, the objective of this work was to predict vertical (z-axis) and cross-axis (x- and y-axes) TR at the head and sacrum between males and females using regional anthropometric and body composition measurements.

Methods

17 males (28±6 yrs) and 22 females (26±6 yrs) were exposed to 0.25 m/s 2 seated vertical sinusoidal WBV at eight discrete frequencies (1,3,5,7,9,11,13,15Hz). Exclusion criteria included: back and/or pelvis injury within the past 4 years and/or current pregnancy. Vertical acceleration was measured at the input, and triaxial accelerations were measured at the sacrum and head. Vertical and cross-axis TR were calculated using the RMS method (ISO 2631-1). Anthropometric measurements (mass, height, seated height, and chest/waist/hip circumferences) were taken using a scale, stadiometer, and measuring tape. Body composition measurements (bone-mineral density, lean mass% and body fat%) were determined using dual-energy x-ray absorptiometry. Vertical and cross-axis TR were predicted using multiple stepwise linear regression models for anthropometric and body composition measures. Lean mass% was omitted to avoid multicollinearity with body fat%.

Results

Significant results ($p<0.05$) are presented in table 1.

Discussion

Males with greater chest, hip and waist circumference and greater body fat%, and females with greater hip circumference and mass may be at increased injury risk due to vertical and cross-axis vibration TR during vertical WBV exposure. Greater cross-axis TR is associated with increased shear forces at the spine, where tolerance for shear forces is much lower than for compression. The most important cross-axis TR predictors for males were hip and waist circumference and body fat% whereas for females they were hip circumference and mass. Vibration mitigation strategies that consider sex-specific TR predictors may reduce injury risk.

Images (Optional)

Table 1: **Transmissibility predictors for males and females**. Results from multiple stepwise linear regression models predicting vertical (z-axis) and cross-axis (x- and y-axes) transmissibility by anthropometric and body composition measurements for males and females. Predictors were included if $p<0.05$ and adjusted $R^2>0.4$.

Sex	*Location (axis)*	*Variable*	*p-value*	*Adj. R^2*	*Unstandardized β*
Male	Head (x)	Hip Circumference	<0.001	0.608	0.012
	Head (z)	Waist Circumference	<0.001	0.625	0.059

Effects of Accelerometer Orientation and Sex on Transmissibility During Seated Whole-Body Vibration Exposure

Ms. Eliza Cazzola B.Eng, MASc[1,2], Mr. Ian Scagnetti MSc, PhD Candidate[1], Dr. Megan Govers[1], Dr. Michele Oliver P.Eng[1]

[1]University of Guelph, Guelph, Ontario, Canada. [2]HumanSystems Inc., Guelph, Ontario, Canada

Introduction

Whole-body vibration (WBV) exposure from heavy mobile machinery operation can result in back injuries, with females at greater injury risk than males. Transmissibility (TR) is one way to quantify injury risk associated with WBV exposure. It is measured using accelerometers and defined in a basicentric coordinate system (BCS) according to ISO 2631-1. The internal axes of accelerometers attached to the sacrum (S1) and thoracic spine (T6) have been shown to deviate from the BCS dependent on participant sex, however, the effects on TR measurements are unknown. The objectives of this work were to determine the effect of correcting accelerometer orientation on TR at S1 and T6 and to investigate sex differences in original and corrected TR.

Methods

17 males (28.6±6.2 years) and 22 females (26.0±6.5 years) were exposed to 16 vertical sinusoidal vibrations (1,3,5,7,9,11,13, and 15Hz at 0.25 and 0.50m/s^2) while sitting upright on a rigid seat with no backrest. Four orthogonal motion capture markers were attached to a tri-axial accelerometer at S1 and a uniaxial accelerometer at T6. Acceleration data were corrected to the BCS using motion capture data. Vertical and cross-axis TR to S1 and vertical TR to T6 were calculated using original and corrected accelerations. Differences in TR between orientations and sexes were examined using a mixed factorial ANOVA (p<0.05).

Results

At T6, females had significantly greater vertical TR than males, and the differences were greater with the corrected accelerations. At S1, female vertical TR at resonance (7Hz) was significantly larger by 1.5 times than males. Females had greater cross-axis TR at S1 at all frequencies and sex differences were greater in the corrected orientation. Cross-axis TR at S1 was significantly larger with the corrected accelerations.

Discussion

Accelerometer orientation had different effects on TR between males and females highlighting the importance of correcting acceleration to accurately measure TR for both sexes. Larger cross-axis TR with corrected accelerations suggests that fore-aft spine motion is underestimated when acceleration data are not corrected. Moreover, despite exposure to the same vertical input vibration, females experienced greater vibration transmission through the spine which may be associated with higher compressive and shear forces.

Investigation of an Objective Measurement of Lumbar Spine Segmental Stiffness

Dr. Erinn McCreath Frangakis BSc, DC, Dr. Jack P. Callaghan PhD

University of Waterloo, Waterloo, Ontario, Canada

Introduction

Clinical assessment of the lumbar spine commonly includes manual segment palpation via a posterior-to-anteriorly directed force. This test results in an inference of spinal stiffness, informing target treatment [1]. Because this methodology is subjective, devices have been developed to reduce clinician-based variability and objectify findings. The purpose of this study was to ascertain the variability of stiffness measurements across consecutive lumbar spine segments using such a device. It was hypothesised that there would be no difference in stiffness measurements.

Methods

Participants (n=9) were recruited from the University of Waterloo graduate student population. Individuals were included if they had no low back pain or injury in the last 12 months, no known deformity, malignancy, or inflammation of the lumbar spine, no history of spinal surgery, and were not currently pregnant. Participants were randomly assigned to two groups, which determined the starting order of spinal stiffness testing: cranial-caudal (e.g., L1-L5) or caudal-cranial. A spinal indentation device [2] applied known preloads (8 N) and forces (80 N) to each lumbar spinal segment through the spinous process. Load-displacement values were measured, and lumbar segmental stiffness was calculated. Stiffness values were averaged (three per segment) and smoothed using a 6^{th}-order polynomial function.

Results

Average smoothed stiffness curves demonstrate an increased stiffness at the level of L3 (5.54 N/mm ±1.7), with a descending trend in values cranially (4.94 N/mm ±1.6) and caudally (4.99 N/mm ± 1.16) *(Figure 1)*. Initial results suggest that while there is variability of lumbar spinal stiffness at the joint level, no significant differences were found between segmental levels ($F_{(4,28)}$=1.52; P=0.255).

Discussion

This study is the first to assess a spinal indentation device on multiple segmental lumbar spinal stiffness measurements. Preliminary data suggests that in healthy populations, this stiffness is consistent across the lumbar spine. Further work should look to establish

normal stiffness curves in healthy individuals and how these may deviate in a clinical population.

Powered Back Exoskeleton Reduces Epaxial Electromyography and Lumbar Moments During Lifting With Some Redistribution of Effort to the Lower Limbs

Dr. Grace Hunt[1], Dr. Tommaso Lenzi[1,2]

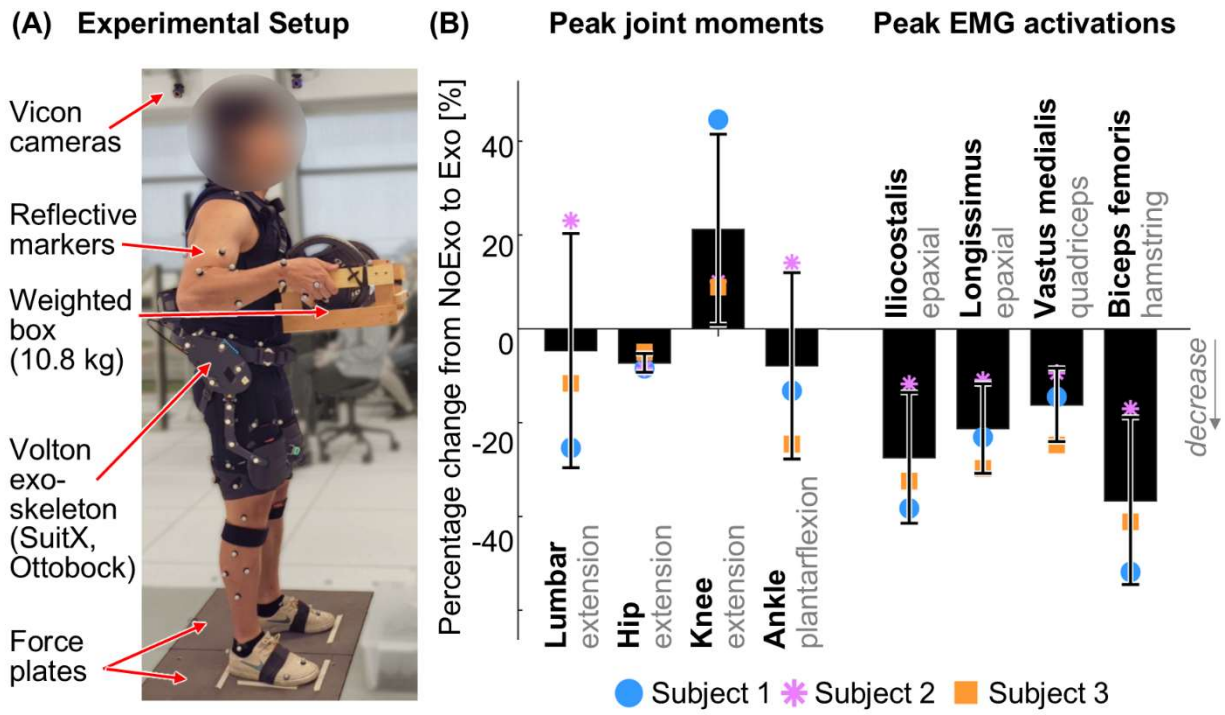
[1]HGN Lab for Bionic Engineering, Salt Lake City, UT, United States. [2]Rocky Mountain Center for Occupational and Environmental Health, Salt Lake City, UT, United States

Introduction

Powered back exoskeletons have the potential to prevent workplace injuries among manual material handlers by providing assistive torques as needed to reduce back strain [1,2,3]. However, powered back exoskeletons may have unintended consequences, like increasing joint and muscle effort in the lower limbs [1]. Unfortunately, no previous study has simultaneously evaluated lumbar and lower-limb muscle and joint effort with powered back exoskeletons. Therefore, the objective of this study is to assess the impact of a powered back exoskeleton on lumbar and lower-limb biomechanics during lifting. We hypothesize that a powered back exoskeleton can lower EMG activity in lumbar muscles and reduce lumbar moments with minimal impact on the lower limbs.

Methods

Three able-bodied subjects (2M/1F) lifted weighted boxes (10.8 kg) with and without a powered back exoskeleton (Volton, SuitX). We recorded full-body motion capture, forces, and electromyography (EMG) from bilateral epaxials (iliocostalis, longissimus), quadriceps (vastus medialis), and hamstrings (biceps femoris) [FigureA]. The biological lumbar moment was calculated by subtracting the exoskeleton moment from the net lumbar moment. Percentage changes in peak metrics (EMG and joint moments) from NoExo to Exo were calculated per side, then averaged across sides per subject. In time-domain figures, sides were averaged per subject. Cross-subject averages and standard deviations are reported.



Results

EMG peaks decreased in all measured muscles for all subjects with the exoskeleton (iliocostalis: 27.5±13.9%; longissimus: 21.3±9.6%; quadriceps: 16.2±7.8%; hamstring: 36.7±17.8%) [FigureB]. The exoskeleton decreased the lumbar moment (4.7±25.0%), hip moment (7.3±2.0%), and ankle moment (7.9±19.9%) on average, although it increased the knee extension moment (21.2±20.3%). Subject 2 responded to the exoskeleton with increased lumbar and ankle moments.

Discussion

The powered back exoskeleton reduced the average biological moments at the lumbar, hip, and ankle joints, while reducing the peak muscle effort of the lumbar and lower-limb muscles. However, knee extension torque increased with the exoskeleton. This study suggests that powered back exoskeletons can reduce workplace injuries and overuse by reducing lower back strain.

The Effects of Height and Sex on Two-Person Team Lifting

Ms. Joanna M. Misquitta[1], Mr. Ryan Chhiba[1], Mr. Ryan V. Hogan[1], Dr. Daanish M. Mulla[2], Dr. Peter J. Keir[1]

[1]McMaster University, Hamilton, Ontario, Canada. [2]York University, Toronto, Ontario, Canada

Introduction

Team lifting is used to handle heavy objects that exceed individual lifting capacity [1]. Despite its frequent use in the workplace, current guidelines and research are lacking. The purpose of this study was to examine the effects of height and sex on kinematics and kinetics during several two-person lifting tasks when pairs of lifters were matched and unmatched for height.

Methods

Twenty-three female and eighteen male participants made 19 unique height-matched (≤5cm) and unmatched (≥10cm) pairs and performed four manual materials handling tasks (knee-to-waist and chest lifts, left-right and forward-backward carries) using a 42.6kg apparatus. Upper body motion and hand forces were captured using marker-based motion capture and four 6-DOF force transducers affixed to each corner of the apparatus. Joint angles and moments for the shoulder, elbow, and trunk were determined in Visual3D.

Results

During knee-to-waist lifts in the matched condition, taller participants had greater trunk flexion, while shorter participants had greater shoulder extension and elbow flexion. These observations were amplified in the unmatched condition. During height matched knee-to-chest lifts, shorter participants had greater elbow flexion and trunk extension than taller participants. Shoulder extension was not significantly different between participants. In the unmatched condition, shorter participants had greater shoulder extension, while elbow flexion and trunk extension did not differ significantly between participants. During the carries, shorter participants had greater shoulder extension and elbow flexion, particularly in the unmatched condition. Taller participants had a more neutral trunk posture compared to shorter participants in both conditions. These posture changes were also noted in hand forces and internal joint moments. Further analyses will examine sex-based differences.

Discussion

Depending on the lifting task, height differences during two-person team lifting result in unique postural requirements for each lifter. Taller participants tend to adjust their shoulder posture, while shorter participants adjust using their elbows and trunk. These postures lead to differences in joint loading and injury risk, between both shorter and taller individuals as well as males and females. These findings provide evidence for the role of height differences in two-person team lifting to formulate guidelines for team lifting in the workplace.

A Non-Invasive Rat Model of ACL Rupture-Induced Osteoarthritis: Progression and Treatment Response Assessed by Mechanical and Histological Analysis

Ms. Jasmine Doan, Dr. Colleen Mathieu, Dr. Sotcheadt Sim, Dr. Eric Quenneville, Dr. Martin Garon

Biomomentum Inc, Laval, Quebec, Canada

Introduction

Osteoarthritis (OA) is a progressive joint disease causing cartilage loss, pain, and reduced mobility. Its prevalence—7.7% globally in 2021—is rising with aging and obesity. Animal models are essential for studying OA and testing therapies. Unlike traditional surgical ACL transection, non-invasive ACL rupture better mimics post-traumatic OA without surgical trauma. This study uses a refined non-invasive ACL rupture model in rats to track OA progression and evaluate intra-articular treatment.

Methods

Forty-four female Lewis rats (14-week-old) were assigned to Control(N=12), ACL Rupture Non-Treated(N=24), and Treated(N=8) groups. ACL rupture was induced mechanically using a custom fixture and Mach-1 tester, confirmed by anterior drawer test and necropsy. Treated rats received weekly Hyaluronan injections during weeks 4-6. Cartilage thickness and instantaneous modulus (IM) were measured at 4-, 7-, and 10-weeks using automated indentation mapping (~30 sites/surface). Histology included SafO/FG staining with OARSI and modified Mankin scoring. Data were analyzed by linear model.

Results

All injured joints showed complete ACL rupture with intact surrounding ligaments. In Non-Treated joints, significant thinning of the medial anterior condyle appeared by 4-weeks (p<0.001 vs. Control) and persisted through 10-weeks (Fig.1A). IM initially increased at 4- and 7-weeks before declining at 10-weeks (Fig.1C). The lateral condyle swelled between 4- and 7-weeks, then thinned at 10-weeks (Fig.1B), with IM stable until a final increase at 10-weeks (Fig.1D). Hyaluronan treatment mitigated these changes: Treated joints showed no significant differences in thickness or IM compared to Controls, though localized erosion was observed histologically. Non-Treated joints exhibited severe OA changes, including cartilage denudation in the medial anterior condyle by 7-weeks and bone remodeling by

10-weeks (Fig.1E). The lateral anterior condyle remained intact at 4-weeks but developed focal defects by 10-weeks.

Discussion

This non-invasive ACL rupture model reliably induces post-traumatic OA, revealing progressive structural and mechanical changes. Degeneration was most pronounced in the medial anterior condyle, consistent with increased load after ACL injury. Posterior and tibial regions also showed changes, indicating widespread biomechanical disruption. Treatment slowed mechanical deterioration but did not fully prevent structural damage. Overall, this model provides a clinically relevant platform for studying OA progression and testing potential treatments.

Development of an *In Vitro* Knee Model for Dynamic Biomechanical Evaluation of Meniscus Allograft Positioning

Dr Aiqin Liu PhD CEng MIMechE[1], Dr Blake McCall[2,3], Dr John Brewster[3], Dr Sanjeev Anand[4], Prof. Louise M Jennings[3]

[3]Institute of Medical and Biological Engineering, School of Mechanical Engineering, University of Leeds, Leeds, Yorkshire, United Kingdom. [4]Leeds Teaching Hospitals NHS Trust, Leeds, Yorkshire, United Kingdom

Introduction

Meniscus allograft transplantation (MAT) can restore meniscal function and alleviate symptoms, but graft extrusion remains common and may accelerate osteoarthritis progression. Extrusion is associated with root positioning, and can alter tibiofemoral contact mechanics; however, most previous studies examined biomechanical changes under static conditions rather than dynamic loading during gait. Therefore, we developed an *in vitro* knee model to evaluate how MAT root positioning influences joint kinematics, shear forces, and contact mechanics under dynamic loading.

Methods

Six human cadaveric knees were tested under four conditions: intact meniscus, anatomic MAT root position (original position), and two non-anatomic positions (5 mm medial or posterior shift; Fig. 1a). For each specimen, the native root was detached and refixed in these positions using validated techniques. A force-controlled gait profile was applied on a knee simulator to measure joint kinematics and shear forces, while contact mechanics were assessed under specimen-specific displacement-controlled profiles. Data were analysed using one-way repeated measures ANOVA ($p < 0.05$) to determine the impact of root positioning on knee biomechanics.

Results

Kinematic analysis showed no significant differences among conditions for anterior–posterior displacement, internal-external tibial rotation, or shear forces ($p > 0.05$; Fig. 1b–d). All MAT root positions significantly reduced contact area compared to the intact meniscus ($p < 0.05$; Fig. 1e), with the anatomic position (OgPos) restoring only 61–64% of

intact values. Average pressures were significantly higher for all root conditions compared to intact ($p < 0.05$; Fig. 1f), and peak pressure was significantly elevated for the anatomic and medial positions, while the posterior position did not show statistically significant increase (Fig. 1g). Peak pressure locations shifted posteriorly ($p>0.05$) and medially ($p < 0.05$) for all root conditions (Fig. h-i).

Discussion

MAT root positioning within ±5 mm of the anatomic site maintained knee stability but did not fully restore native contact mechanics, with all positions shifting contact pressure posteriorly and medially. These findings are consistent with previous evidence indicating MAT cannot fully replicate native knee biomechanics, and that altered load distribution remains a biomechanical challenge following transplantation. As this study used time-zero cadaveric models, future research should incorporate healing and remodelling effects and evaluate long-term clinical implications.

Acute Functional Instability and Long-Term Structural and Behavioral Changes in Mice After Medial Meniscus Destabilization

Ms. Olivia Dyer, Ms. Haylie Silbernagel, Mr. Ethan Stoecker, Dr. Stephanie Cone PhD

University of Delaware, Newark, Delaware, United States

Introduction

Medial meniscus destabilization (DMM) is used in mice to study disease progression, risk factors, and healing responses of post-traumatic osteoarthritis (PTOA) [1]. Prior rodent research has assessed changes *in vivo* gait, imaging, and *ex vivo* biomechanical testing [1,2]. Recent innovation in multiaxial robotic testing and movement tracking can improve research precision in the acute effects of DMM on knee function. The objective of this work was to measure immediate functional effects and long-term structural and behavioral changes in mice after DMM.

Methods

Female C57BL/6J mice underwent unilateral DMM (n=5) or SHAM surgery (n=5) [3]. During weeks 2 and 5 post-injury, animals were placed in a custom-built gait arena and activity was recorded for 10min. The total number of rearings was counted and total distance traveled was calculated via custom Python script. At week 6, animals were imaged, and trabecular bone properties were recorded (Bruker SkyScan 1276 Micro-CT). For preliminary robotic testing, a single knee was prepared, loaded with a 1.5N anterior drawer force in intact and DMM states, and resultant tibial translation was calculated [2]. Statistics included ANOVAs and t-tests.

Results

Both DMM and SHAM rearing counts decreased from week 2 to week 5. SHAM animals traveled significantly less distance per trial compared to DMM animals ($p=0.014$). On average, DMM tibiae had a bone mineral density of 0.39g/cm^2 and trabecular thickness of 0.066mm compared to 0.34g/cm^2 and 0.062mm in SHAM tibiae respectively. There were increases of 0.27mm resultant tibial translation, 0.25mm anterior tibial translation, and 0.19mm medial translation after DMM (Figure 1).

Discussion

The immediate effects of DMM injury increase both anterior and medial tibial translation. There were differences in activity between groups suggesting that the injury induces behavioral changes. Our microCT results found structural differences in tibial trabecular

bone in the DMM and SHAM mice potentially due to changes in loading and activity levels. Future work will include analyzing specific spatial-temporal gait changes in the mice as well as extending the injury development period from 6 to 8 weeks.

Images (Optional)

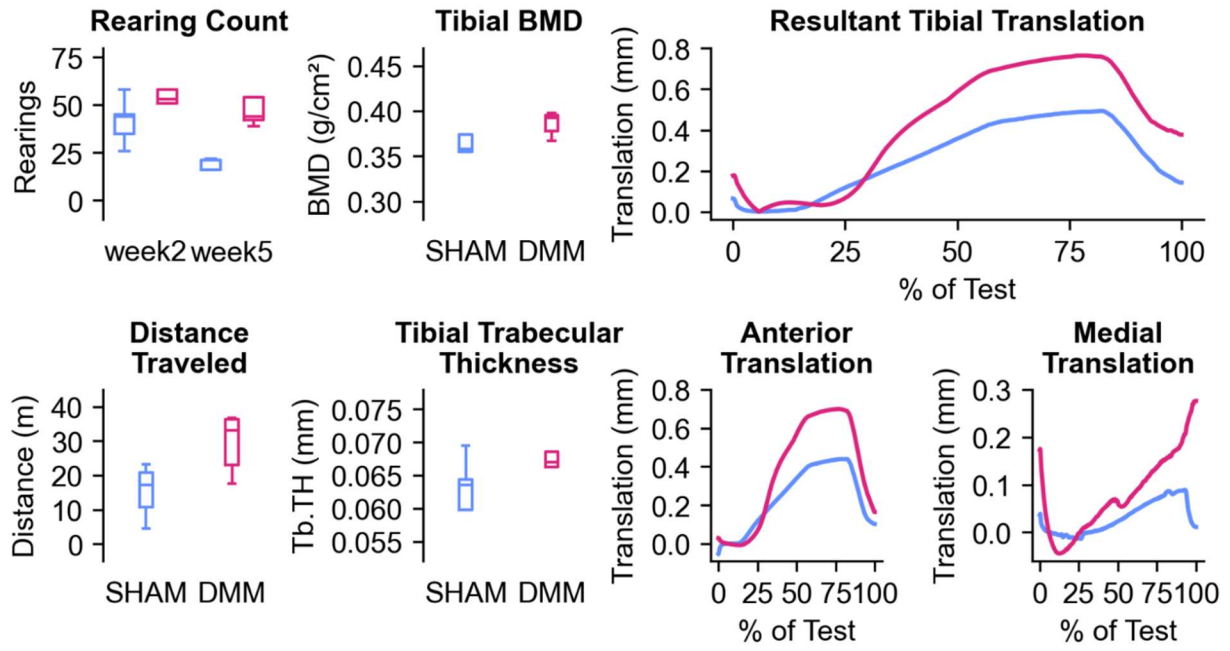

Figure 1. Number of rearings, distance traveled, tibial bone mineral density, tibial trabecular thickness were collected from SHAM (blue) and DMM (pink) injured mice. Eccentric Contraction Improves Functional Outcomes in a Rat Model of Traumatic Muscle Injury

Mr Fuad Bin Enam, Mr Michael Borovik, Mr Trent Hardwick, Mr Patrick Hinkle, Dr Koyal Garg, Dr Alex Reiter

Saint Louis University, Saint Louis, Missouri, United States

Introduction

Volumetric muscle loss (VML) is the irrecoverable loss of muscle resulting in functional impairment [1]. Rehabilitation, including treadmill and wheel running, has shown modest to no functional improvement following VML in animal models [2-3]. Recently, eccentric contraction (EC) has been effective in restoring function of injured tibialis anterior in rats [4]. This study explored the effects of EC on improving function in gastrocnemius injured muscle. A secondary purpose was to assess the capacity of tensiometry [5] adapted for rodents to capture improvements.

Methods

Twelve female Sprague Dawley rats (10-12 weeks old, 200-275g, Inotiv) were divided into three groups: control, VML, and VML+EC. VML groups received a gastrocnemius traumatic injury [6]. Two weeks post-injury, VML+EC received EC training twice per week for four weeks [4]. Both anterior and posterior crural muscles were stimulated while the ankle rotated from plantarflexion to dorsiflexion (±20°); animals received four sets of five stimulations with two-minute rest. At six weeks, muscle function was assessed via ankle torque and a tensiometer, which measures Achilles tendon wave speed, a surrogate for gastrocnemius force. Animals were anesthetized, the right foot secured in the pedal of the torque device, and the knee fixed in a clamp; the tensiometer was placed over the Achilles tendon. Isometric contractions were induced with varying frequencies to record peak torque and wave speed.

Results

Similar trends were captured in torque and wave speed with varying stimulation frequencies (Fig 1). VML had significantly lower torque and wave speed compared to control, but VML+EC showed non-significant reductions from control. VML was significantly reduced from VML+EC in ankle torque at 100Hz but not wave speed.

Discussion

These results highlight the potential for EC to improve function in gastrocnemius injured muscle following VML, building on the previous work in tibialis anterior. They also demonstrate the capacity for tensiometry to capture VML injury deficits and functional recovery. Future work will further optimize the EC protocol and the tensiometer and assess longitudinal recovery.

Images (Optional)

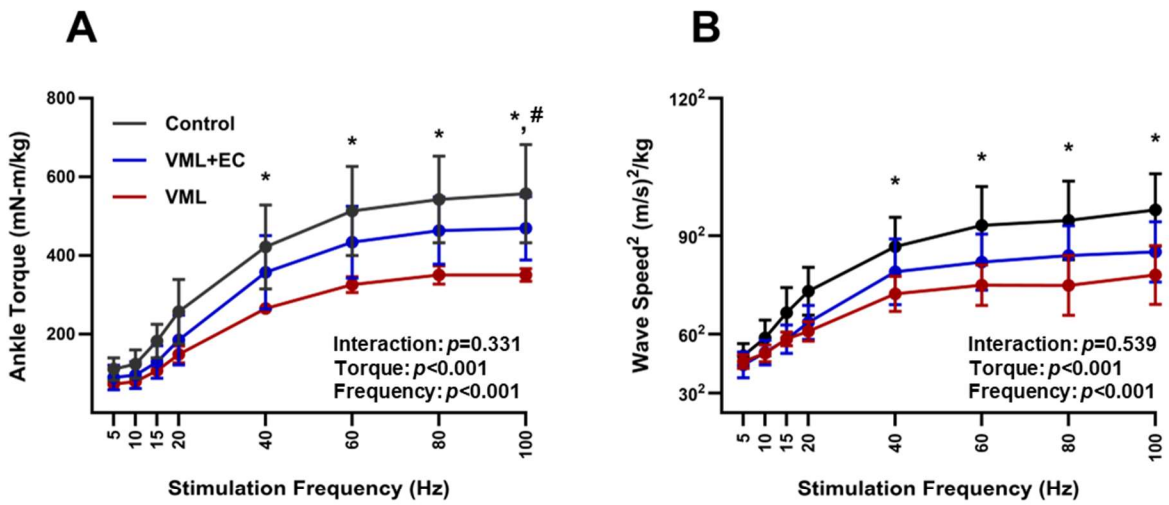

Figure 1. (A) Ankle torque and **(B)** squared wave speed showed similar trends across stimulation frequency. VML was significantly reduced (*) from control in both outcomes at 40-100Hz. VML was significantly reduced (#) from VML+EC in ankle torque at 100Hz but not wave speed. Statistical significance was assessed with two-way ANOVAs for functional outcome and frequency. When significance was detected, post-hoc Sidak's test compared groups within frequency. ($p < 0.05$)

Stiffness Perceived by Cells Inside Microporous, Bio-Combatible Scaffolds: An *in Silico* 3d Modelling Approach for Quantitative Biomechanical Analysis

Mr Oliver Santos-Lopes[1], Dr Dimitrios Tzeranis[2], Dr Vasileios Vavourakis[1,3]

[1]University of Cyprus, Nicosia, Nicosia, Cyprus. [2]University of Crete, Heraklion, Heraklion, Greece. [3]University College London, London, London, United Kingdom

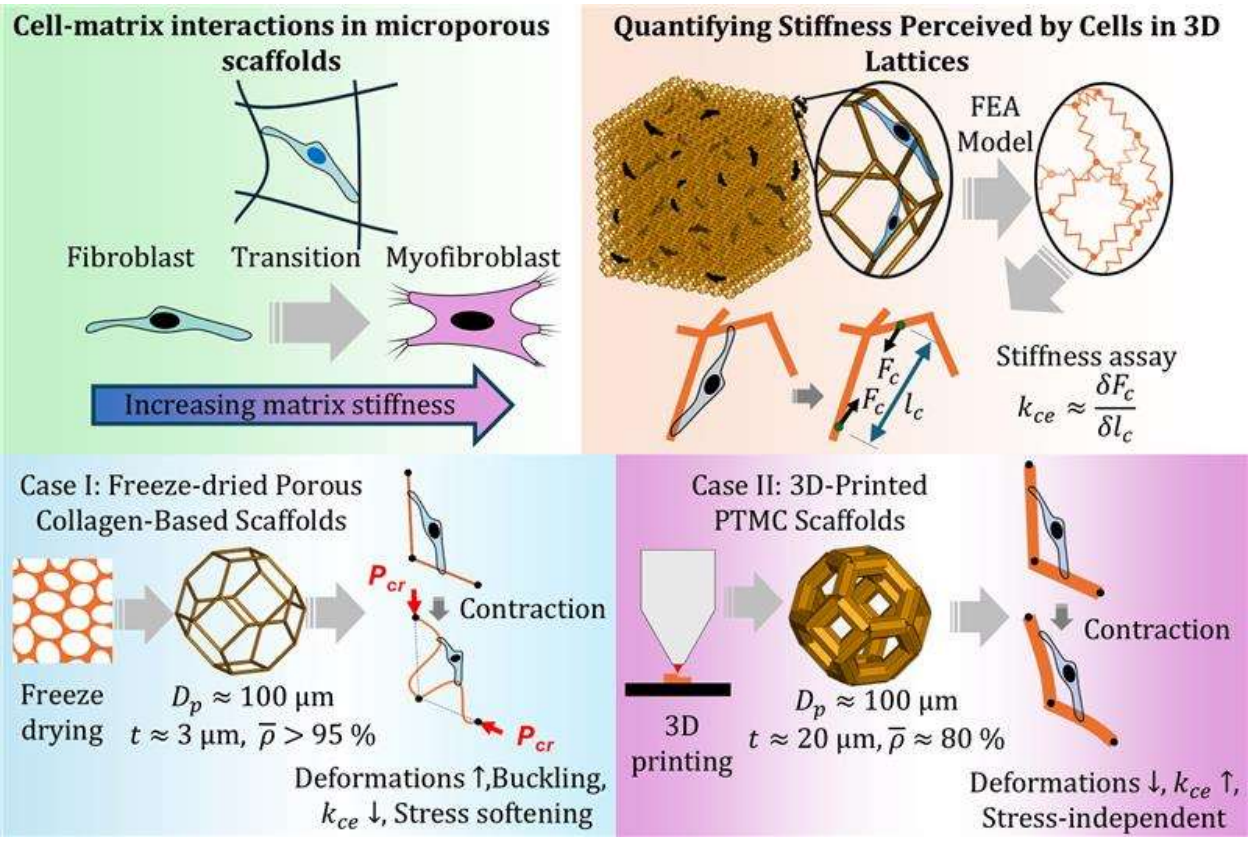
Introduction

Cells can sense and respond to the stiffness of their insoluble microenvironment [1]. Yet, quantifying the stiffness perceived by cells inside 3D matrices is challenging. Here we present an efficient *in silico* approach for modelling biologically relevant microporous scaffolds, a specific type of 3D matrix, with pore diameter within 30-200μm, and utilize it to quantify how cells perceive matrix stiffness when seeded inside them.

Methods

We developed an efficient finite element procedure, using ANSYS, to model two important kinds of cell-seeded microporous biomaterials of physiologically relevant sizes: Porous Collagen-based Scaffolds (PCS) utilized in regenerative medicine grafts, and scaffolds fabricated by 3D-printed methods [2]. Assuming each cell attaches and contracts with force on two points of the scaffold, a relevant approximation for spindle-like cells in microporous biomaterials [3], we calculated the matrix stiffness perceived by each cell ($k_{ce}=\delta F_c/\delta l_c$) by numerically approximating the gradient of their force-displacement (F_c-l_c) relationship.

Results



We quantified the distribution of matrix stiffness perceived by cells as a function of scaffold parameters (material properties, pore diameter, relative density) and cell parameters (contractility F_c, density, orientation). Cells seeded in PCS sensed k_{ce} in the 5--50nN/μM range, which depended on PCS structural parameters, attachment location, and contractility. Cells seeded inside 3D-printed PTMC scaffolds perceived ~3 orders of magnitude higher than cells seeded in PCS and independent of contractile force.

Discussion

Our model revealed that k_{ce} in a PCS depends strongly on both PCS parameters (pore size, relative density) and cell contractility, due to the nonlinear mechanics of open-pore biomaterials. In contrast, cells grown in 3D-printed scaffolds sense a much higher stiffness that is independent of cell contractile force. These force-dependent effects, arising from

the large deformations of PCS struts, may influence cell mechano-responsive pathways and explain reported down-regulation of wound contraction during skin regeneration in PCS. Our model provides novel insights into the mechanical interactions of cells with 3D biomaterials, which can be used to optimize biomaterials or probe phenomena that are difficult to investigate experimentally.

Effect of Mechanical Alterations in Diabetic Red Blood Cells on Their Partitioning Patterns at Microvascular Bifurcations

Ms. Xin Zhou, Prof. Xiaobo Gong

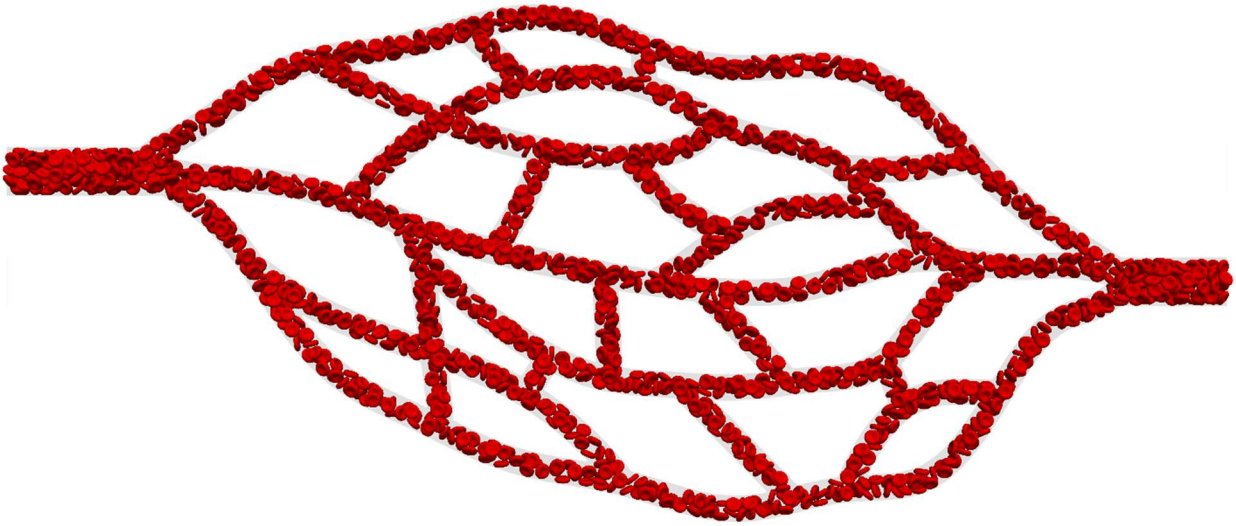
Shanghai Jiao Tong University, Shanghai, Shanghai, China

Introduction

Nonproportional red blood cell (RBC) distribution is a critical feature of the microcirculatory system. Compared to healthy RBCs, diabetic RBCs exhibit increased shear modulus, elevated intracellular viscosity, and morphological alterations, which could contribute to microvascular complications. Current research lacks numerical studies on the partitioning of RBCs with distinct mechanical properties at vascular bifurcations under multicellular interactions. This study investigates the partitioning patterns of healthy and diabetic RBCs in bifurcated vessels to elucidate how cellular mechanical properties influence RBC dynamics in microcirculation.

Methods

The immersed boundary method was employed to simulate fluid-structure interactions between cell membranes and flow fields. The effects of RBC deformability, morphology, and intracellular viscosity on cell partitioning were analyzed under varying branch diameter ratios and hematocrit levels. Subsequently, different proportions of diabetic RBCs were added to normal RBCs to investigate the distribution patterns under their mutual interactions.



Results

The results demonstrate that the scale effects of RBCs lead to more pronounced nonproportional partitioning when branch radius differences increase. At hematocrit levels below 10%, its impact on RBC distribution is negligible; above 10%, higher hematocrit increases RBC preference for low-flow branches. Elevating shear modulus and swelling ratio enhances RBC partitioning into high-flow branches, whereas intracellular viscosity shows negligible influence. When the proportion of diabetic RBCs added to healthy RBCs is less than 20%, healthy RBCs are more likely to flow into high-flow branches than diabetic RBCs. When the proportion of diabetic RBCs exceeds 30%, diabetic RBCs are more likely to enter high-flow branches.

Discussion

Diabetic RBCs demonstrate greater propensity to enter higher-flow branches compared to normal RBCs, consistent with physiological observations. This phenomenon helps elucidate how cellular mechanics contribute to microcirculatory dysfunction in diabetes. Observed distribution patterns of diabetic-normal RBC mixtures provide valuable references for developing microfluidic chips that sort cells by mechanical properties. Future work could incorporate realistic capillary networks reconstructed from imaging data, combined with experiments to investigate cellular distribution patterns involving RBCs and nucleated cells in microcirculation.

Dynamic Astrocyte Volume and Force Modulation as Mechanisms to Regulate Interstitial Flow in the Brain

Ms. Jacqueline van Zyl[1], Professor Seunggyu Kim[1,2], Professor Ming Guo[1], Professor Roger Kamm[1]

[1]Massachusetts Institute of Technology, Cambridge, MA, United States. [2]Korea University, Sejong, Sejong, Korea, Republic of

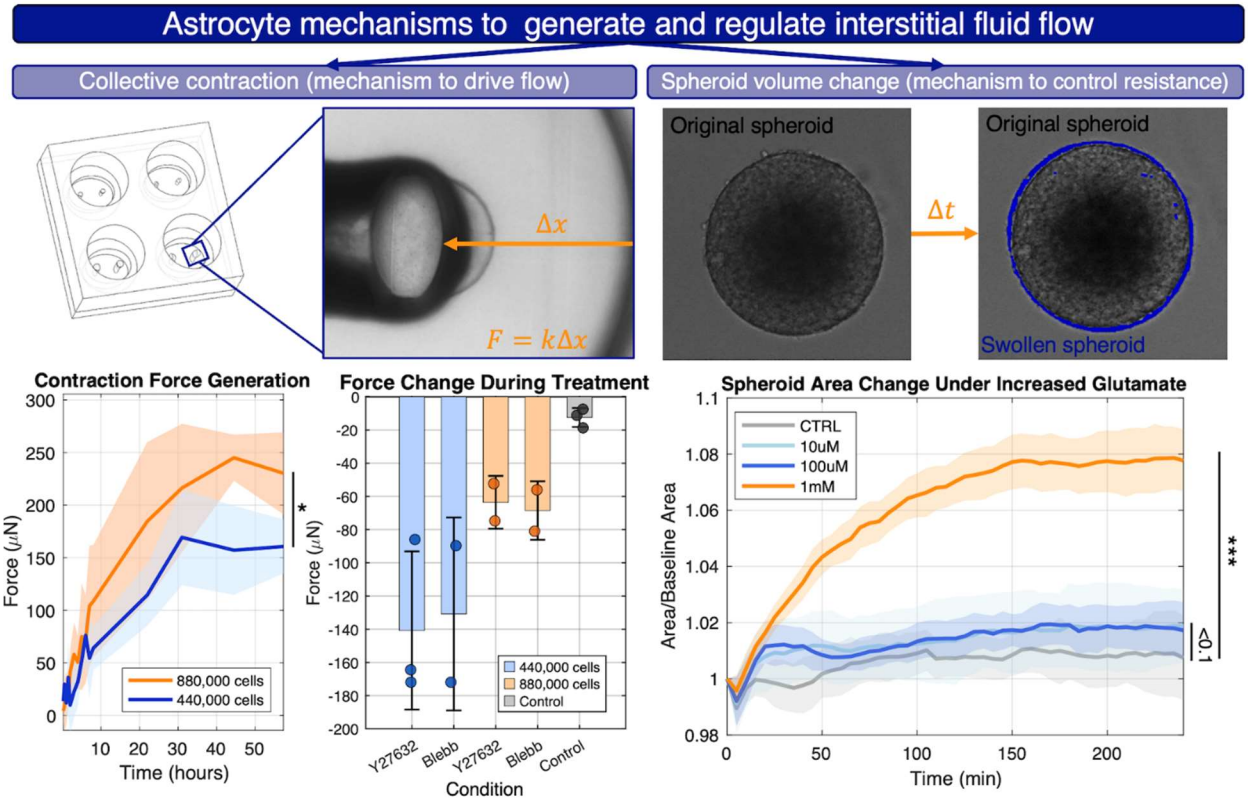
Introduction

A common hallmark of dementia is the aggregation of protein waste, which is exacerbated when the brain's waste clearance, or glymphatic, system is compromised [1]. Despite its importance, the mechanisms regulating glymphatic or interstitial flow, including dynamic flow rate changes across the sleep-wake cycle, remain unknown or contested. Astrocytes, as the brain's primary homeostatic regulators, are well-positioned to influence these flows through two potential mechanisms: generating driving pressures through contractile forces or altering tissue hydraulic permeability through volume-dependent changes. Here, we developed quantitative *in vitro* models to assess how astrocyte mechanics respond to physiologically relevant ionic and neurotransmitter cues and evaluate their potential roles in regulating interstitial transport.

Methods

To investigate contractile mechanics, we used micropillar deflection assays in which pillar displacement was imaged and converted to force using known pillar stiffnesses. We perturbed tissues with myosin II/ROCK inhibitors to assess the mechanisms of force generation and applied ionomycin to investigate calcium-driven modulation of contraction. In parallel, astrocyte volume responses were quantified by confocal imaging of spheroid areas following increased glutamate or potassium concentrations, two stimuli that fluctuate with behavioral state and have been implicated in cell swelling.

Results



Our results show that astrocytes generated substantial collective forces, reaching hundreds of micronewtons. Inhibition by blebbistatin and Y-27632 reduced contraction by more than 50 μN, confirming active, cytoskeleton-driven forces, while ionomycin increased contraction by about 25 μN within 30 minutes, demonstrating a rapid ionic response. Volume responses differed in both magnitude and time scale, providing insight into how astrocytes may alter the extracellular space and ultimately hydraulic resistance. Potassium induced fast, transient spheroid swelling within 20 minutes, while glutamate

triggered sustained swelling over several hours, with pathological levels producing 8% swelling by 4 hours ($p<0.001$).

Discussion

These findings demonstrate that astrocytes dynamically respond to ionic and neurotransmitter cues characteristic of sleep-wake states. Coordinated modulation of contractile forces and volume suggests astrocytes may help regulate interstitial flow by modulating both driving pressures and fluidic resistances. Future work will incorporate neuron-astrocyte co-culture models to directly investigate the impact of neural state on astrocyte mechanics.

Structural Determinants of Internal Cellular Force Balance Under Different Mechanical Stimuli

Ing. Lucie Jadrna[1,2], doc. MUDr. Jaromír Gumulec Ph.D.[3], Assoc. Prof. Eoin McEvoy Ph.D.[4], prof. Ing. Jiří Burša Ph.D.[1]

[1]Dept. of Biomechanics, Faculty of Mechanical Engineering, Brno, Czechia, Czechia. [2]European Society of Biomechanics, Brno, Czechia, Czechia. [3]Dept. of Pathophysiology, Faculty of Medicine, Brno, Czechia, Czechia. [4]School of Engineering, Biomedical Engineering, Galway, Galway, Ireland

Introduction

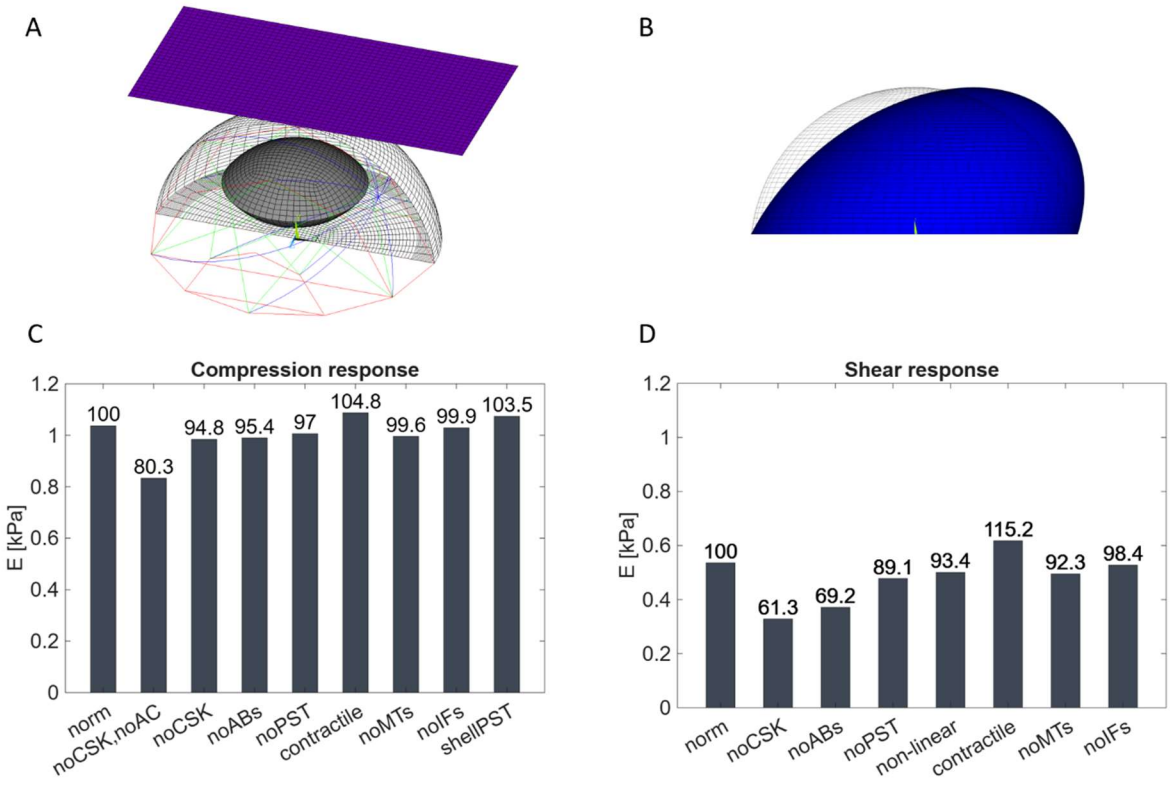
Cellular stiffness is a key determinant of how cells sense and respond to the mechanical properties of their environment. The ability of cells to maintain internal force balance and adapt their internal structure to the mechanical environment clearly underlies disease progression. Despite extensive experimental evidence from manipulations targeting cytoskeletal network, high resolution imaging and stiffness mapping methods, e.g., Atomic Force Microscopy (AFM) and shear flow, the role of the cellular microstructure in mechanical response remains incompletely understood.

Methods

Utilizing the Finite Element Model of a living cell comprising major cytoskeletal constituents (actin bundles, intermediate filaments, microtubules) together with the nucleus, membrane and cytoplasm (Figure, A), we previously demonstrated the impact of cytoskeletal protein density on the mechanical response of the cell [1]. Here, we investigate the contribution of intracellular components under two distinct stimuli: compressive load related to AFM through a low-strain setup and shear. We additionally focus on the impact of prestress, i.e., active contractility, and adhesion on the mechanical response, which are mechanisms facilitating the cell-substrate interaction, supposedly determining the cell internal structure but also prominent phenomena in experimental measurements.

Results

Simulations confirm the predominant role of actin, namely its contractility and elasticity. The impact of internal structure is more pronounced in global shear loading compared to



indentation typical in AFM, where the continuum properties predominate (details in the Figure).

Figure: (A) Structural model with red ABs, blue MTs and green IFs in compression by blue-magenta plate, (B) mesh deformed by low shear values, (C, D) sensitivity study results with percentual change indicated above the bars in both compression and shear.

Discussion

This study reflects on structural modulators related to force sensing to provide insight into stiffness change in diseased cells using computational modelling supported by experimental measurements. Since pathological states disrupt the internal force balance, they can be observed as internal reorganization mainly due to excessive cellular forces. The assumption of internal reorganization being driven by establishing the internal force optimum (homeostasis) calls for adjustment of internal properties of the model, such as focal adhesion count linked with underlying substrate stiffness.

Dynamic Balance Declines With Age Across the Stride Cycle

Dr Lizeth Sloot[1], Dr Matthew Millard[2]

[1]Newcastle University, Newcastle, Tyne and Wear, United Kingdom. [2]University of Stuttgart, Stuttgart, Baden-Württemberg, Germany

Introduction

We fall more as we get older. Mechanical balance looks at how we coordinate our body relative to our foot's base of support (BOS). We recently showed that the functional BOS, which can exert balancing forces, is much smaller than the foot sole [1,2]. Studies have not yet accounted for this or body angular momentum. Therefore, we evaluated age-related changes in dynamic mechanical balance throughout the stride in the largest full-body motion dataset of 207 adults covering 21-90 years of lifespan ([3] and unpublished).

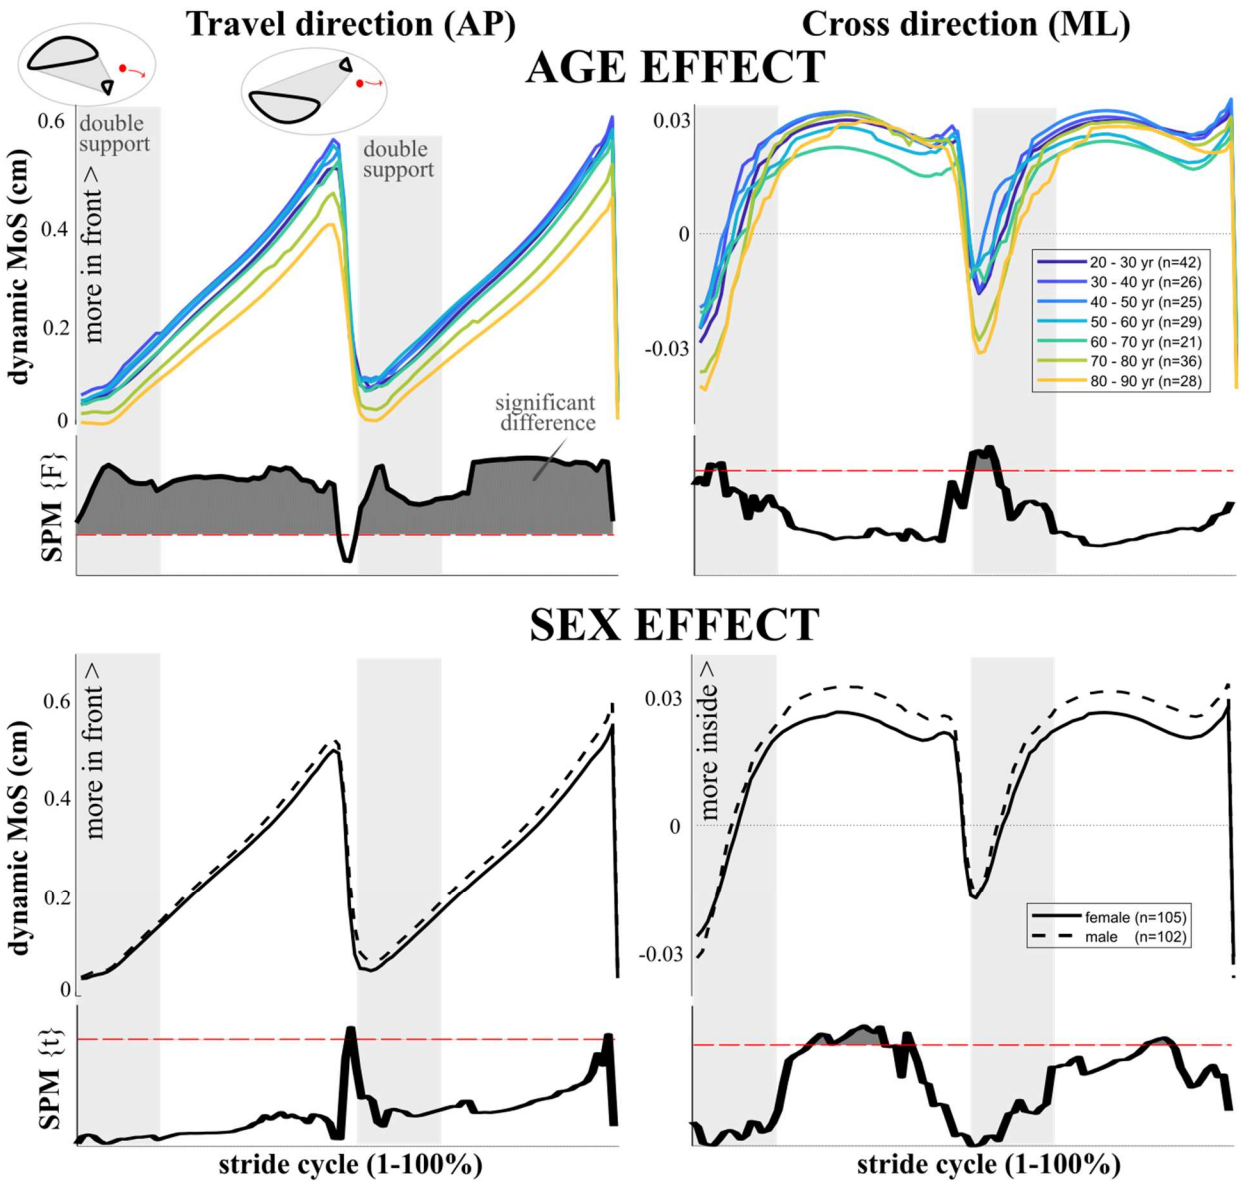
Methods

For body coordination, we calculate the novel foot-placement-estimator (FPE) model that uses both the body's linear and angular momentum to solve for the stepping location, which represents a balanced pose [4]. Our young fBOS model [1,2] was fitted to the foot markers, and the floor contact area was adapted throughout the stance phase. Dynamic balance was calculated as the margin-of-stability (dMoS), the distance between the stepping location and the nearest BOS edge. Age and gender differences were assessed throughout the stride using SPM analysis.

Results

The stepping point is in front and medial of the lead foot at foot contact and moves further ahead and towards the other foot throughout the stance phase (Figure 1).

dMoS decreased with age across almost the whole stride in the travel direction ($p<0.002$; Figure 1). Post-hoc analysis shows that balance declined from 70 years and above compared with those aged 20-60 years. There was no age effect for the cross direction, except for a short difference between 40-50yrs and 80-90yrs.



dMoS was lower in females compared to males during single stance in the cross direction ($p<0.03$), but not the travel direction.

Discussion

This large mechanical balance dataset shows that older adults and females are more cautious, staying closer to being dynamically balanced. Next, we will create age-specific

fBOS models and account for declining walking speed. Generalizability is limited to non-frail and pre-frail adults-no frail adults were measured. This detailed analysis helps us better identify people at risk of falling.

Working Harder to Walk Slower: Treadmill-Based Gait Assessment Systematically Underestimates Overground Performance in Older Adults

M.Sc. Keven Santamaria-Guzman[1], Ph.D. Tyrone Loria-Calderon[2], Ph.D. Mynor Rodriguez-Hernandez[2], M.Sc. Brandon Peoples[1], M.Sc. Bria Smith[1], M.Sc. Damaris Cifuentes[1], M.Sc. Silvia Campos-Vargas[1], M.Sc. Kenneth Harrison[1], Ph.D. Jaimie Roper[1]

M.Sc. Kenneth Harrison

Introduction

Although treadmill-based gait assessments offer controlled analysis, most comparisons focus on level walking in young adults. Real-life ambulation involves slopes, yet treadmill–overground equivalence on inclines is largely unknown. Older adults remain underrepresented despite likely using different strategies. This study evaluates whether laboratory-determined self-selected speeds mirror real-world walking across inclinations.

Methods

Twenty-six older adults (70±6 years) completed six randomized 2-minute walking trials: treadmill (TR) and overground (OG) conditions across flat, uphill, and downhill terrain (5.2°, 9.1% grade) at comfortable speed. TR speeds were determined using a bidirectional protocol: incremental (0.5 m/s baseline, +0.05 m/s every 3 seconds) and decremental (1.5 m/s baseline, −0.05 m/s every 3 seconds) tests; averages determined TR speed. Kinematics were captured using six IMUs; GRF via pressure-sensing insoles. Heart rate (HR) and perceived exertion (RPE) was recorded. Participants rested until baseline HR between trials. Sensory integration was assessed via CTSIB. Paired t-tests compared conditions (α=0.05).

Results

TR systematically underestimated OG gait speed: flat (1.04±0.20 vs 1.37±0.15 m/s; Δ=24.1%), uphill (0.94±0.20 vs 1.23±0.16 m/s; Δ=23.6%), downhill (1.06±0.22 vs 1.30±0.18 m/s; Δ=18.5%; all $p<.001$) (Figure 1). TR also underestimated peak force (Δ=11–23%) and loading rate (Δ=31–41%; all $p<.001$). Paradoxically, HR was higher: flat (111±15 vs 101±13 bpm), uphill (118±14 vs 105±12 bpm), downhill (106±15 vs 99±13 bpm; all $p\leq.002$), and RPE followed the same pattern (all $p<.05$). CTSIB sensory ratios (visual, somatosensory, vestibular) showed no correlation with speed discrepancy across inclinations (all $p>.05$).

Discussion

TR underestimated OG speed by 18.5–24.1%, while simultaneously eliciting higher HR and RPE, indicating that participants worked harder to walk slower. This paradox suggests TR imposes demands beyond the absent optic flow, potentially including postural stabilization costs and altered motor control strategies. Individual sensory reliance did not correlate with discrepancy magnitude, suggesting a broad effect in older adults. Critically, the ~0.3 m/s underestimation in this sample exceeds thresholds for meaningful change in gait speed, suggesting that TR-based assessments may misclassify functional mobility status in older adults.

Images (Optional)

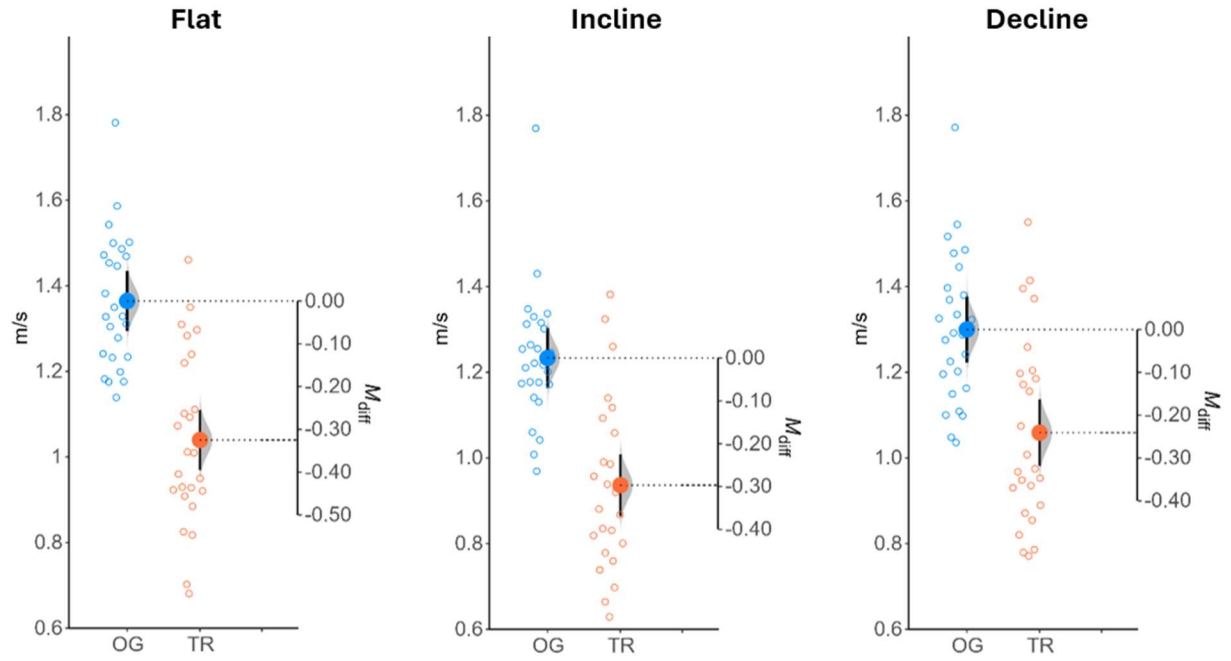

Figure 1. Gait speed comparison between overground (OG; blue) and treadmill (TR; orange) across terrain inclinations. Open circles represent individual participants; filled circles indicate group means. Difference scores (M_{diff}) reflect the speed discrepancy: flat (−0.33 m/s), incline (−0.29 m/s), decline (−0.24 m/s); all $p<.001$.

Beta- and Gamma-Band Cortical Connectivity During Destabilizing Pivoting Stepping Movement on a Robotic Elliptical Trainer

Ms Soyoung Lee PhD, Ms Peiwen Fu, Mr Matteo Pergami-Peries PhD, Mr Li-Qun Zhang PhD

University of Maryland Baltimore, Baltimore, Maryland, United States

Introduction

Off-axis instability during stepping contributes to lower-limb injury and post-traumatic joint degeneration, yet the cortical networks supporting control of off-axis motion are poorly understood. Using a robotic off-axis elliptical stepping paradigm, we examined how beta- and gamma-band directed connectivity reorganizes when participants stabilize pivoting under destabilizing conditions.

Methods

Eight healthy adults (three female, age=32.0±3.5, BMI=22.8±2.3) stepped on a robotic elliptical trainer with adjustable pivoting. Three modes were presented in random order: (1) normal stepping; (2) free mode, in which transverse friction was removed ("walking on ice") from the right foot; and (3) perturbation mode, in which 3 Nm internal rotation torques were applied while participants resisted. Visual feedback instructed participants to maintain a zero position. Each mode lasted 10 s with 10 s rest, repeated for 15 blocks. Pivoting instability was quantified as root-mean-square pivot angle (RMSAngle) during free mode. High-density EEG (128 channels) was source-reconstructed to frontal eye fields, dorsolateral prefrontal, primary motor (MC) and somatosensory (S1) cortices, superior parietal lobule, temporo-parietal junction (TPJ), and visual cortex. Directed connectivity in beta (15–29 Hz), low-gamma (30–59 Hz), and high-gamma (60–90 Hz) bands was estimated using Phase Transfer Entropy (PTE); net PTE outflow and inflow were derived for each region. Linear mixed-effects models tested effects of mode (free, perturbation vs normal), and Pearson correlations between regional PTE outflow and RMSAngle were computed during free mode.

Results

In beta and low-gamma, perturbation (vs normal) reduced PTE outflow from left MC and right VC and increased outflow from bilateral TPJ (all $p < 0.05$), whereas free mode showed no significant changes. In high-gamma, perturbation decreased outflow from left S1 and

increased outflow from right TPJ ($p < 0.05$), with a trend toward reduced left-VC outflow. PTE outflow correlated moderately with RMSAngle, particularly in beta band.

Discussion

Pivoting perturbations during robotic elliptical stepping reconfigure cortical PTE connectivity across beta and gamma bands, shifting influence from primary sensorimotor-visual cortices to temporo-parietal association regions. Positive TPJ–RMSAngle correlations in beta and low-gamma indicate that individuals with greater pivoting instability recruit TPJ more strongly, highlighting TPJ-mediated multisensory integration as a potential target for neuromechanically informed balance rehabilitation.

Images (Optional)

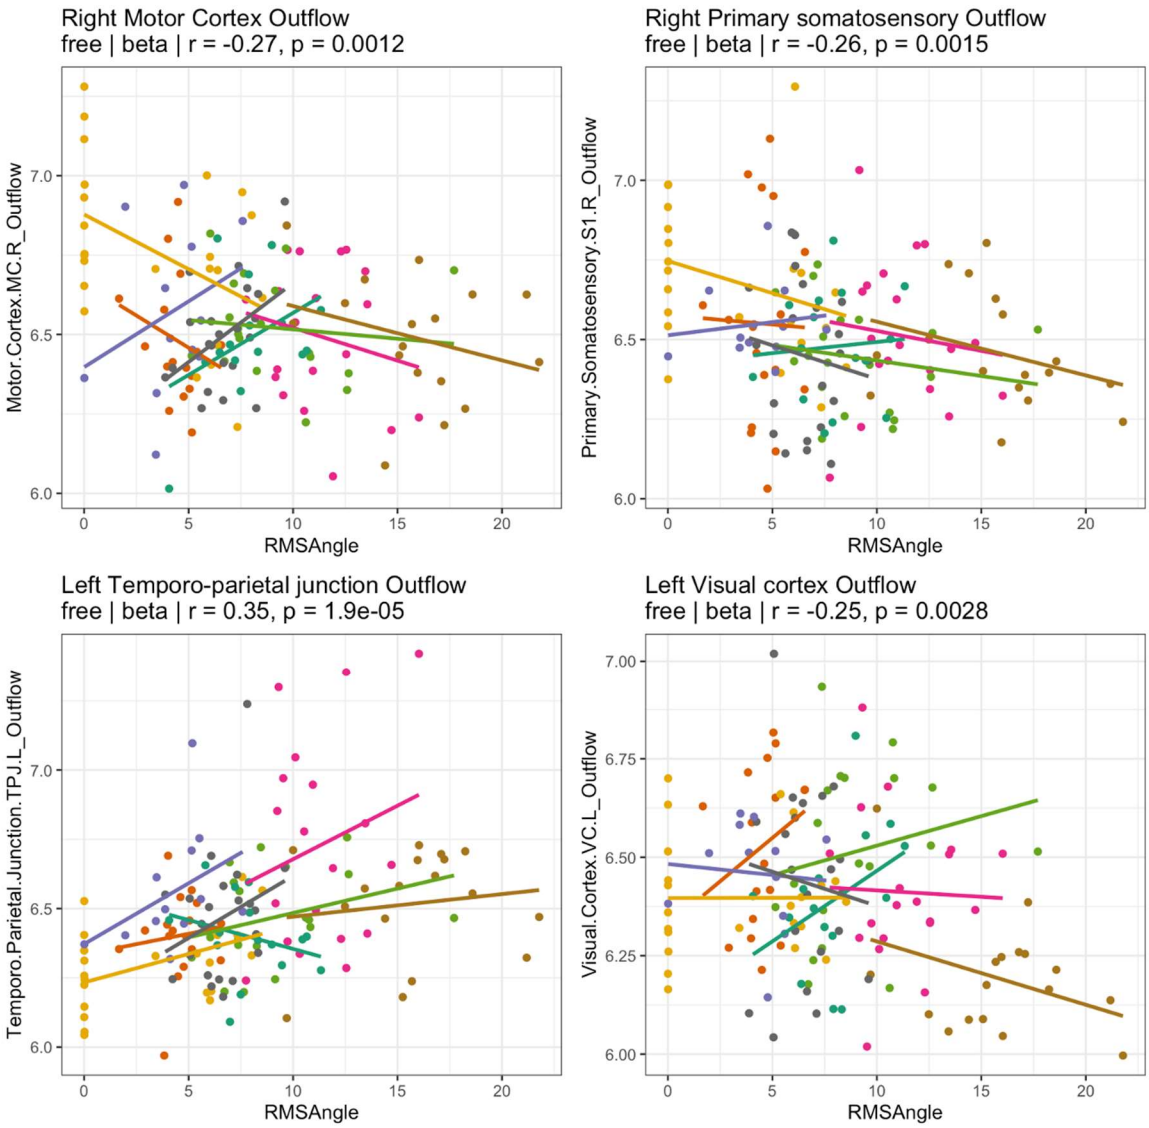

Figure 1. Scatter plots showing the relationship between PTE outflow and RMSAngle in four cortical regions during free mode. Each point represents one block and colors indicate individual participants. All four regions showed moderate, significant correlations with RMSAngle, with the strongest and most consistent associations in the temporo-parietal junction, suggesting greater engagement of this multisensory area with increasing pivoting instability.

Objective Gait Performance Does Not Predict Mobility Satisfaction in Older Adults

MSc Damaris Cifuentes[1], MSc Silvia Campos-Vargas[1], MSc Eduardo Santiago[2], Ph.D. Francisco Siles[2], Ph.D. Jaimie Roper[1]

[1]Auburn University, Auburn, Alabama, United States. [2]University of Costa Rica, San Jose, San Jose Province, Costa Rica

Introduction

Aging involves considerable variability in independent functional ability. Clinical guidelines have established objective ranges in spatiotemporal gait parameters (GPs) to define "healthy" mobility in older adults [1,2]; however, it remains unclear whether these objective ranges align with perceived functional adequacy and satisfaction in older adults. This study investigated the relationship between objective GPs and self-rated mobility satisfaction to determine whether normative metrics represent perceived functional health within this population.

Methods

Forty-four older adults (age: 69±9 years) performed a 40-meter walk test at their self-selected walking speed. Gait parameters (GPs) were collected using IMU sensors. Participants rated their mobility satisfaction on an analog scale from 0 to 100 (0= very poor; 100= excellent). Responses were categorized into low (0-33), medium (34-66), and high (67-100) satisfaction groups. MANOVA was conducted to examine differences in GPs across mobility satisfaction levels in older adults. GPs were compared to normative values for older adults aged 70-79 years [1].

Results

MANOVA revealed significant differences in gait speed and stride length across satisfaction groups ($p=.004$; $\alpha=0.05$). The high satisfaction group closely aligned with the normative values (gait speed: 1.23±0.12 vs. 1.10±0.19 m/s; stride length: 1.21±0.11 vs. 1.22±0.19 m). The low mobility satisfaction group demonstrated the fastest gait speed (1.31±0.19 m/s) and longest stride length (1.31±0.15 m) across all groups and exceeded the normative values. The medium mobility satisfaction group showed reduced performance in both measures (1.07±0.19 m/s, 1.14±0.16 m) compared to normative values.

Discussion

These findings suggest that mobility satisfaction relates more closely to gait consistency than to normative performance metrics, with the low mobility satisfaction group paradoxically exceeding normative values despite reporting dissatisfaction in mobility. This discrepancy highlights the importance of integrating patient-centered outcomes into clinical mobility assessments to capture perceived effort and efficiency, components overlooked by objective measures alone, to fully understand mobility capacity. Future work should explore how to best incorporate patient perspectives into clinical assessments to provide a more holistic evaluation of mobility in older adults.

Images (Optional)

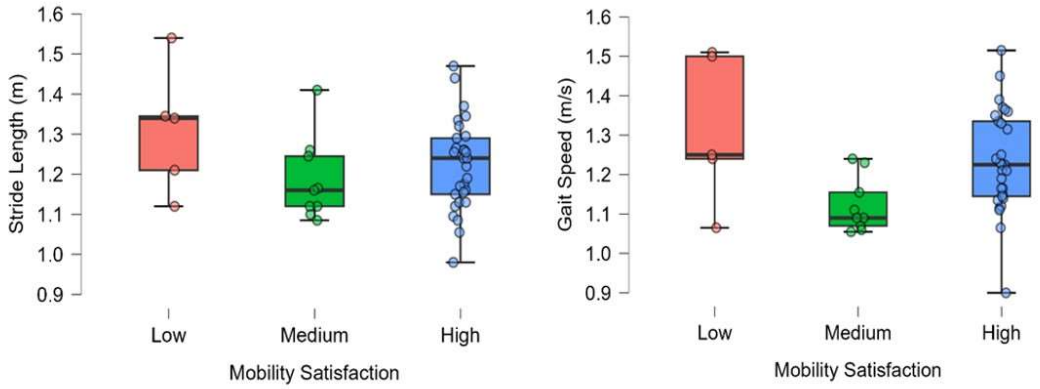

Figure 1. Box plots depicting stride length (m) and gait speed (m/s) across three levels of self-rated mobility satisfaction: low, medium, and high. The low satisfaction group demonstrated the fastest gait speed (1.31±0.19 m/s) and longest stride length (1.31±0.15 m) across all groups. The medium satisfaction group showed the slowest gait speed (1.07±0.19 m/s) and shortest stride length (1.14±0.16 m) across all groups. The high satisfaction group exhibited the lowest variability in both metrics (gait speed: 1.23±0.12 m/s; stride length: 1.21±0.11 m).

Differences Between Young and Older Adult Knee Kinematics Can Inform Knee Arthroplasty Prosthesis Design and Selection

Ms. Emelia Krakora, Mr. Tom Gale, Dr. Malcolm Dombrowski, Dr. Alan Wilson, Dr. Johannes Plate, Dr. Kenneth Urish, Dr. William Anderst

University of Pittsburgh, Pittsburgh, PA, United States

Introduction

Total knee arthroplasty aims to restore native knee kinematics, guiding prosthesis design and surgical technique. Most existing native knee kinematics data come from cadaver studies or skin-mounted motion capture which can introduce measurement error [1]. This study used dynamic biplane radiography (DBR) to characterize knee kinematics, symmetry, center of rotation (COR), and femoral rollback during gait in younger and older asymptomatic adults. We hypothesized that older healthy knees would be less extended and less symmetric than younger healthy knees and that there would be no differences in older and younger healthy knees in COR location and femoral rollback.

Methods

Bilateral knee kinematics during treadmill gait were measured using DBR in 19 younger (31±6 years) and 20 older (65±9 years) adults. A validated tracking system matched digitally reconstructed radiographs of the femur and tibia, created from CT scans, to the biplane radiographs to track tibiofemoral motion [2]. Statistical Parametric Mapping assessed differences in kinematics waveforms and symmetry, while generalized estimating equations assessed differences in COR and lowest point locations.

Results

Older knees were more flexed at foot strike and less flexed during early stance with significant differences from 0% to 3% and from 24% to 49% of stance. The tibias in younger knees were more anterior compared to the older knees with significant differences at 1-47% and at 82-100% of stance (Figure 1). The COR was more proximal in stance extension (0.1 vs -13.42% of condyle height) and terminal stance (6.39 vs -1.19 %) in older knees (Figure 1). The lowest point in the medial compartment was more anterior at initial peak flexion (8.6 vs -1.4% of tibia depth) and toe off (5.4 vs -2.5%) in older knees. No differences in symmetry were observed.

Discussion

This study provides evidence demonstrating there are differences in *how much* the knee moves and *how* the knee moves in young and older healthy knees. These insights may be useful for guiding implant design as well as a serving as a reference standard for assessing if healthy kinematics have been restored after surgery.

Step Variability Is Linked to Yaw Vestibular Sensitivity

Dr. Shawanee' Patrick Ph.D, Ms. Shauntelle Cannon, Ms. Sophia Chirumbole, Dr. Daniel Merfeld Ph.D, Dr. Ajit Chaudhari Ph.D

Ohio State University, Columbus, OH, United States

Introduction

Age-related vestibular decline contributes to mobility loss and fall risk, with one-third of adults over 65 falling each year [1]. Vestibular perceptual thresholds quantify sensory noise and increase with age [2], and roll-tilt thresholds relate to postural sway [3]. However, the link between vestibular perceptual sensitivity and gait is unclear, even though most falls occur during walking [4]. This study examined whether spatiotemporal gait measures and dynamic stability during a 6-minute walk test (6MWT) relate to vestibular perceptual thresholds in healthy adults.

Methods

Vestibular thresholds were measured using validated direction-recognition procedures for roll-tilt (0.5, 2 Hz), yaw rotation (2 Hz), and y- and z-translation (1 Hz) [2]. Participants completed a self-paced 6MWT along a 35.7 m hallway. Inertial measurement units (IMUs) were placed on both ankles, the pelvis, neck, and head. Straight-walking segments were extracted for spatiotemporal analysis. Step and stride metrics were derived from ankle IMUs, and short-term Lyapunov exponents were estimated from trunk motion. Linear models tested associations between gait outcomes and vestibular thresholds, adjusting for age.

Results

Thirty-nine adults (mean age = 44.77 ± 18.20 years) completed testing. Of all thresholds evaluated (roll 0.5 Hz, roll 2 Hz, yaw 2 Hz, y-translation 1 Hz, z-translation 1 Hz), only yaw 2 Hz was significantly associated with gait variability. Significant relationships were found for Step Time Coefficient of Variation (Step CoV; $R^2 = 0.19$, $p = 0.00062$), Step Time Standard Deviation (Step SD; $p = 0.00352$), and Step Frequency ($p = 0.0401$). No other threshold showed significant associations with Step CoV, Step SD, stride metrics, or short-term Lyapunov exponents ($p > 0.05$). Thus, yaw 2 Hz sensitivity was the only vestibular variable linked to gait variability.

Discussion

Findings demonstrate a selective link between 2-Hz yaw perceptual noise and step-level gait variability during prolonged walking, indicating an axis-specific vestibular contribution to locomotor control. Yaw sensitivity may influence foot placement consistency and the ability to maintain stable forward progression over time.

Mechanisms for Maximal Leaping Across a Wide Range of Locomotion Speeds

Dr Kat Daniels PhD[1], Dr J.F. Burn PhD[2]

[1]Manchester Metropolitan University, Manchester, Greater Manchester, United Kingdom. [2]University of Bristol, Bristol, Avon, United Kingdom

Introduction

Leaping is a locomotor manoeuvre that enables traversal of terrain regions that cannot safely support body weight or facilitate foot placement. The performance limits of this manoeuvre reveal how the sensorimotor system coordinates force production and momentum redirection to preserve stable locomotion near the limits of adaptive gait. Research into athletic long jump has shown a positive relationship between approach speed and jump distance but the mechanisms enabling maximal-distance leaping across everyday gait speeds are not well understood. Thus, the aim of this study was to investigate whole-body dynamics during maximal leaping across a range of speeds, from walking to high-speed running.

Methods

Fifteen healthy adults (8F/7M, aged 18-31) walked or ran along a level runway at five prescribed speeds. Each trial incorporated one maximal-length leap, taking off from one foot and landing on the other. Whole-body kinematics were recorded using optical motion capture and used to calculate the dynamics of the body centre of mass (CoM).

Results

Net mechanical energy change during leap take-off stance was positive at low approach speeds but decreased with speed, becoming negative at the fastest speeds. High-speed trials showed no net energy addition; instead, longer leaps arose from redirecting momentum vertically. Horizontal momentum increased at low speeds but decreased at approach speeds Fr>1.1 (Fr = Froude number). A decrease in net kinetic energy occurred above Fr=1.3. Across all speeds, gravitational potential energy increased during stance, primarily due to the more-upright leg angle and greater effective leg length at toe-off. Leap length increased with approach speed; however, the length increase from the penultimate step to the leap step remained constant.

Discussion

The observed mechanical energy changes suggest that two mechanisms contribute to maximising leap distance. At low speeds, muscular work increases CoM mechanical energy, although this capacity diminishes with speed due to shorter stance durations and increased requirement for lost energy replacement. At high speeds, leap length is increased by redirecting momentum, analogous to long-jump take-off dynamics and consistent with spring-mass model behaviour. The interaction between these two mechanisms results in a capacity to increase step length that is remarkably invariant across diverse locomotion speeds.

Ultrasound-Derived Leg Blood Flow Associates with the Metabolic Cost of Human Walking

Mr. Jose Anguiano-Hernandez MS[1], Dr. Jenna Burnett PhD[1], Mr. Cody Anderson BS[2], Dr. Song-Young Park PhD[2], Dr. Kota Takahashi PhD[1]

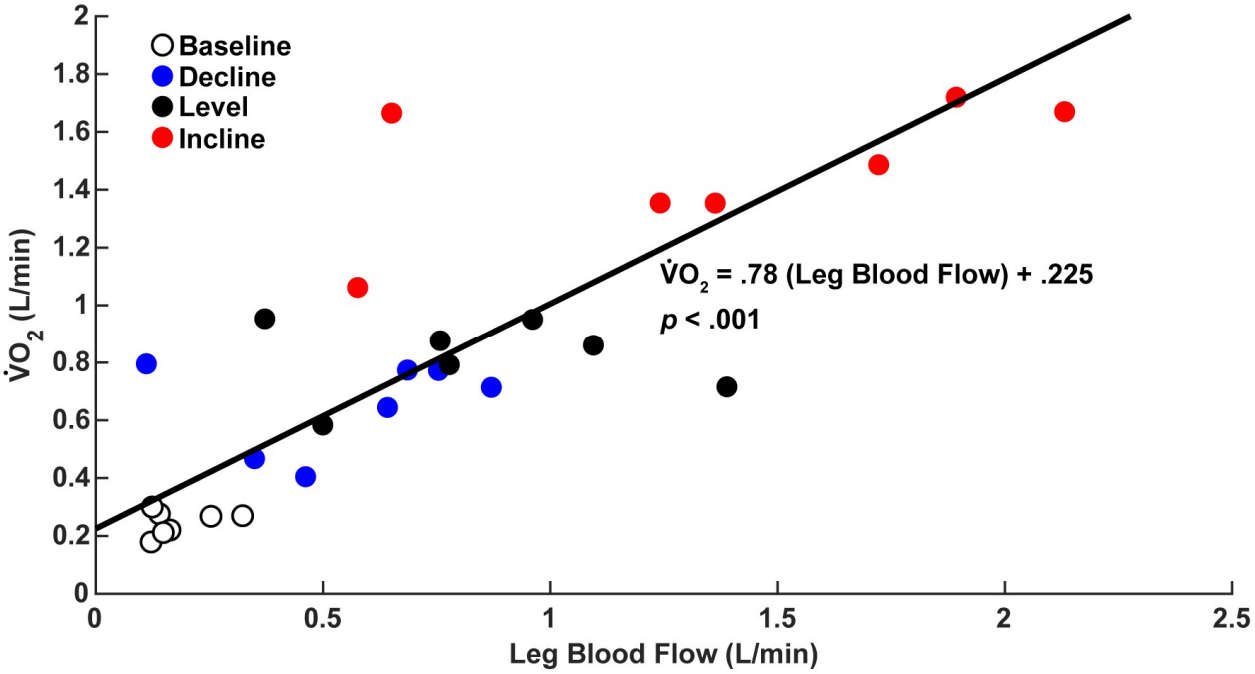
[1]University of Utah, Salt Lake City, UT, United States. [2]University of Nebraska at Omaha, Omaha, NE, United States

Introduction

The metabolic cost of walking ($\dot{V}O_2$) is often a key outcome of locomotion studies. However, gold-standard methods like indirect calorimetry describe whole-body metabolic cost and cannot parse out what portion is attributed to the legs. One method of parsing out the leg's contribution to the whole-body metabolic cost is measuring leg blood flow (LBF). While LBF has been measured using Doppler ultrasound during dynamic tasks like cycling [1], such a technique has not been used to quantify LBF in response to walking. The purpose of this study is to use an ultrasound-based method to determine whether walking-induced LBF reflects whole-body $\dot{V}O_2$ during walking.

Methods

Seven healthy young adults walked on a treadmill at a 0° slope, followed by a -5° and 5° slope in random order for 10 minutes at 1.2 m/s. A Doppler ultrasound probe was fastened over the dominant-side common femoral artery to measure LBF during quiet standing immediately before walking. Indirect calorimetry measured breath-by-breath $\dot{V}O_2$ before and during each walking condition. After walking, LBF was recorded for 5 minutes while participants stood quietly. Walking $\dot{V}O_2$ was calculated by averaging $\dot{V}O_2$ measurements during the final two minutes of each walking condition. Post-walking LBF was calculated by averaging LBF during the first ten seconds of each post-walking period. A linear mixed model was used to determine the association between post-walking LBF and walking $\dot{V}O_2$ at $\alpha = 0.05$.



Results

Post-walking LBF associated with walking $\dot{V}O_2$ ($p < .001$), where a 1 L/min increase in LBF associated with a .78 L/min increase in whole-body $\dot{V}O_2$ (Figure 1).

Discussion

Our ultrasound method showed that leg metabolic demands may drive whole-body $\dot{V}O_2$ during walking, supporting our experimental framework to study mechanisms underpinning changes in walking $\dot{V}O_2$. This framework could also elucidate metabolic contributions of individual legs in those with gait asymmetry (e.g., stroke, amputation) or vascular impairments (e.g., diabetes, peripheral artery disease). This ultrasound technique could also measure changes in LBF when using interventions like exoskeletons or assistive devices to improve walking.

Birds of a Feather *Walk* Together: A Simple Model Predicts Energy-Optimal Phase during Entrainment

Assistant Professor Ryan Schroeder PhD, Undergraduate Researcher Ryan Anderson

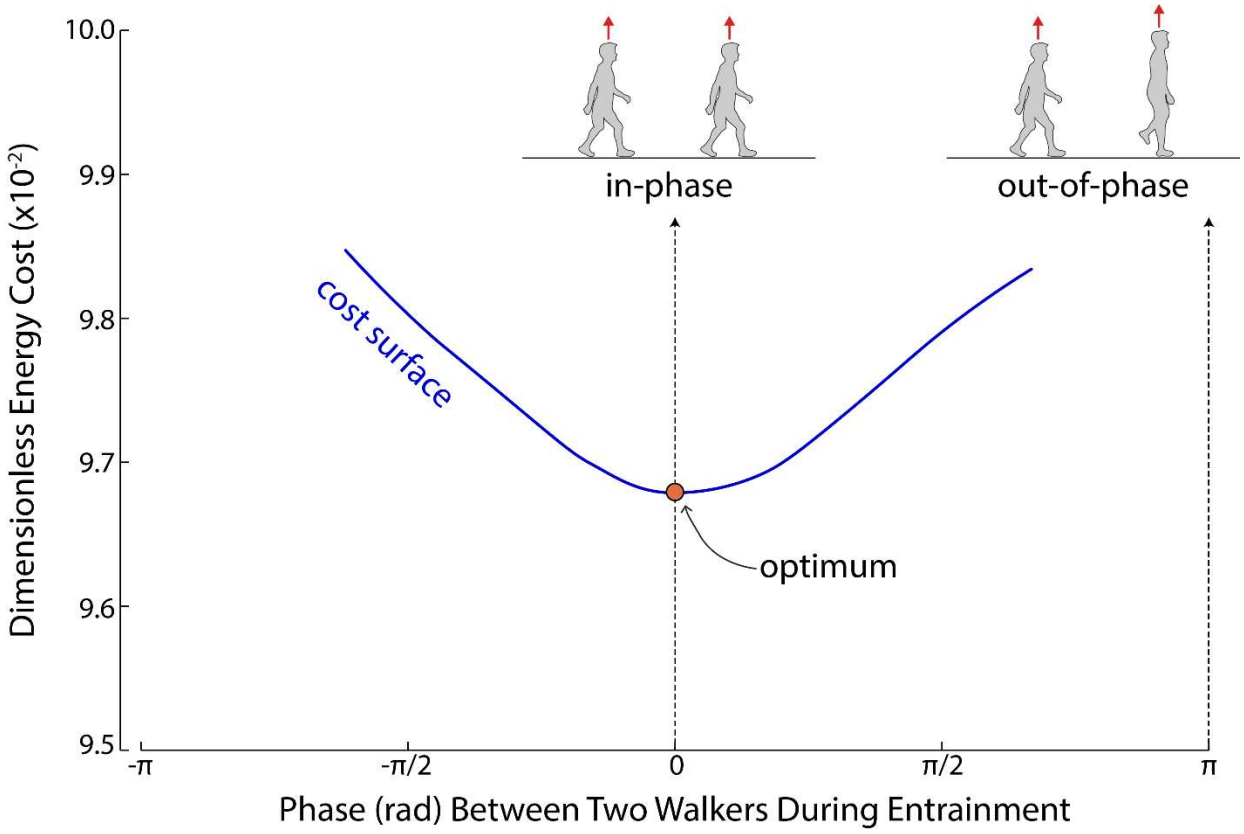
Brock University, St. Catharines, Ontario, Canada

Introduction

Human gait entrainment occurs when walking is synchronized with external oscillations from wearable robots or periodic forces at the center of mass (CoM) [1,2]. During entrainment, gait frequency is matched to the external oscillation, but phase is unknown *a priori*. Here we propose an energy minimization model to predict optimal phase during entrainment. Two walkers on separate treadmills are coupled by a spring pulling upward near the CoM. We hypothesize energy is minimized with in-phase walking such that peak spring forces reduce leg work done during the step-to-step transition. This work demonstrates a novel entrainment-based rehabilitation strategy to be applied in human experiments.

Methods

We developed a trajectory optimization model with JuMP and InfiniteOpt in Julia. Two inverted pendulum-like walkers comprise point masses (CoM) and massless legs that actively extend. The model's states are position and velocity of the CoM and controls are the leg extension forces. The objective function sums absolute mechanical work and force rate costs to model energy. Upward spring force is proportional to vertical displacement of the CoM. The optimization produced energy cost with variable spring stiffness and phase between walkers.



Results

Energy cost decreased by 10.7% as peak upward force increased from 2.8 to 13.8% body weight force from a stiffer spring. Decreased cost was primarily due to reduced leg work at the step-to-step transition. Energy cost was minimal during in-phase walking and increased toward out-of-phase walking (see Figure). Specifically, in-phase walking led to maximal peak upward forces occurring at the step-to-step transition, helping to reduce the leg work required to redirect the CoM from falling to rising.

Discussion

The results suggest that spring coupling could have strong potential for gait rehabilitation in clinical and healthy populations, given evidence of human energy minimization [3], but empirical validation is still needed. Future work could pair healthy and rehabilitating individuals in an entrainment protocol to motivate increased walking cadence and improved gait regularity in individuals recovering from stroke and other neuromotor injuries.

Importance of Considering the Metabolic Cost of Walking in Gait Retraining Interventions

MSc Ellen Hellman[1], MD Jari Arokoski[2], PhD Rami Korhonen[1], PhD Lauri Stenroth[1]

[1]Department of Technical Physics, University of Eastern Finland, Kuopio, Finland, Kuopio, North Savo, Finland. [2]Department of Internal Medicine and Rehabilitation, Division of Rehabilitation, Helsinki University Hospital and University of Helsinki, Helsinki, Uusimaa Region, Finland

Introduction

Real-time electromyography (EMG) feedback has been proposed as a method for gait retraining to modify knee joint loading [1, 2], a common target in non-surgical knee osteoarthritis treatments [3]. In natural locomotion, humans tend to select muscle activation and kinematic patterns that minimize the energy cost of transport (CoT) [4]. This may be in contrast with the targets of gait retraining, limiting the feasibility or effectiveness of interventions. Here, we investigated the effects of EMG-based calf muscle modification intervention on the walking CoT in older adults.

Methods

Twenty-nine healthy adults (65–75 y) participated in an 8-week intervention including weekly gait retraining sessions on an instrumented treadmill and pre- and post-intervention outcome assessments. The training aimed at modifying the activation ratio of the soleus (SOL) and medial gastrocnemius (MG) muscles, ideally by increasing SOL and decreasing MG activation. As feedback, the ratio of the root mean square of the SOL and MG EMG signals during push-off, normalized to baseline walking, was shown on a monitor. In the pre- and post-intervention sessions, EMG and respiratory gases were measured during 5-minute walking trials (1.25 m/s). CoT (last-2-minute average) and SOL-to-MG activation ratio (last-minute average) were analyzed.

Results

There was a significant shift in the SOL-to-MG activation ratio toward a more soleus-dominant pattern, both before and after intervention. CoT increased under the feedback condition by 43% (d_z:2.073, $p<0.001$) compared to normal walking in the pre intervention measurements and by 35% (d_z:1.862, $p<0.001$) in the post measurement (Fig. 1). From pre to post, CoT decreased 8% in the normal condition (d_z:0.816, $p<0.001$) and by 13% in the feedback condition (d_z:0.764, $p<0.001$).

Discussion

The gait retraining intervention reduced the energy cost of producing intended changes in muscle activity, suggesting that training improves the feasibility of implementing an altered coordination strategy. Still, the energy cost of walking was 35% higher during modified muscle activations compared to normal walking, highlighting that energetics should be considered when designing new locomotor interventions.

Sequencing Leg Forces Drives the U-Shaped Metabolic Cost-Speed Relationship in Walking Across Adulthood

Ms. Elham Alijanpour M.Sc., Ph.D. (ABD), Dr. Ashwini Kulkarni PT, Ph.D., Dr. Hunter Bennett Ph.D., Dr. Patrick Wilson Ph.D., Dr. Heather Hamilton DPT, Ph.D.

Old Dominion University, Norfolk, Virginia, United States

Ms. Elham Alijanpour

Dr. Ashwini Kulkarni

Dr. Hunter Bennett

Dr. Patrick Wilson

Introduction

Redirecting the center of mass is a key contributor to walking energy costs. Theoretical models propose that humans decrease redirection cost either by sequencing push-off and collision forces (walking) or by using elastic leg mechanics (running). The Sequence index (S-index) quantifies the overlap between push-off and collision forces during redirection phase, ranging from 0 (complete separation, running) to 1 (simultaneous forces, standing). S-index decreases with increases in walking speed until it reaches a ceiling point. Contrarily, metabolic cost of walking (MCoW) has a U-shape relationship with walking speed. We aimed to test whether the U-shaped relationship between walking speed and metabolic cost is driven by changes in force sequencing (S-index). We hypothesized that at slower speeds, improved force sequencing (lower S-index) would reduce MCoW despite increasing speed; however, at faster speeds, when force sequencing reaches its biomechanical ceiling, further increases in walking speed would lead to increased MCoW.

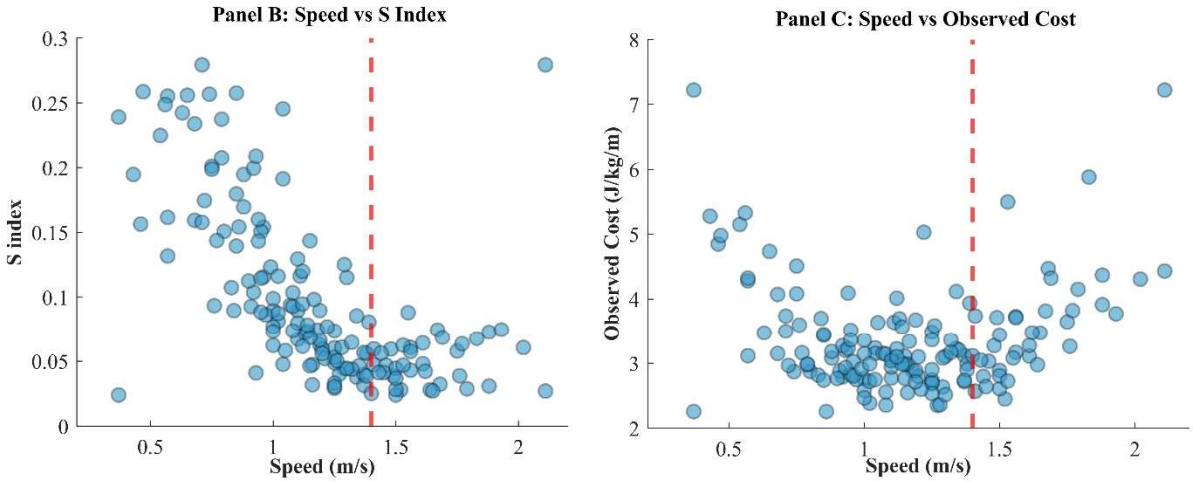
Methods

Fifty healthy adults (18-79 years) walked on an instrumented treadmill at three speeds (80%, 100%, and 120% of preferred walking speed). S-index and MCoW were calculated from the last three minutes of each trial. Linear mixed models examined S-index, age, and speed as predictors of MCoW across: (M1) all speeds, (M2) speeds <1.4 m/s, and (M3) speeds ≥1.4 m/s (selected as critical threshold based on prior research).

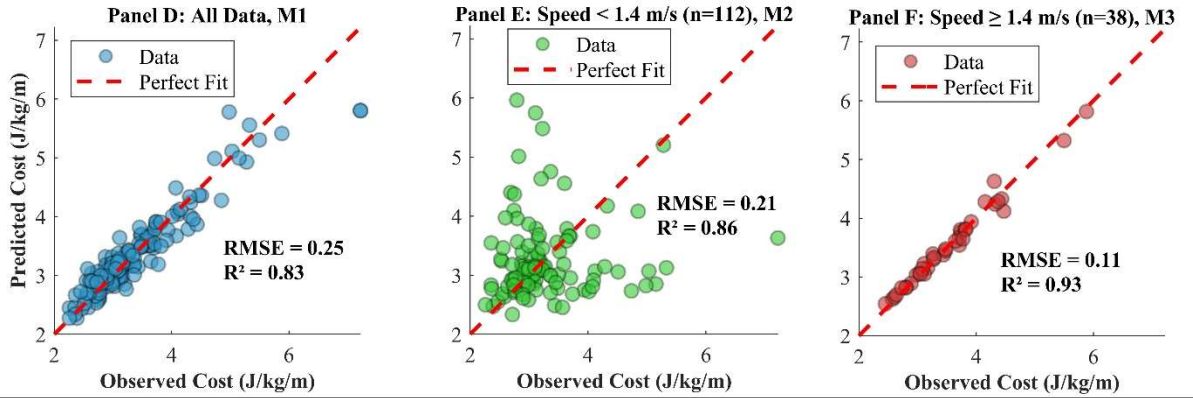
Results

Across all speeds (M1), S index, age, speed, and S index × speed interaction significantly predicted 83% of the MCoW variation (Figure 1D). At speeds below 1.4 m/s (M2), S index, age, and S index × speed interaction significantly predicted 86% of the MCoW variation (Figure 1E). At speeds above 1.4 m/s (M3), only speed significantly predicted 93% of MCoW variation (Figure 1F).

Discussion



We experimentally validated Ruina et al.'s force sequencing theoretical model: improved force sequencing reduces MCoW for speed <1.4 m/s. These results have meaningful implications for gait rehabilitation in individuals who walk slower. Interventions targeting improved force sequencing can be effective to improve MCoW in these populations. The S index is a sensitive metric for identifying changes in gait efficiency at speeds relevant to daily function.



Images (Optional)

Figure 1. Mixed-effects model predictions of metabolic cost during walking. (A) Descriptive statistics of the study sample. (B) S index versus walking speed, (C) Metabolic cost versus walking speed, at speeds below 1.4 m/s as walking speed increases S index decreases, (sequencing leg forces improves) and metabolic costs decreases, however, at speeds above 1.4 m/s, S index reaches a saturation point and increases in walking speeds leads to increase in metabolic cost. (D) Model 1 (M1, all speeds): Predicted versus observed metabolic cost (RMSE = 0.25 J/kg/m, $R^2 = 0.83$). Cost = 0.95 + 0.017×Age + 12.58×S index + 1.27×Speed − 11.98×S index×Speed. Main effects significant: Age ($p<0.001$), S index ($p<0.001$), Speed ($p<0.001$), S index×Speed interaction ($p<0.001$). Age×S index interaction was not significant ($p=0.845$), indicating sequencing leg forces effects on metabolic cost are age-independent. (E) Model 2 (M2, speeds <1.4 m/s): Predicted versus observed metabolic cost (RMSE = 0.21 J/kg/m, $R^2 = 0.86$). Cost = 2.75 + 0.018×Age + 7.06×S index − 10.38×S index×Speed. Significant effects: Age ($p<0.001$), S index ($p=0.009$), S index×Speed interaction ($p<0.001$). Speed effect was not significant ($p=0.766$), indicating age and S index are critical predictors at slower speeds. (F) Model 3 (M3, speeds ≥1.4 m/s): Predicted versus observed metabolic cost (RMSE = 0.11 J/kg/m, $R^2 = 0.93$). Cost = −1.99 + 3.05×Speed. Speed was the only significant predictor ($p<0.005$). Age and S index effects were not significant (p's>0.10), indicating biomechanical constraints limit sequencing leg forces optimization at faster speeds.

Effects of Aging on Lower Extremity Joint Loading and Energy Cost of Walking at Different Gait Speeds and Step Rates

Mr. Dante Goss, Dr. Siddhartha Angadi, Dr. Jay Hertel

University of Virginia, Charlottesville, Virginia, United States

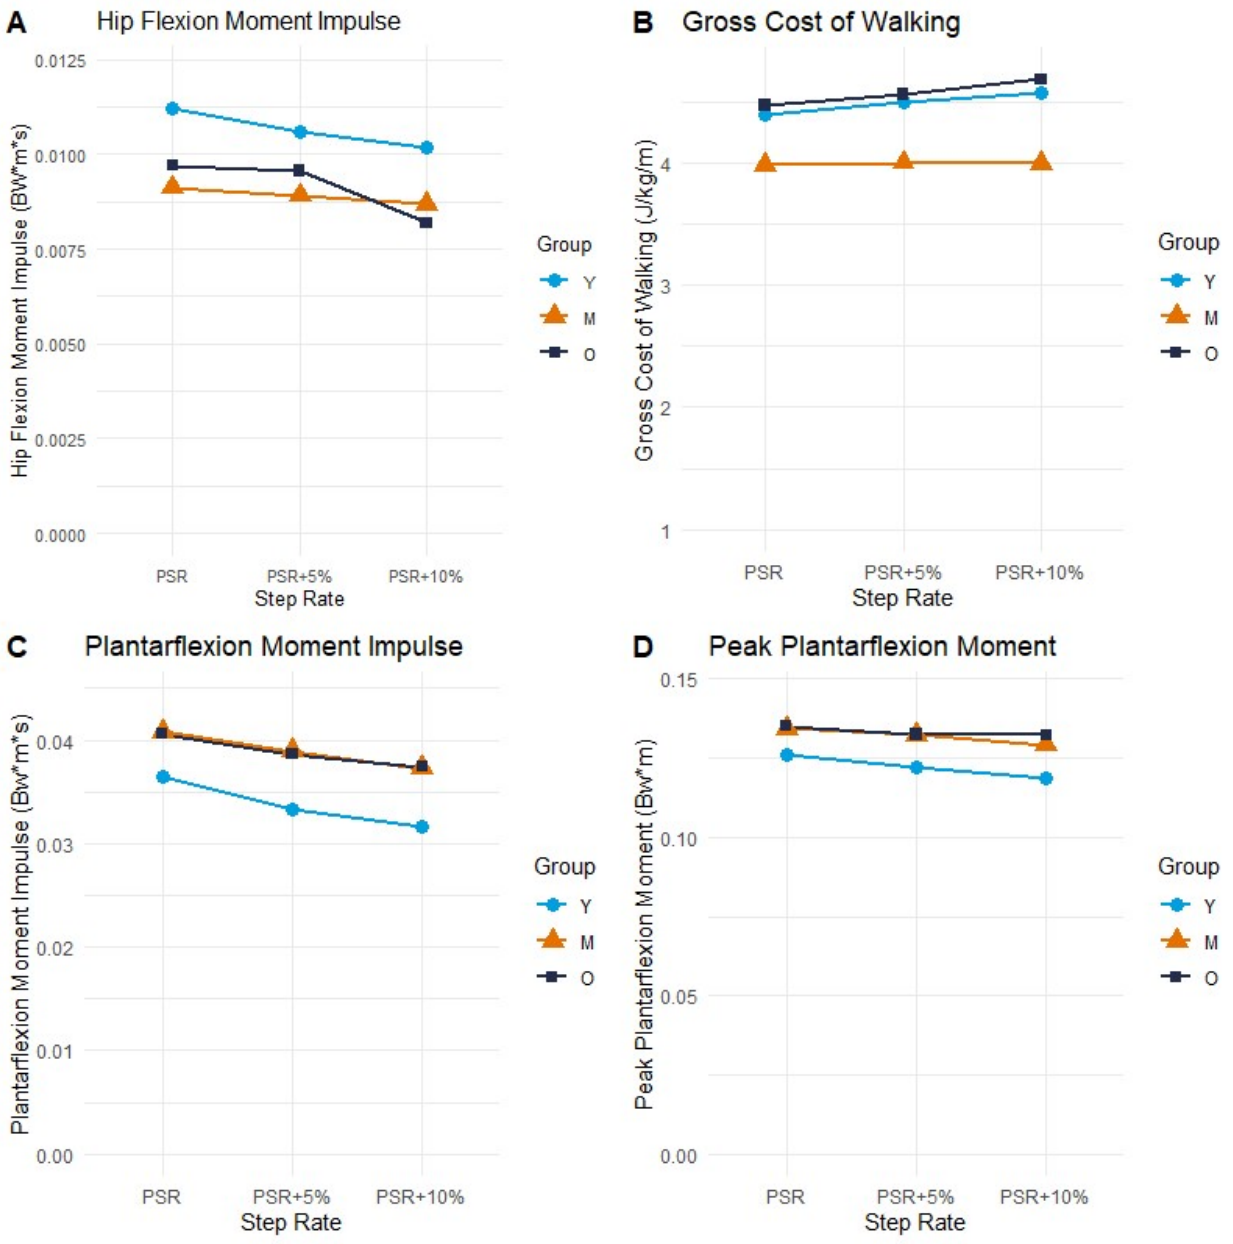
Introduction

The distal-to-proximal shift in joint kinetics from the ankle and knee towards the hip has been proposed as a mechanism for the worsening of walking economy associated with aging, but it is unknown how manipulating gait speed and step rate influence this trend as well as walking economy. The purpose of this study was to examine how changes to gait speed and step rate influence walking economy and lower extremity sagittal plane kinetics between adults in three age groups.

Methods

Fifty-two healthy adults were classified into three age groups: Young (18-39 yrs), Middle (40-59 yrs), Old (60-75 yrs) completed nine trials of gait analysis on an instrumented treadmill while oxygen uptake was measured from indirect calorimetry. Walking trials were completed under three gait speed conditions: preferred gait speed, 10% below preferred gait speed, and 10% above preferred gait speed, and three step rate conditions: preferred step rate, 5% above preferred step rate, and 10% above preferred step rate. Linear mixed effects models were used to test the effect of gait speed, step rate, and age group on peak and impulse values for hip flexion, knee flexion, and ankle plantarflexion, as well as energy expenditure and cost of walking.

Results



Significant interactions existed between age group and step rate for hip flexion moment impulse ($p = 0.05$), gross cost of walking ($p = 0.05$), peak plantarflexion moment ($p = 0.005$), and plantarflexion moment impulse ($p = 0.03$). The middle and old age groups had significantly higher plantarflexion moment impulse values at both 5% above preferred step rate ($p=0.026$) and 10% above preferred step rate ($p=0.018$) compared to the young group. The middle age group had significantly lower gross cost of walking values compared to the old group at 10% above preferred step rate (0.013).

Discussion

This sample did not exhibit changes consistent with age-related distal-to-proximal shift in joint kinetics and showed largely consistent changes across gait speeds with increased

step rate. Older adults may decrease cumulative plantarflexion moment loading with increased step rate less than younger and middle-aged adults, but this change is not reflected in their walking economy.

Left Ventricular Deformation and Strain Reconstruction from Limited CT Frames Using Physics-informed Inverse Modeling

Mr. Weiqiang Liu[1], Dr. Hristo Valtchanov[2], Mr. Sadaival Singh[2], Dr. Francois Guibault[2], Dr. Rosaire Mongrain[1]

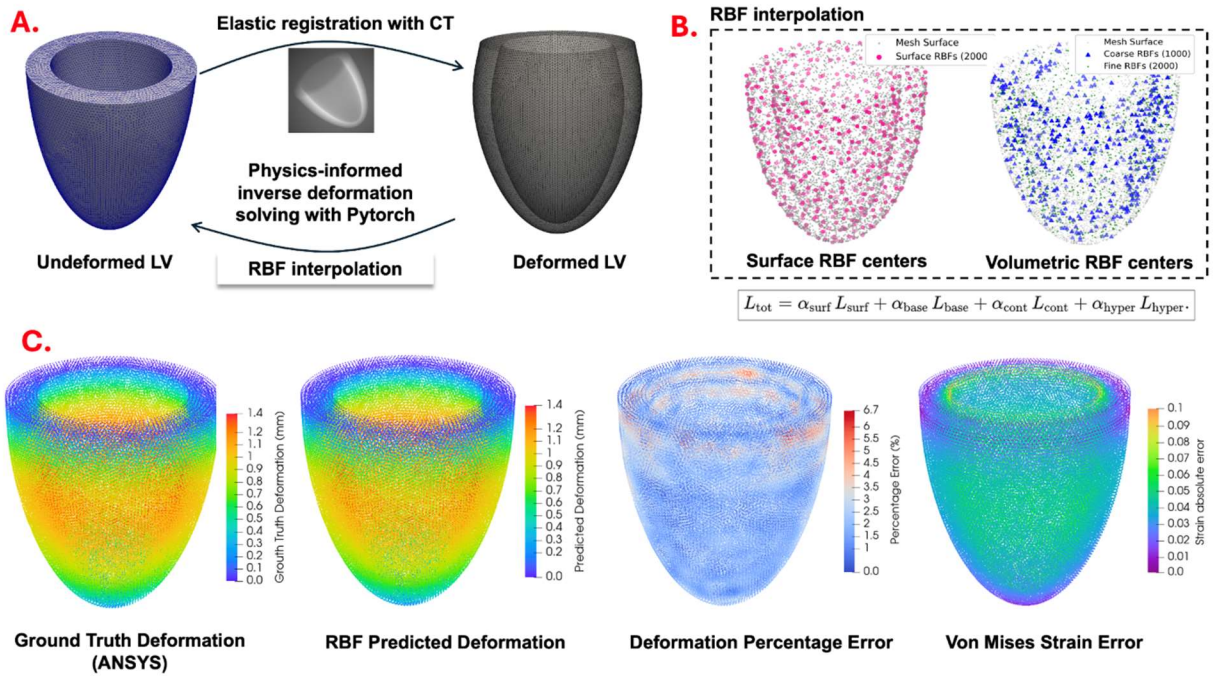
[1]McGill University, Montreal, Quebec, Canada. [2]Polytechnique Montreal, Montreal, Quebec, Canada

Introduction

Reconstructing left-ventricular (LV) deformation and strain is essential for biomechanical assessment and patient-specific cardiac modeling, as these metrics reveal regional contractile dysfunction and lack of perfusion. Hypokinetic wall motion often indicates impaired myocardial viability due to ischemia, necrosis, or microvascular dysfunction[1]. Quantifying such abnormal 3D deformation is crucial to clinical decision-making. Conventional finite-element analysis (FEA) requires high-quality imaging, segmentation, meshing, and computationally intensive solvers—tools rarely combined in clinical routine CT protocols. To address these limitations, we present a meshfree, physics-informed inverse-modeling framework that reconstructs volumetric LV deformation and strain from only a few CT frames.

Methods

The framework uses a hierarchical Gaussian radial basis function (RBF) representation. Surface RBFs first control the vertices' movements during elastic registration between the undeformed LV mesh and multiview CT projections, using mutual information as the optimization objective. The registered surface then provides boundary conditions for an inverse problem solved directly with volumetric RBF interpolation. Two volumetric RBF layers, a coarse layer for global deformation and a fine layer for local variations, are used to interpolate the full displacement field. A combined loss enforces surface displacement matching, fixed base boundary condition, continuity, and constitutive behavior. To evaluate performance, a forward FEA simulation of a truncated-ellipsoid LV (E = 0.5 MPa, 10 kPa endocardial pressure [2]) deformation was conducted in ANSYS as reference values.



Results

On the LV dataset used for validation (~100k nodes), the hybrid RBF reconstruction achieved a mean deformation error of 3.1% and a maximum error of 6.7% relative to the finite-element reference values from ANSYS (Figure 1C).

Discussion

This physics-informed, mesh-free approach enables fast and fully automatable LV biomechanics reconstruction without segmentation or volumetric meshing. The entire pipeline runs in ~10 minutes on an NVIDIA RTX 4070, making it suitable for clinical workflows that rely on sparse CT imaging. As a proof of concept, this study adopts a simplified physical model but the framework already provides clinically meaningful deformation estimation and has potential for extension to patient-specific fiber architecture, multiscale 0D-3D hemodynamics, full heart geometries, and transient simulations.

Bayesian Inference of Lumped Cardiovascular Models Reveals Sex Differences in Ventricular–arterial Function

Ir. Beatrice Moscoloni[1,2,3], Prof. Dr. Ernst Rietzschel[4], Dr. Ir. Mathias Peirlinck[2], Prof. Ir. Patrick Segers[1]

[1]Institute of Biomedical Technology - BioMMedA, Ghent University, Ghent, East Flanders, Belgium. [2]Department of BioMechanical Engineering, TU Delft, Delft, South Holland, Netherlands. Introduction

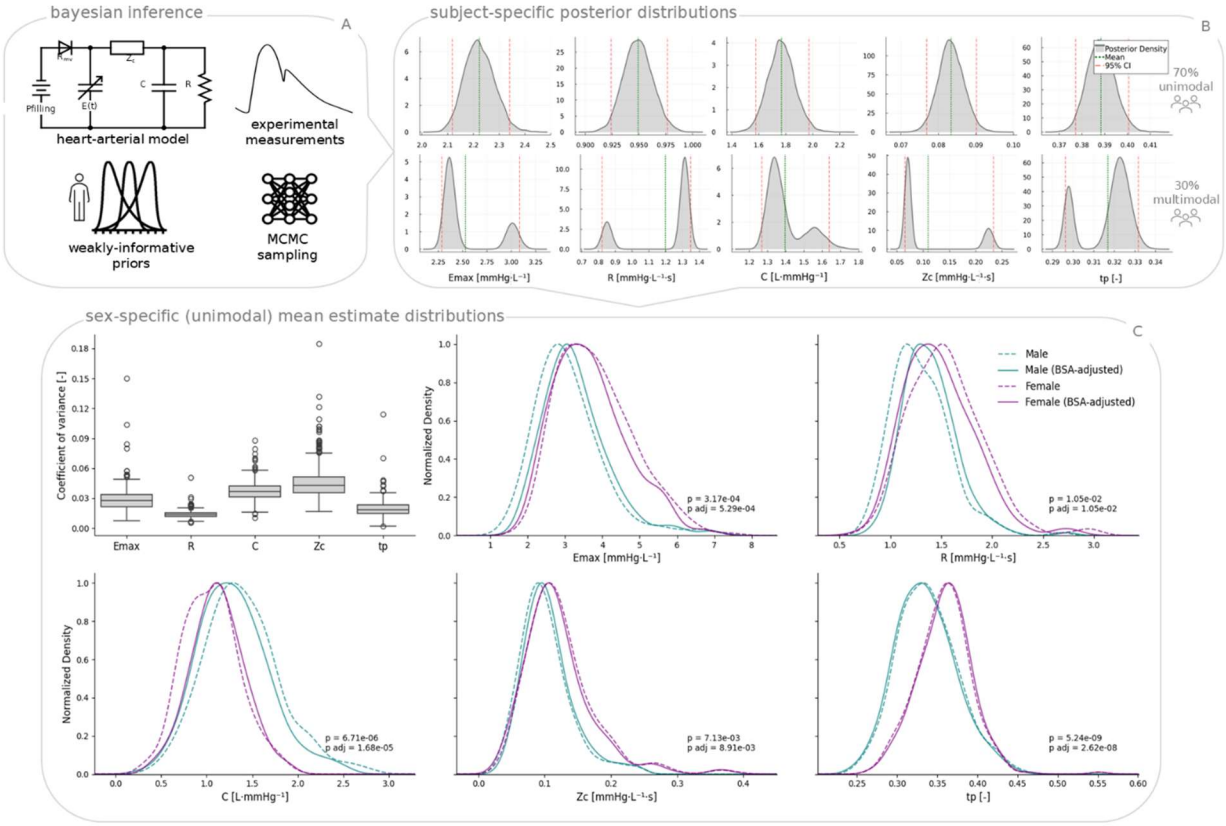
Sex differences in cardiovascular disease are increasingly recognized, yet several questions about sex-specific vascular aging and ventricular–arterial coupling remain pending. Understanding these differences requires robust, mechanistic quantification of cardiovascular model parameters across large populations. Lumped parameter network models (LPNs) offer fast and interpretable estimates of cardiovascular function, yet traditional fitting strategies might fail to resolve parameter uncertainty or practical identifiability, particularly in noisy experimental data. To overcome this, we explore Bayesian inference of an open loop heart–arterial interaction model, using non-invasively recorded central pressure and flow waveforms from the 1st round of the Asklepios study, a longitudinal population study focused on healthy cardiovascular ageing.

Methods

Our LPN consists of a normalized time-varying elastance representing ventricular contraction coupled to a three-element Windkessel arterial system model representing the time-varying arterial afterload (Figure 1A). We estimate five parameters: peak ventricular elastance (Emax), peripheral resistance (R), aortic compliance (C), characteristic impedance (Zc), and timing of the elastance peak (tp)- while holding all others fixed. We work in two stages; we first perform (i) deterministic gradient-based optimization to design weakly informative priors, followed by (ii) subject-specific Markov-chain Monte Carlo sampling to obtain full posterior distributions and credible intervals of the parameters. We deploy the pipeline on a subset of 734 subjects (387F/348M) balanced for covariates.



Results

We found that approximately 30% of subjects exhibited multimodal posterior distributions, indicating distinct parameter combinations capable of reproducing the observed hemodynamics (Figure 1B). Characteristic impedance (Zc) showed the greatest uncertainty, with a median normalized coefficient of variation of 0.046, followed by aortic compliance (0.037), peak elastance (0.028), and timing and resistance parameters (0.019 and 0.014 respectively – Figure 1C). Bayesian inferred model performance remained acceptable given model assumptions, with average R^2 values of 0.82 for aortic flow and 0.87 for aortic pressure. Finally, after adjusting for body surface area, we observed statistically significant sex differences in the posterior mean estimates of all (unimodal) parameters (Figure 1C).

Discussion

Our results highlight the need for uncertainty quantification to obtain reliable parameter estimates from experimental hemodynamic data and demonstrate the potential of Bayesian LPN modeling for mechanistic characterization of sex-specific ventricular–arterial function.

CardioGraphFENet: A Rapid Deep-Learning Surrogate for Cardiac Myocardial Finite Element Modelling

Mr Siyu Mu, Dr Wei Xuan Chan, Miss Niimura Ai, Dr Choon Hwai Yap

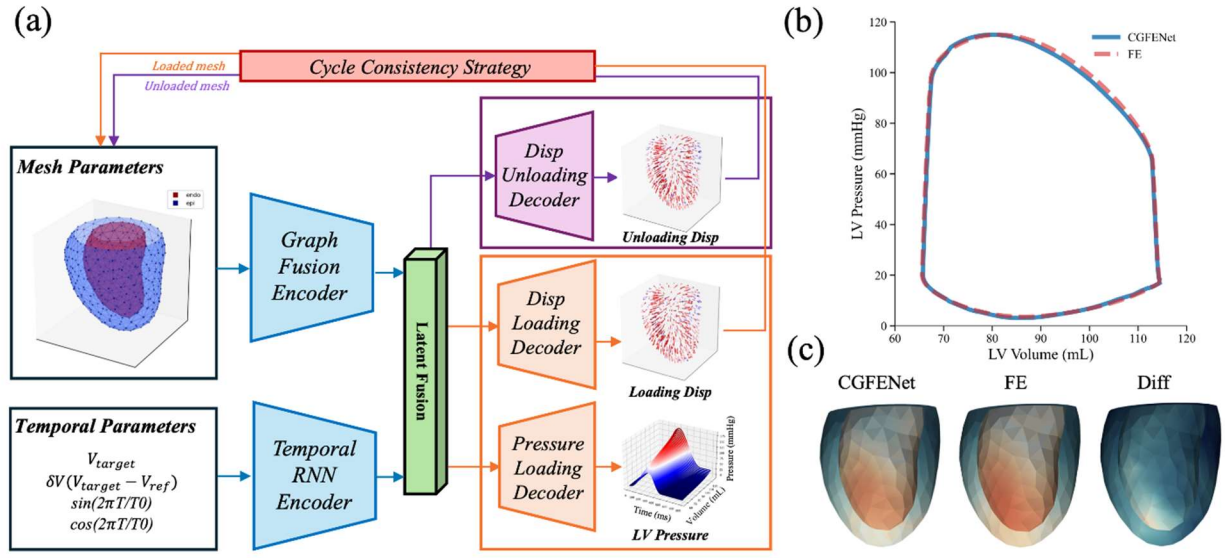
Imperial College London, London, Greater London, United Kingdom

Introduction

Finite element modelling (FEM) is a foundational tool for cardiac biomechanics investigations but often requires hours for a full-cycle simulation, discoursing clinical adoption [1]. Deep learning (DL) offers a faster alternative. However, PINN-FEM require reduced-order modelling that reduces accuracy, and still need many minutes for inference, while existing one-shot networks have succeeded in modelling only passive diastolic mechanics and not systolic contractions [2]. Here, we introduce CardioGraphFENet, a DL graph-based surrogate enhanced with a cycle-consistency framework, for full-cycle FEM left ventricle (LV) modelling with any arbitrary LV 3D mesh input.

Methods

CardioGraphFENet functions as a unified surrogate for both forward FEM (predicting pressure and displacement fields) and inverse FEM (predicting the zero-pressure load-free configuration). The architecture integrates a graph fusion encoder to extract mesh features and used GRUs to encode time-dependent mechanics. It trained with a self-supervised cycle-consistent strategy, where the predicted forward FEM step is enforced to match the predicted reversal of the step. The framework was trained on a synthetic dataset of over 1.8 million LV states, generated from a range of LV shapes from a statistical shape model [3] and varying physiological conditions.



Results

CardioGraphFENet was benchmarked against GraphUNet and MeshGraphNet and demonstrated the best performance. For loading displacement prediction, the model achieved an accuracy of 90% of nodes having <1mm error and 99% <2mm error, and R^2>0.98 for pressure prediction. When combined with a lumped parameter model, the predicted P–V loop closely matched the FEM ground truths. For a full cycle simulation of 50 time points, CardioGraphFENet reduced computation time from several hours to under one minute, a 70-fold acceleration.

Discussion

CardioGraphFENet is fully supervised by mass FEM simulations. This is more effective than PINN, which incurs very high computational costs, unless reduced order is utilized, but which reduces accuracy. CardioGraphFENet allows anyone without FEM skills to perform FEM very quickly, potentially encouraging clinical adoption and enabling large clinical trials. Being robust, fast and flexible, it can be used in various secondary optimization loops.

Aneurysm Forecasting Studio: A Machine Learning Based Tool for Time-Series Prediction of Wall Growth and Lumen Remodeling in Abdominal Aortic Aneurysms

Ph.D. Candidate Juan Restrepo[1], Ph.D. Amanda Fernandez[1], Ph.D. Seungik Baek[2], M.D. Satish Muluk[3], M.D. Mark Eskandari[4], M.D. Vikram Kashyap[5], M.D. Eanas Yassa[5], Ph.D. Ender Finol[1]

[3]Allegheny General Hospital, Pittsburgh, Pennsylvania, United States. [4]Northwestern University, Chicago, Illinois, United States. [5]Corewell Health, Grand Rapids, Michigan, United States

Introduction

Artificial Intelligence in cardiovascular medicine has advanced segmentation, surveillance, and risk prediction, yet time-series models for full-geometry forecasting remain limited. Most prior work predicts scalar measures such as maximum diameter or volume, overlooking spatial heterogeneity of aneurysm remodeling. This work introduces a patient-specific framework for forecasting 3D wall and lumen remodeling in Abdominal Aortic Aneurysm (AAA), enabling anticipatory surveillance and future anatomical estimations.

Methods

We modeled the AAA wall and lumen independent evolutions using local linear heterogeneity via patient-specific linear mixed-effects modeling applied in a standardized cylindrical grid within follow-ups enabling node-wise estimation of local linear trends and regional variability. We used data from 79 patients under surveillance in a multicenter cohort totaling 249 computed tomography exams. Performance was assessed using per-patient means of spatial similarity (HD95) across centerline, cylindrical, and cartesian domains, and geometric errors in maximum diameter and volume. The resulting models were integrated into an interactive forecasting interface that generates future geometries, enabling rapid visualization, threshold timing, and patient-specific monitoring.

Results

Forecasts achieved sub-millimetric spatial similarity in the cylindrical representation (HD95 wall: 0.7 mm; HD95 lumen: 0.9 mm) and low geometric errors in maximum diameter and volume (≤ 2%). Model fitting required 7–15 seconds per patient and inference produced real-time predictions, significantly reducing computation compared to growth-

and-remodeling alternatives. Predicted geometries remained anatomically coherent and captured regional remodeling patterns for diverse temporal intervals and anatomical layers. A representative evaluation case and interface output are shown in the figure.

Discussion

Our findings demonstrate that patient-specific mixed-effects modeling can accurately forecast short-term AAA wall and lumen remodeling, capturing both global trends and localized heterogeneity without requiring complex biomechanical simulations. The approach is fast, interpretable, and driven solely by past imaging and time, enabling real-time estimation of future morphology, threshold timing, and trajectory exploration. Integration into an interactive forecasting interface supports clinical use by providing instant 3D geometry previews at any prospective time point. A key limitation is the absence of clinical covariates, which may restrict physiological interpretability. Broader, globally representative datasets will be essential to validate robustness and ensure applicability across diverse patient populations.

Images (Optional)

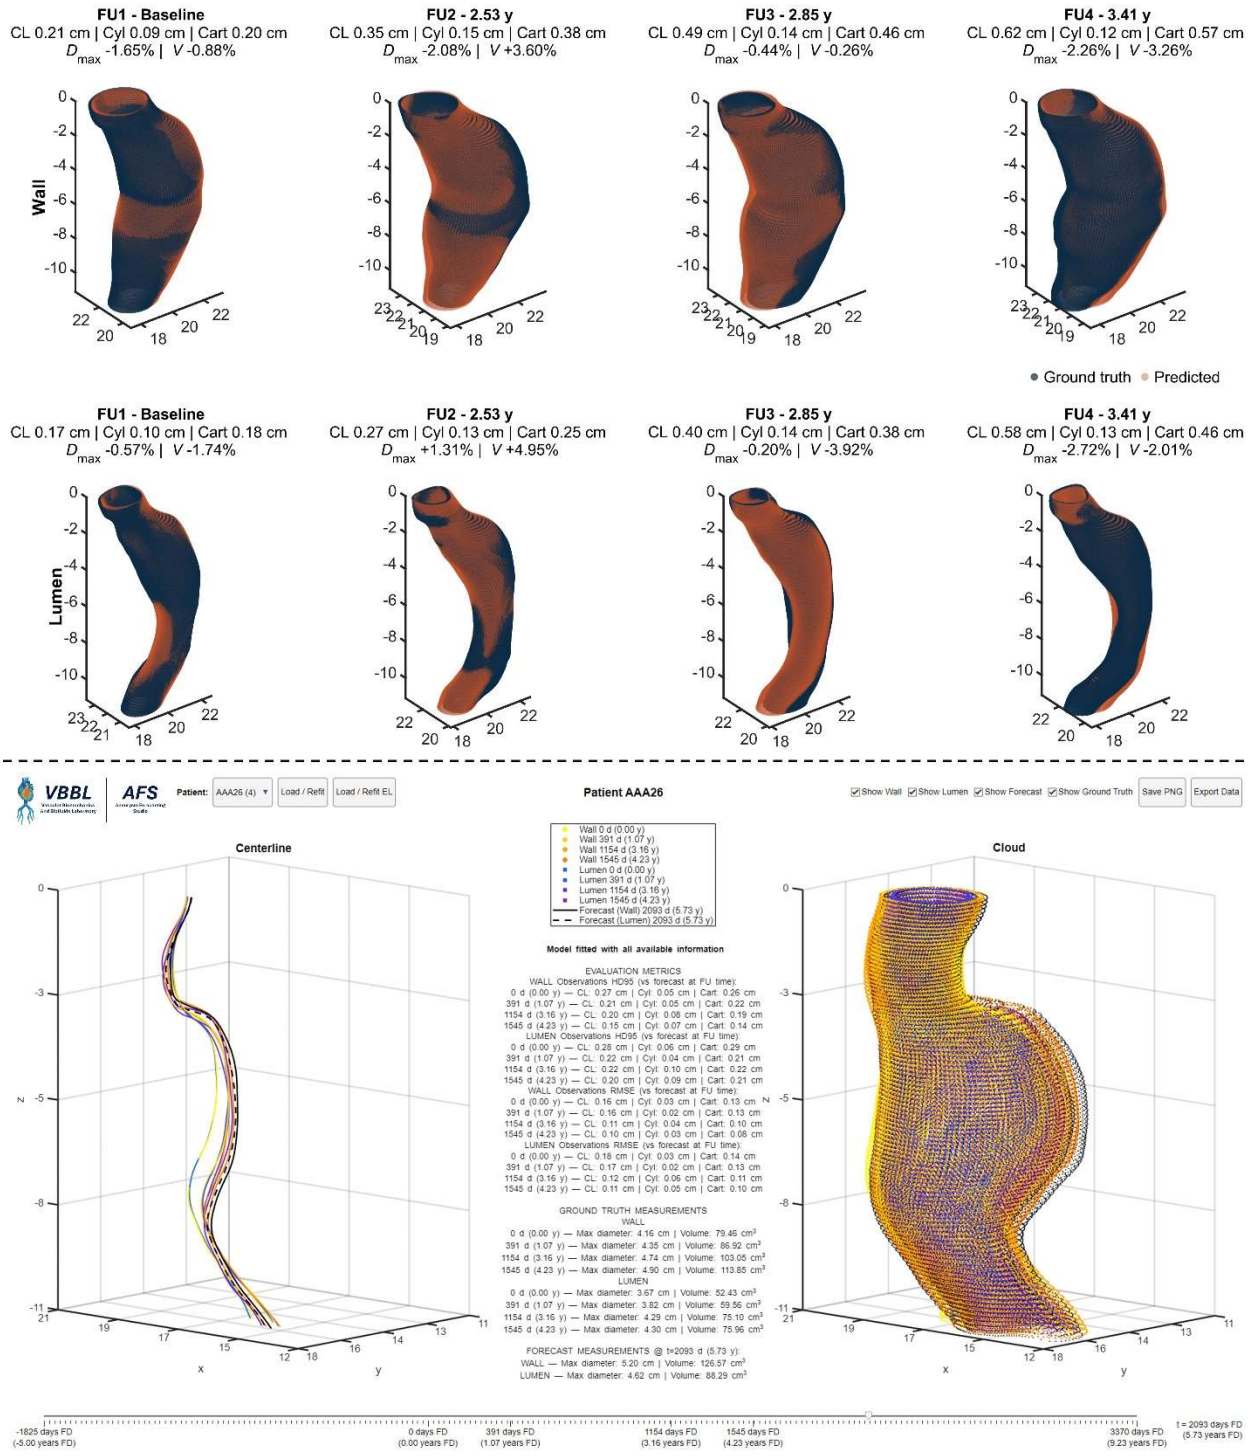

Figure. Top: Reconstruction example for a patient with four follow ups. Navy clouds show ground truth wall (top) and lumen (bottom) surfaces, and orange clouds show their corresponding predictions. Reported values are HD95 centerline (CL), cylindrical (Cyl), and Cartesian (Cart) with relative deviations in maximum diameter (D_{max}) and volume (V). Bottom: Aneurysm Forecasting Studio (AFS) display for a different patient, including a forecast 18 months beyond the last scan. Wall colors progress yellow to orange and lumen blue to purple by time, with forecasts in black. The evaluation panel reports HD95, RMSE, and forecasted D_{max} and V at a prescribed time in the future. AFS supports visibility toggles and data export for analysis and reuse.

Semi-Automated Subject-Specific Foot Modeling for Efficient and Accurate Plantar Pressure Analysis Across Arch Types

Ms. Olamide Hassan BSc, MSc Student, Ms. Jungeun Gwon BSc, MSc Student, Prof. Jeicheong Ryu PhD, Prof. Taeyong Lee PhD

Ewha Womans University, Seoul, Seoul, Korea, Republic of

Introduction

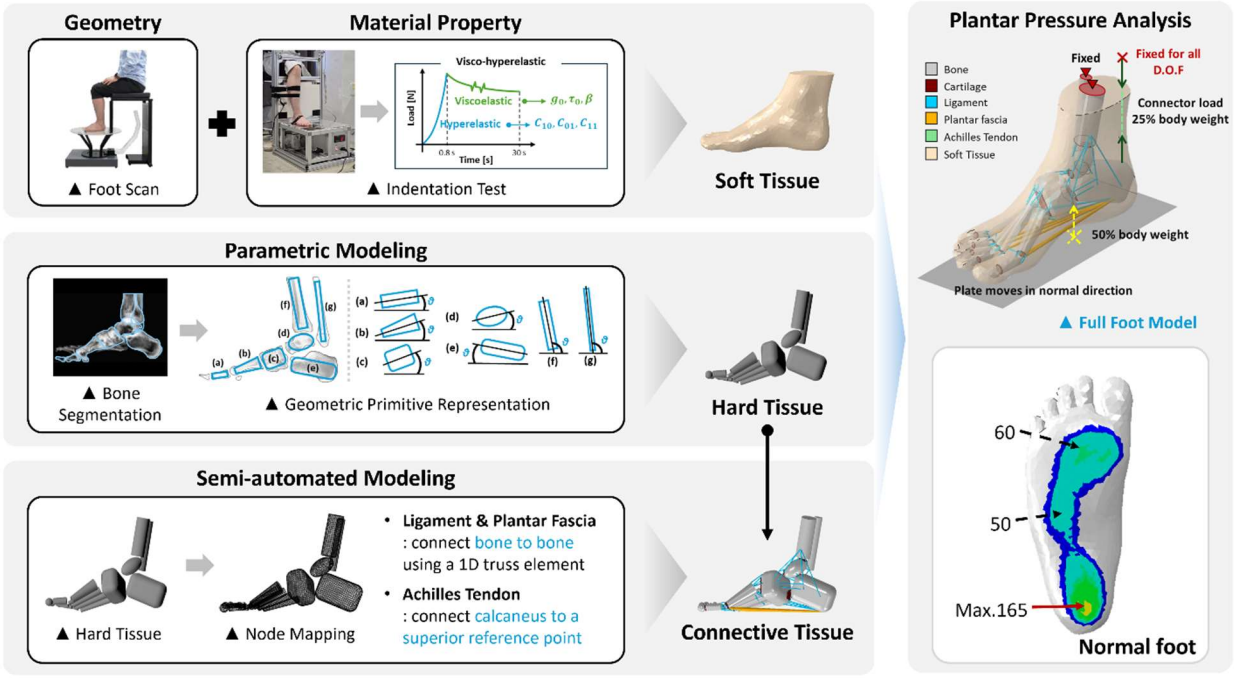
Excessive plantar pressure is linked to pain and deformity and is strongly influenced by foot geometry, particularly arch type, and by plantar soft-tissue mechanics. Finite element analysis (FEA) can provide detailed insight into plantar loading, but existing models are time-consuming to build and typically rely on generic soft-tissue properties and manually defined ligaments, fascia, and tendons, limiting scalability. Scalable foot analysis is essential for population studies and mass-personalized insoles. This study presents a semi-automated, subject-specific foot modeling framework that integrates individual geometry, indentation-derived plantar soft-tissue properties, and semi-automated connective tissues to analyze plantar pressure across normal, flat, and high-arched feet.

Methods

Twenty adults (10 normal, 5 flat, 5 high-arched feet) underwent 3D foot scanning, weight-bearing imaging, and quiet-standing plantar pressure measurements. An X-ray–driven parametric pipeline reconstructed rigid bones from geometric primitives and embedded them in the scanned foot surface. Plantar soft tissue was represented by an indentation-calibrated visco-hyperelastic model with hyperelastic loading and viscoelastic relaxation.

Connective tissues were added semi-automatically: ligaments and plantar fascia as truss elements between bony attachments, and the Achilles tendon as a tensile connector from the calcaneus to a reference node generated with an Abaqus node-mapping script. The tibia was fixed, a rigid plate applied 50% body weight beneath the foot and 25% body weight transmitted through the Achilles connector; plantar pressure was evaluated at the plate–soft tissue interface.

Results



All 20 cases were successfully simulated using the proposed framework. Compared with a previously studied high-fidelity CT-based model, the X-ray–based parametric bones reduced computation time from about 5 hours to 30 minutes and preprocessing from 7

days to 3, while the proposed semi-automated connective tissue module further reduced preprocessing to under 1 hour per subject. Across subjects, simulated plantar pressure distributions showed arch-type-dependent patterns and remained within 15% error of experimental measurements.

Discussion

These findings indicate that combining subject-specific plantar soft tissue mechanics with semi-automated connective tissue generation enables scalable, biomechanically plausible plantar pressure analysis across arch types. The framework substantially reduces modelling time while preserving accuracy, providing a basis for large cohort in silico studies and future evaluation of orthotic or footwear interventions.

Introduction

Human muscle biopsies are often required to study or diagnose diseases, offering insights into muscle fiber mechanics, fiber composition, and molecular pathways. However, traditional biopsy approaches are limited by sample size, inconsistent fiber orientation, and patient discomfort. Fine-gauge needle biopsies (≥14-gauge) reduce invasiveness but frequently yield insufficient tissue for multidimensional and simultaneous analyses of biomechanical, biochemical, and histological properties. To address these limitations, we developed an ultrasound-guided, vacuum-assisted, single-insertion multiple-sampling technique capable of providing high-quality muscle samples suitable for integrated analysis.

Methods

In 19 healthy subjects (mean age: 30.1 years±10.6 (SD), 42% male) we collected 2-3 muscle samples from a single needle insertion into the vastus lateralis (VL) and tibialis anterior (TA) muscles. Fiber cross-sectional area (fCSA), fiber number, and satellite cells were histologically quantified. Portions of each biopsy were allocated for mitochondrial respirometry, RT-PCR, and collagen content. Permeabilized single fibers were isolated from biopsy-derived bundles for measurement of active force and passive elastic modulus. Pain ratings and adverse events were recorded immediately and 24 hours post-procedure.

Results

Ultrasound-guided biopsy allowed visualization of vasculature and nerves, preventing adverse events, and optimal needle orientation parallel with muscle fascicles. Summed VL and TA sample masses from a single needle insertion averaged 148±38mg and 166±64mg,

with dimensions of 15.83±8 x 2.9±0.6mm^2 (VL) and 15.07±7 x 3.1±0.9mm^2 (TA). VL had a mean fCSA of 4,347±1,931µm^2, with 221±86 fibers quantified. Samples were of sufficient size and quality for thorough analyses from a single biopsy procedure, including mitochondrial respirometry, RT-PCR, collagen content, satellite cell quantification. Single-fiber mechanics were successfully performed in permeabilized fibers, yielding typical isometric stress values of 187kPa with a passive modulus of 239kPa (peak) and 79kPa (stress-relaxed). This procedure was well tolerated, with mean pain ratings of pain rating of 1.5±1 (range:0-4, scale: 1-10) immediately and 1.7±1 (range:0-4) at 24-hours.

Discussion

This biopsy approach consistently yielded high-quality muscle samples suitable for integrated structural, molecular, metabolic, and single-fiber mechanical analyses. By overcoming key limitations of traditional biopsy approaches, this minimally invasive, fascicle-aligned method now provides a scalable platform for multidimensional biomechanical research and translational human studies.

Full-Field Quantification of Anisotropic Elasticity in Skeletal Muscle During Contraction

Dr. Roberto Pineda Guzman[1], Dr. Melissa Hooijmans[1,2,3], Ms. Carly Lockard[1], Dr. Crystal Coolbaugh[2], Ms. Evelyn Bombard[4], Dr. Bruce Damon[1,2,4], Dr. Callan Luetkemeyer[4]

[1]Carle Foundation Hospital, Urbana, Illinois, United States. [2]Vanderbilt University, Nashville, Tennessee, United States. [3]Amsterdam University Medical Center, Amsterdam, North Holland, Netherlands. [4]University of Illinois Urbana-Champaign, Urbana, Illinois, United States

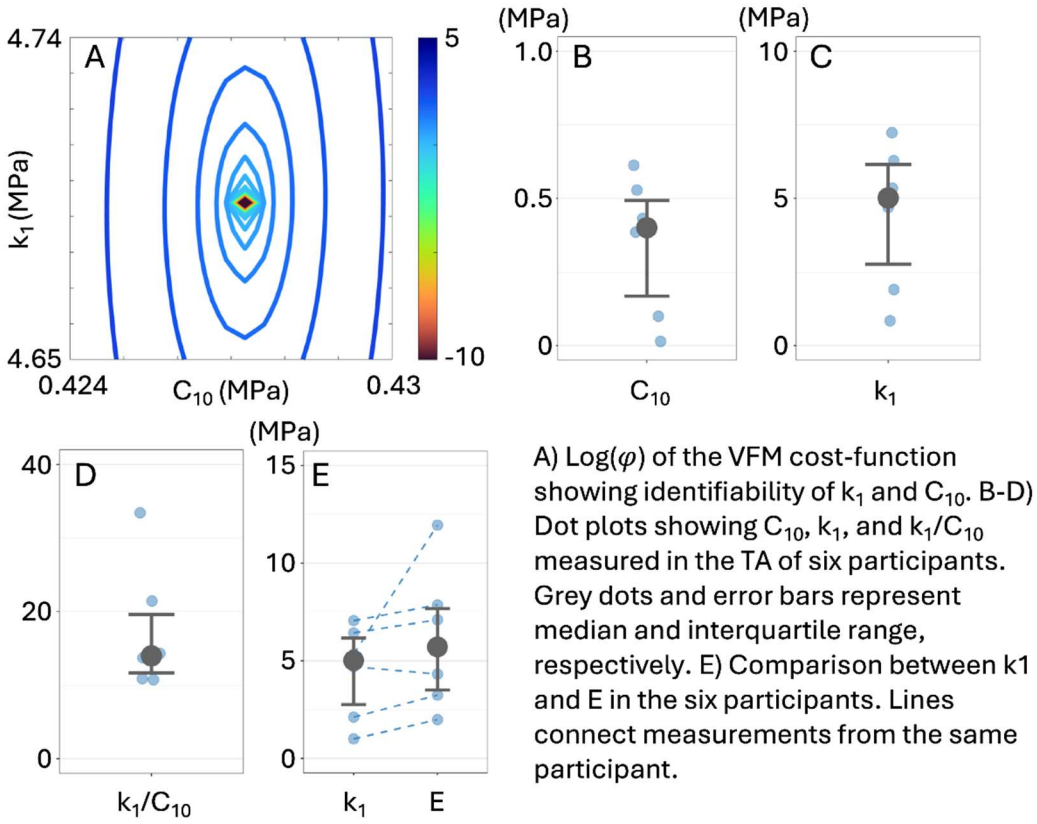
Introduction

Skeletal muscle has anisotropically-organized microstructural components, which may contribute to complex mechanical behavior. Disease-related microstructural disruptions alter elasticity, impair function, and increase susceptibility to damage during contraction. Microstructure-informed characterization of muscle elasticity during contraction is therefore essential for understanding disease-induced functional changes. Currently, anisotropic elasticity during contraction is measured with ultrasound-based elastography (USE) [1], which assumes mechanical linearity, provides only local 2D measurements, and does not account for fiber orientation changes during contraction. In contrast, MRI-based methods enable full-field measurements of whole-muscle fiber orientation and strain during contraction 2], enabling more comprehensive assessment. This study quantified anisotropic mechanical properties of contracted skeletal muscle using MRI-based data and the Virtual Fields Method (VFM), a microstructurally-informed and full-field inverse approach [3].

Methods

Seven healthy participants performed isometric ankle dorsiflexion at 40% maximum voluntary contraction force during 3T MRI. Full-field strain and fiber orientation data from the tibialis anterior (TA) were obtained [2]. TA force was estimated following published methods [4]. The VFM was implemented to identify parameters of the non-linear and anisotropic Holzapfel-Gasser-Ogden (HGO) model that best matched the MRI-based measurements. A non-linear cost function () incorporating three virtual fields –targeting longitudinal, transverse, and shear deformation – was minimized to obtain optimal HGO parameters. Along-fiber elastic modulus (k_1) and shear modulus (C_{10}) and the mechanical anisotropy ratio (k_1/C_{10}) were computed. For comparison, an apparent elastic modulus (E)

was computed using mean end-to-end displacement and maximum transverse cross-sectional area.



Results

The VFM cost function () was successfully minimized in six participants, yielding stable estimates of k_1 and C_{10} with well-defined local minima (Fig. 1A). Participant-specific values are shown in Figures 1B-D. Estimates of k_1 were consistent with E, while exhibiting a lower coefficient of variation.

Discussion

We demonstrate that the VFM can quantify the elasticity of skeletal muscle during contraction using the passive HGO model. The resulting k_1/C_{10} ratios align with previously reported USE measurements [1], and the agreement between k_1 and the apparent Young's modulus (E) supports using k_1 to describe along-fiber elasticity. Future work will apply this framework to diseased muscle and incorporate active contraction into constitutive models.

Images (Optional)

A) Log(φ) of the VFM cost-function showing identifiability of k_1 and C_{10}. B-D) Dot plots showing C_{10}, k_1, and k_1/C_{10} measured in the TA of six participants. OA168-04

Female Pelvic Floor Muscle Strength Measured by Intravaginal Dynamometry Is Impacted by Arm Design and Protocol

Ms Olena Klahsen MSc, Dr Marina Petter Rodrigues PhD, Dr Linda McLean PhD

University of Ottawa, Ottawa, Ontario, Canada

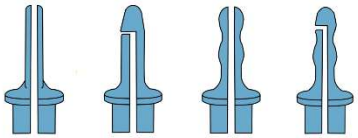
Introduction

Intravaginal dynamometry (IVD) is the gold standard for measuring pelvic floor muscle (PFM) strength, however, the impact of variation in IVD arm designs among studies is unknown. Further, intra-abdominal pressure (IAP) may influence force outcomes. To reduce IAP crosstalk, authors have suggested using asymmetric arms to protect the measurement arm from the influence of IAP and having participants gently bear down (BD) while adjusting the arm position to ensure that IAP does not influence output force [1]. We sought to determine how IVD outcomes are impacted by arm design and device adjustment using the BD maneuver.

Methods

Four IVD arm styles were generated based on published literature: flat, rounded and saddle-shaped (symmetrical and asymmetrical) [2,3]. Twenty-two adult females attended a single laboratory session. Using each design in a random order, and using the same aperture, three trials of maximum voluntary contractions (MVCs) were performed with and without the arm position adjusted using a BD protocol. Baseline, maximum and relative peak (maximum – baseline) forces and rate of force development were computed. Separate generalized linear mixed models were used to determine the effect of arm design and BD adjustment on each outcome (α=0.05).

Results



Force outcomes are presented in Table 1. There was no interaction between arm design and BD adjustment for any outcome. Arm design and BD adjustment independently influenced baseline, maximum and relative peak forces, but not the rate of force development. The highest baseline, maximum and relative peak forces were observed using the flat arms. Maximum force was lower when recorded using rounded arms than symmetrical saddle-shaped arms. In comparison to unadjusted trials, the BD adjustment resulted in lower baseline and maximum forces, and higher relative peak forces but no difference in rate of force development.

Discussion

Measures of PFM strength are not comparable among studies where different IVD arms have been used. The significant impact of BD adjustment, independent of arm design, suggests that this approach may indeed limit IAP crosstalk.

Images (Optional)

Table 1. Effect of intravaginal arm design and device adjustment on IVD measures

IVD Arm Designs  A B C D		*IVD Measures of PFM Strength*

Novel 3-D Characterization of *in Vivo* muscle Properties Illustrates Directional Dependence in Resistance to Stress

Dr Ridhi Sahani[1,2], Dr Qifeng Wang[1], Dr Amr Mahrous[1], Research Assistant Professor Matthieu Chardon[1], Professor Kenneth Shull[1], Research Assistant Professor Daniel Ludvig[1,2], Professor Eric Perreault[1,2]

[1]Northwestern University, Chicago, Illinois, United States. [2]Shirley Ryan AbilityLab, Chicago, Illinois, United States

Introduction

Skeletal muscle injuries have debilitating impacts on daily function. The material properties of muscle govern its ability to resist stresses during injury and *in vivo* measures of these properties would help explain how and why injuries occur during physiological conditions. To characterize the full material properties of living muscle (i.e. shear (u) and Young's (E) moduli in the planes parallel (II) and perpendicular (T) to muscle fibers) we coupled micro-indentation and uniaxial extension in cat soleus muscles, with finite-element modeling. We hypothesized that Young's (E_{II}, E_T) and shear (u_{II}, u_T) moduli would increase with stress and vary between active and passive muscle, suggesting that muscles' resistance to loading is dependent on stress and activation.

Methods

In vivo material properties were measured in the soleus muscles of anesthetized cats (n=4; 2M, 2F) at active and passive lengths corresponding to 25-100% of optimal force. At each length, the short-range stiffness of the muscle-tendon-unit was used to calculate the Young's modulus parallel to muscle fibers (E_{II}) [1]. The mid-belly of the muscle was indented parallel and perpendicular to muscle fibers, using an ultrasound for visual guidance. The remaining moduli were estimated using the force-displacement data from indentation, E_{II}, and a finite-element modelling-based optimization [2].

Results

The shear modulus was greater in the parallel (u_{II}) compared with the perpendicular (u_T) plane at stress above ~50% of optimal force. u_{II} increased with both active and passive stress while u_T only increased with passive stress (Fig 1 A-B). The Young's modulus was greater in the parallel (E_{II}) compared with the perpendicular (E_T) plane at all levels of stress. E_{II} increased with both active and passive stress while E_T only increased with passive stress (Fig 1 C-D). Similar trends were observed in another cat and will be evaluated across animals.

Discussion

Our approach is the first to determine the full material properties of living muscle. Shear and tensile moduli were greater parallel than perpendicular to muscle fibers at higher stresses, suggesting a directional dependence in *in vivo* material properties and thus injury susceptibility.

Images (Optional)

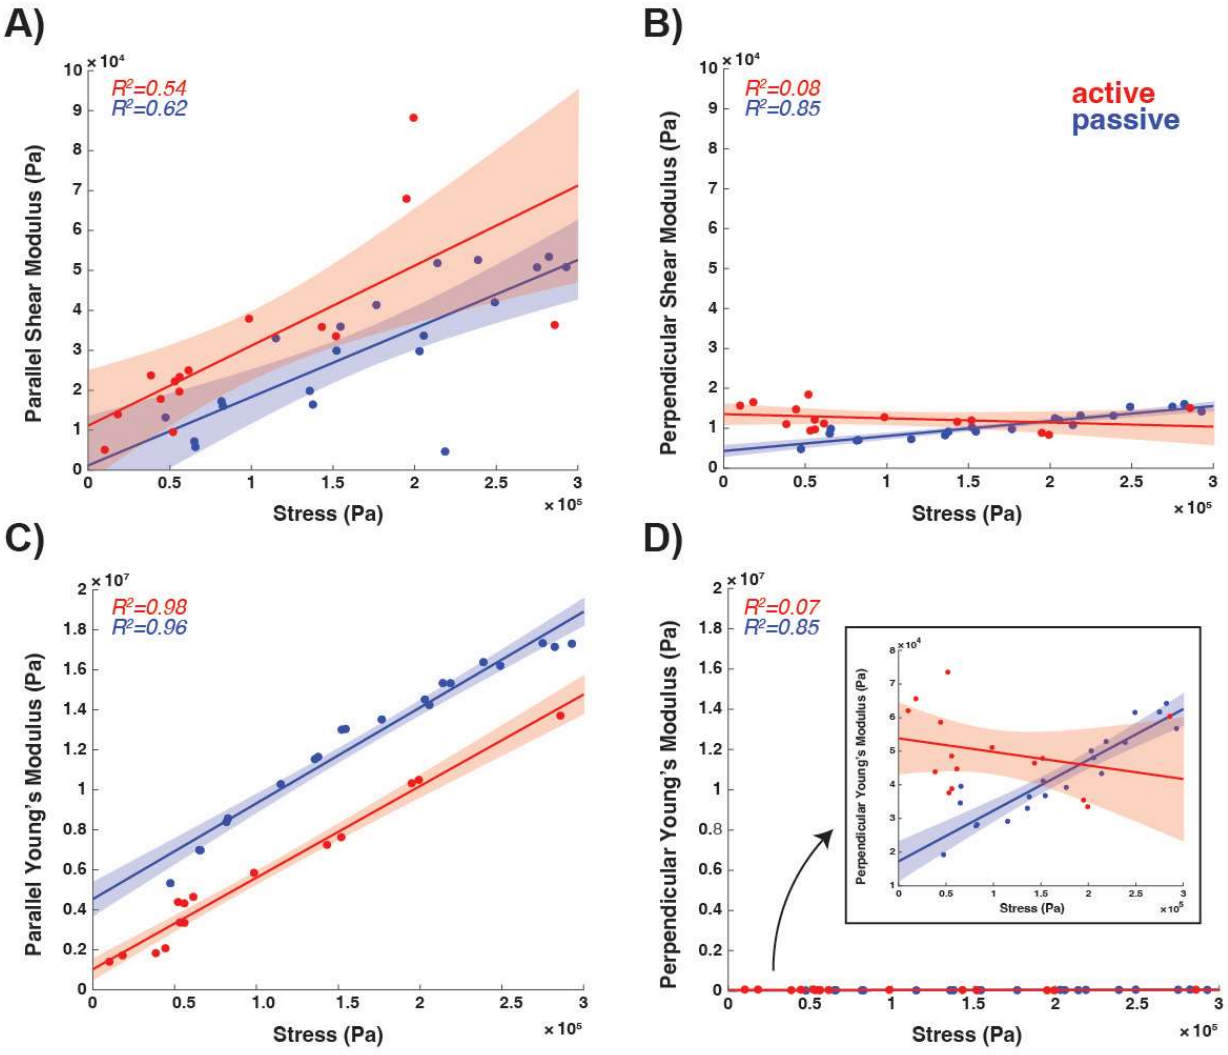

Figure 1. Data from one representative cat. Individual trials (o) in passive (blue) and active (red) muscles at approximately matched stresses. Trends from linear regression (solid line) with 95% confidence intervals (shaded region). Relationships between stress and shear modulus parallel (**A**) and perpendicular (**B**) to muscle fibers. Relationships between stress and Young's modulus parallel (**C**) and perpendicular (**D**) to muscle fibers.

Vessel Softening from TBI Increases Brain Vulnerability to Subsequent Head Trauma

Mr. Farshid Shojaeianforoud PhD Candidate[1], Mr. Alexander Venezie[1], Dr. Jose Rubio[2], Dr. Jaques Reifman[2], Dr. Brittany Coats Professor[1], Dr. Ken Monson Associate Professor[1]

[1]University of Utah, Salt Lake City, Utah, United States. [2]Department of Defense Biotechnology High Performance Computing Software Applications Institute, Fort Detrick, Maryland, United States

Mr. Farshid Shojaeianforoud

Mr. Alexander Venezie

Dr. Brittany Coats

Introduction

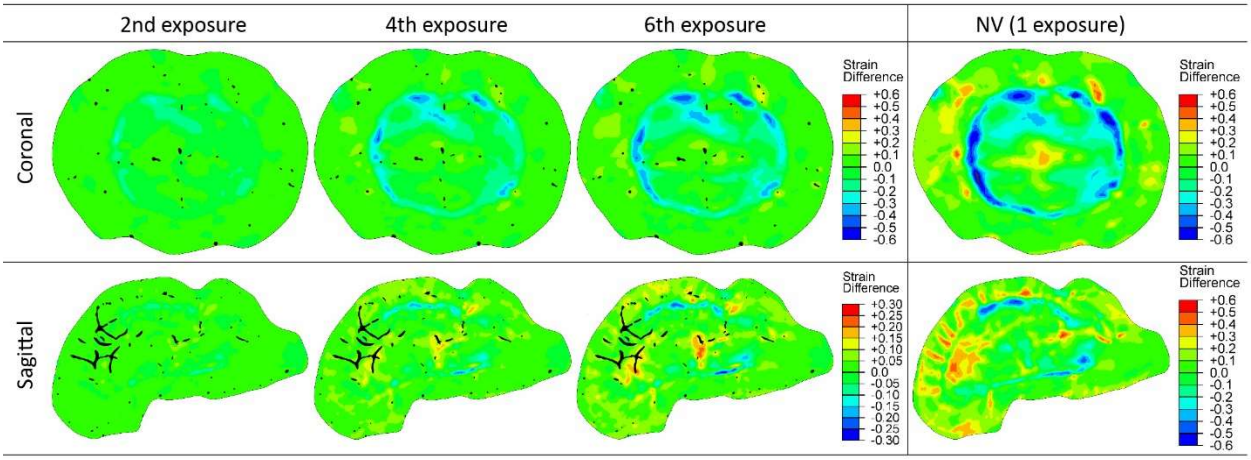
Repeated traumatic brain injury (TBI) is a significant concern among military personnel, athletes, and abuse victims, but little is known about the mechanisms that drive the brain's apparent increase in injury susceptibility with repeated loading. One critical factor may be the softening of cerebral blood vessels, which are significantly stiffer than brain tissue and influence its mechanical response during trauma. In this study, we employed a finite element model of a Göttingen minipig head to investigate how progressive vascular softening influences strain changes in brain tissue during both repeated blast and rapid rotation (coronal and sagittal directions).

Methods

The model, previously validated for single blast exposure, incorporated pig-specific anatomical detail and material properties, including detailed cerebral vasculature. Simulations included six repeated exposures of either blast overpressure or coronal or sagittal rotations at three severity levels (18 simulations). Additional "no-vasculature" (NV) cases were included for each loading condition (3 more simulations; 21 simulations in total) to benchmark the mechanical contribution of blood vessels. Vessel softening was

applied after each exposure based on previous experiments on Göttingen minipig cerebral arteries.

Results



While blast exposures did not generate sufficient strain to induce vessel softening and accumulation of damage, rotational events led to progressively increasing brain strain with repetition, especially in regions adjacent to softened vessels (Fig. 1). These increases progressed toward the NV condition with repetition, consistent with diminishing structural support by softened vessels. Results also showed increasing risk of vessel rupture and axonal injury with repetition.

Figure 1: Distribution of strain difference, relative to the baseline simulation (1st exposure), in brain tissue during severe coronal and sagittal rotations. Results for coronal and sagittal rotations are shown on mid-coronal and mid-sagittal sections, respectively.

Discussion

Results demonstrate an overall increase in brain tissue strains as vessel damage accumulated with repeated loading. These findings provide novel insight into how vessel damage can amplify local brain tissue strain in repeated TBI. Progressively increasing brain tissue strain elucidate the biomechanical role of vessel softening in repeated TBI and suggest that even sub-failure vessel damage may exacerbate brain strain in repeated exposures and elevate injury risk.

A Biomechanical–Mathematical Model Linking Brain Impact Biomechanics to Tau Protein Accumulation in Chronic Traumatic Encephalopathy

MSc Jose González Cabrero[1], MSc Carlos G.S Cardoso[1], PhD Inés Moreno González[2], PhD Ricardo J. Alves de Sousa[1]

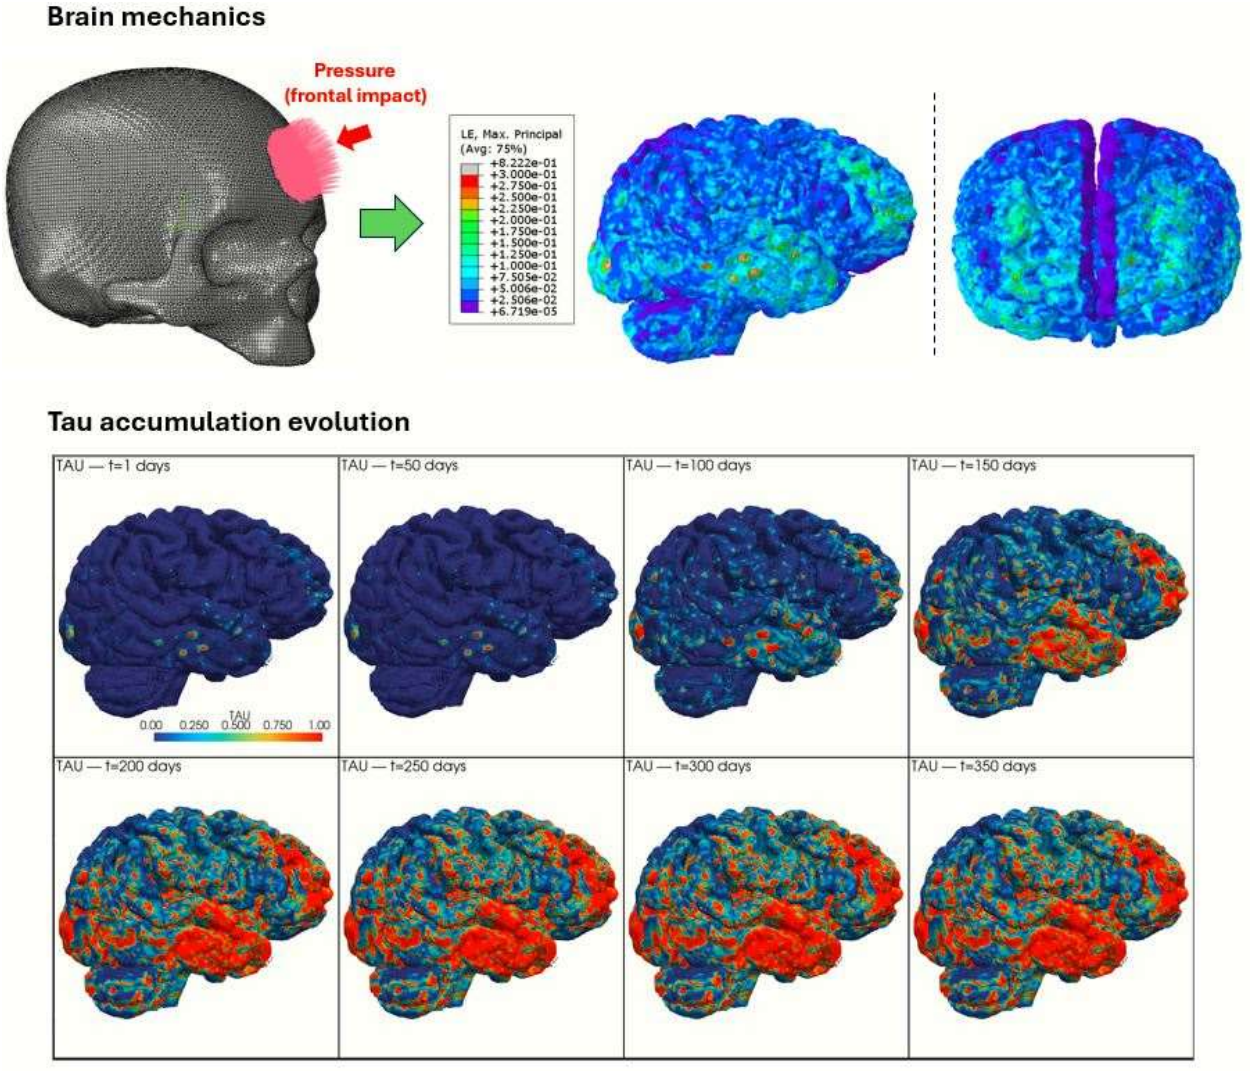
[1]University of Aveiro, Aveiro, Aveiro, Portugal. [2]University of Málaga, Málaga, Málaga, Spain

Introduction

Chronic traumatic encephalopathy (CTE) is linked to repetitive traumatic brain injury (TBI) and long-term cognitive decline [1]. Post-mortem studies show hyperphosphorylated tau around small vessels and in cortical sulci, implicating biomechanics. Axonal strain during head impacts can damage white matter and trigger tau aggregation that later spreads through vulnerable networks [2,3]. However, most computational models describe large-scale propagation and do not quantify how impact mechanics set the initial pattern of tau pathology. Here we present a biomechanical–mathematical framework that links impact-induced brain strain to the spatiotemporal evolution of tau burden, providing a quantitative bridge between head-impact biomechanics and progressive tau pathology in CTE.

Methods

Tau-percentage measurements from controlled TBI tauopathy mouse models at early, intermediate and late stages [3] were used to calibrate a deterministic kinetic equation for the growth of tau-affected regions. A head finite-element (FE) model reconstructed from MRI data [4] was subjected to a short frontal impact to compute maximum principal strain (MPS), a marker of axonal vulnerability [2]. The normalized strain field weighted the kinetic law so that highly strained regions accumulated tau faster.



Results

The calibrated parameters of the equation reproduced the experimental tau time course, with a slow early phase, accelerated accumulation at intermediate times and later saturation [3]. FE simulations showed elevated MPS in frontal and sulcal cortex, which subsequently developed the highest predicted tau levels. Spatiotemporal maps revealed early tau clusters in high-strain areas that expanded and merged over several months.

Discussion

This framework helps explain why CTE lesions often appear in regions exposed to the largest impact-induced strains [1]. By combining FE-derived strain fields with biologically constrained kinetics, the model links acute mechanical loading to long-term tau accumulation and provides a quantitative basis for integrating head-impact biomechanics with progressive neurodegeneration. Although simplified, it can be extended to repeated impacts, anisotropic propagation and subject-specific brain mechanics.

Development and Validation of Physics-Informed Neural Networks for Rapid Prediction of Brain Strain in Traumatic Brain Injury Modeling

Dr. Inyani Keri MD, MSc[1], Ms. Pippa Kolking BSc[2], Dr. Kesava Reddy MD[1], Dr. Christopher R. Dennison PhD[2]

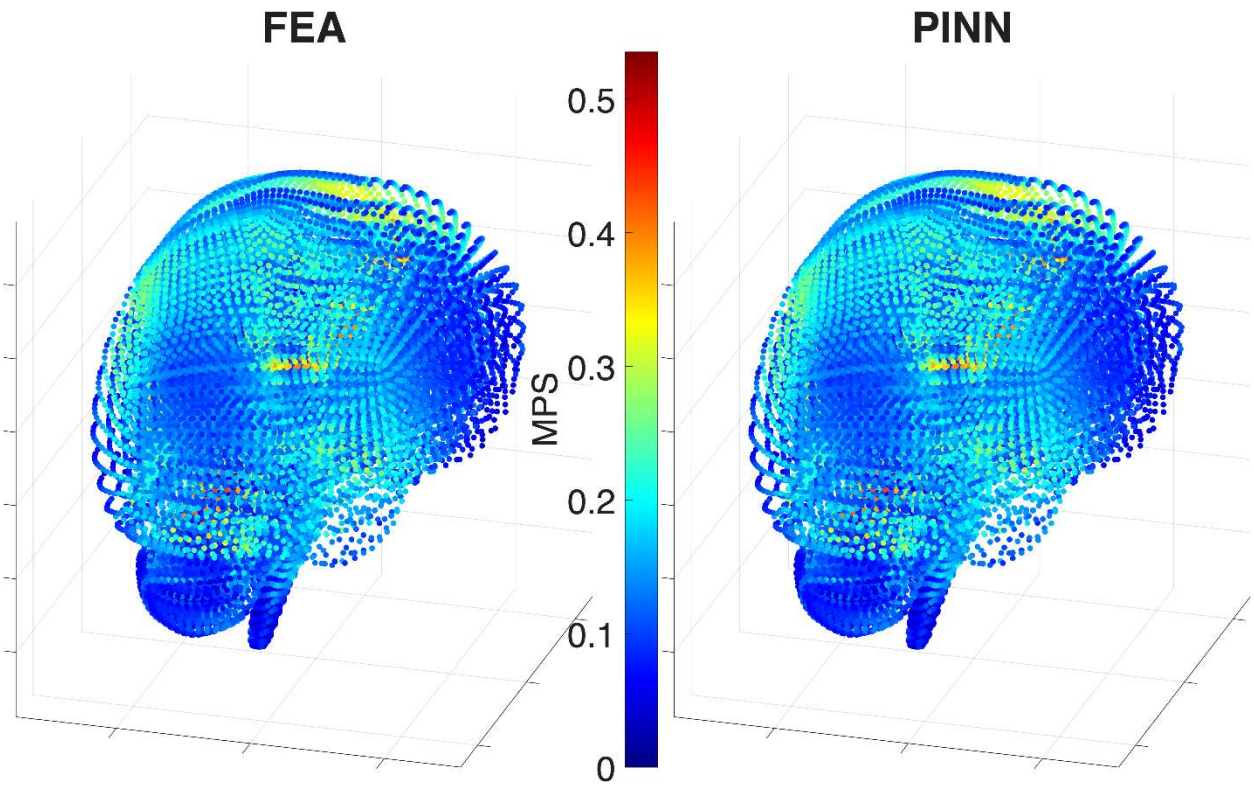
[1]Division of Neurosurgery, McMaster University, Hamilton, Ontario, Canada. [2]Department of Mechanical Engineering, University of Victoria, Victoria, British Columbia, Canada

Introduction

Finite element analysis (FEA) has advanced modeling of traumatic brain injury (TBI) **[1]**, but long run-times limit real-time use and studies with large throughput requirements. Physics-Informed Neural Networks (PINNs) blend machine learning with physical laws **[2,3]**, enabling rapid predictions grounded by mechanics. This study evaluates whether a PINN can accurately reproduce maximum principal strain (MPS)—a validated injury metric **[1]**—across parenchymal regions and do so more rapidly than a legacy FE model.

Methods

The bespoke PINN model was trained using legacy kinematic data drawn from football impacts, spanning 10–120g severity, both centric and oblique, with SIMon-predicted MPS (i.e., the FE model **[1]**). A bespoke set of region-specific tissue mechanics loss functions were implemented to anchor model predictions in material physics. For PINN training, inputs were head impact kinematics (n=300) recorded using j211-compliant methods/equipment and spatiotemporal MPS data computed from SIMon for the cerebrum, cerebellum, and brainstem. The PINN was constructed to allow prediction of spatiotemporal MPS from supplied head impact kinematics. Accuracy between the PINN and FEM was quantified using RMSE (PINN versus FEA) and inference time, using a single GPU.



Results

Focusing on data on which it had no *a priori* training upon, the PINN accurately reproduced SIMon-derived MPS across all three parenchymal regions, with the cerebrum and cerebellum achieving mean strain RMSE < 0.01 (n=45). A graphical means of conveying this finding is shown by PINN-produced spatiotemporal MPS distributions relative to SIMon (Figure 1). Average inference time was 0.35 s per impact simulation.

Discussion

Using legacy data and a brain FEM, we have demonstrated the ability of a bespoke PINN to accurately predict brain MPS with sub-second simulation times. The trained PINN, requiring only head kinematics as inputs, could allow more rapid estimation of brain tissue strain, thereby enabling inferences on brain injury in research settings where time and throughput prevent widespread application of finite elements (e.g., sports settings, helmet assessment with large experimental datasets, etc.).

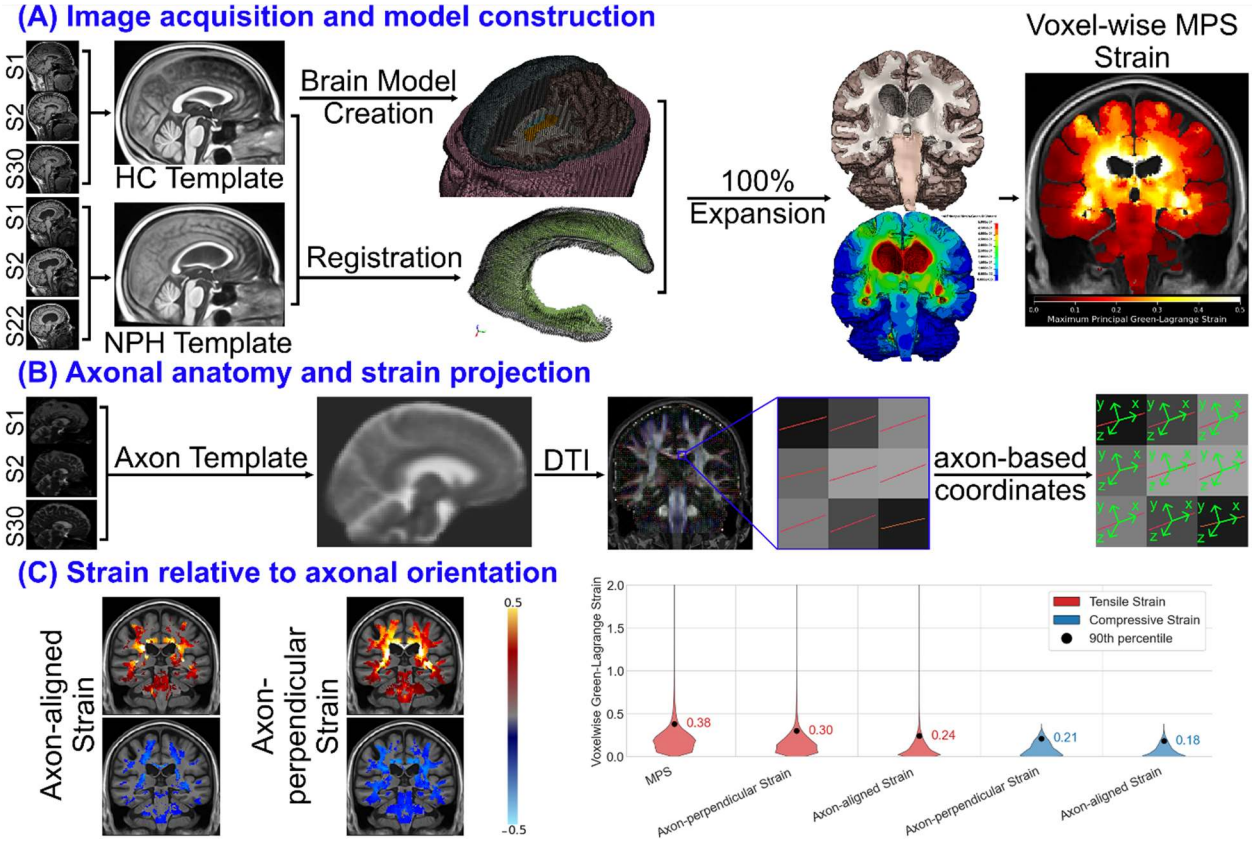
Introduction

Mechanical loading of brain tissue can cause axonal injury, a key determinant of clinical outcome, but investigating their relationship remains a challenge due to limited data. Normal pressure hydrocephalus (NPH), characterised by ventricular enlargement and white matter damage, provides a clinically relevant context to investigate links between mechanical loading and axonal injury. Our aim is to determine the distribution of mechanical strain with respect to axonal orientation after ventricular expansion, using a detailed finite element brain model.

Methods

MRI scans of 22 NPH patients (14 males, age=71.91±7.06) and 30 healthy controls (HC) (16 males, age=73.80±5.71) were acquired. T1-weighted images were averaged to create templates, from which a finite element brain model was generated[1]. The ventricular linings were loaded with displacement fields derived from registering images of HC to NPH ventricles. Changes in brain morphology and maximum principal Green-Lagrange strain (MPS) distribution were predicted (Fig1.A).

HC diffusion-weighted images were averaged to generate a template. This template was used to extract voxel-wise axonal orientations and construct local coordinate systems and corresponding rotation matrices (Fig1.B). These matrices were used to project global strain tensors into axon-based coordinates, yielding strain components parallel and perpendicular to axons.



Results

The brain model accurately reproduced imaging measures of brain morphological changes, including the callosal angle and Evans Index, with 0.7% and 4.4% relative errors respectively. The model predicted strain concentration in periventricular regions, e.g. the corpus callosum. Both tensile and compressive strains parallel and perpendicular to axons were predicted in white matter tracts. Notably, the 90^{th} percentile tensile and compressive strains were higher in the direction perpendicular to axons than parallel to them (Fig1.C).

Discussion

The model predicts large strain in corpus callosum, a tract where white matter abnormality in NPH has been reported in several studies. Despite large MPS values, strain projection into axon-aligned coordinates reveals some fibers experience tension while others experience compression, both parallel and perpendicular to their orientation. Future work will use voxel-based diffusion imaging data to investigate how these loadings relate to axonal injury. These studies can advance our understanding of biomechanics of axonal injury.

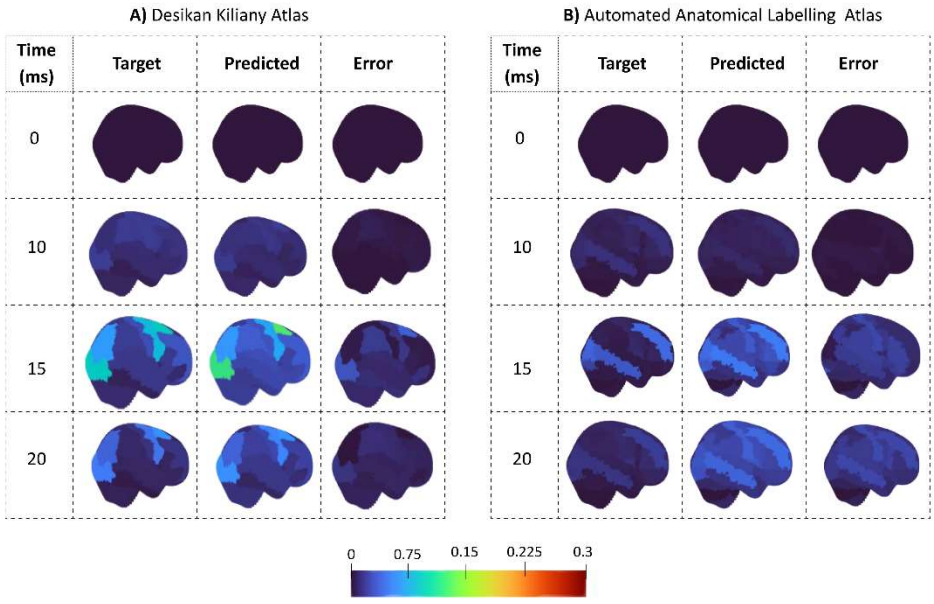
Introduction

Sports-related injuries are the second leading cause of hospitalization for traumatic brain injury. Although FE simulations can provide important clinical insights by predicting brain deformation patterns from head impacts, they are computationally expensive and impractical for clinical use. Deep learning models can rapidly approximate FE-derived brain strains, but these they require thousands of impacts for training. This study aims to accelerate brain strain prediction using machine learning that requires only 15 impacts per athlete and extend these predictions to anatomical regions defined by the Desikan–Killiany (DK) and Automated Anatomical Labelling (AAL) atlases.

Methods

Twenty male high school rugby players (age 16 ± 0.6 years) were recruited for a longitudinal study over a single rugby season. Exclusion criteria included self-reported mTBI prior to study enrolment and any neurological conditions. Subject-specific anisotropic, viscoelastic FE brain models were generated from T1-weighted and diffusion MRI using our validated pipeline. Head kinematics were measured using instrumented mouthguards (HitIQ Nexus), recording angular accelerations for all head acceleration events (HAE). Brain strains for each HAE were computed by running each athlete's FE brain model with the specific HAE using FEBio. The resulting strains were parcellated to both DK and AAL atlases (containing 84 and 116 parcellations respectively) using a nearest-neighbour mapping between FE elements and voxel-wise atlas labels. Total of 15 paired parcellated average strain curves and corresponding kinematics recording per athlete were used to train multi-output nonlinear regression models using Random Forest, with TsFresh-based feature extraction applied to the angular acceleration time series.



Results

Across both parcellation schemes, the median root-mean square error (RMSE) for predicted time-dependent parcellated strain profiles ranged from 0.002 to 0.007, indicating high accuracy despite the small training set. Representative visualisations of predicted strain across DK and AAL regions for an unseen impact are shown in Figure 1.

Discussion

We present a framework that integrates atlas-based brain parcellations with machine learning to predict regional brain strain directly from wearable sensor kinematics. This work captures location of injury as well as magnitude of strain. Ongoing work focuses on extending the approach to more subjects and elementwise strain predictions to improve spatial resolution and anatomical detail.

Associations of Repetitive Head Impact Exposure With Brain Myelin Imaging and Multidomain Neurological Function

Dr Adam Clansey[1], Dr Rebecca Kenny[1], Mr Zaryan Masood[1], Mr Daniel Bondi[1], Mr David Luke[1], Mr Alexander Jaffray[1], Dr Songbai Ji[2], Mr Chaokai Zhang[2], Dr Shambhu Adhikari[3], Dr Alexander Rauscher[1], Dr Paul van Donkelaar[3], Dr Lyndia Wu[1]

[1]University of British Columbia, Vancouver, BC, Canada. [2]Worcester Polytechnic Institute, Worcester, MA, United States. [3]University of British Columbia, Kelowna, BC, Canada

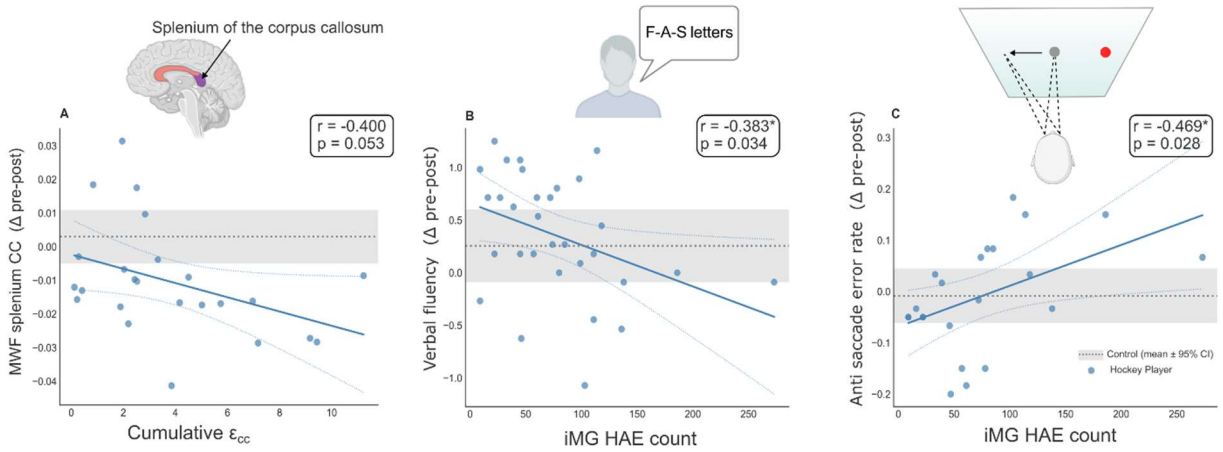
Introduction

Repetitive head impacts in contact sports such as ice hockey are associated with changes in brain structure and impairments in neurological function, yet evidence remains limited. The corpus callosum has been shown to be vulnerable to rotational forces experienced during head impacts, with previous reports showing a disruption in myelin in the splenium of the corpus callosum following concussion. This prospective investigation aims to investigate the association between cumulative subconcussive impacts sustained across ice hockey seasons to changes in myelin and neurological functional outcomes.

Methods

Thirty-four male ice hockey players (22.06 ± 1.46 yrs) and 18 age-and sex matched controls (21.26 ± 2.00 yrs) were recruited. Players wore instrumented mouthguards (iMG) across a span of two varsity ice hockey seasons (2021-2023). Missing iMG head acceleration events (HAEs) were imputed to determine cumulative head impact outcomes. All participants completed pre- and post-season MRI brain scans for myelin water fraction (MWF) calculations and a full neurological test battery assessing neurocognitive function, sensorimotor function, symptoms and mood. Linear regression was used to examine the relationship between head impact exposure and pre- to post-season outcome changes in players. Linear mixed effects models examined group by time interactions comparing players and controls, with participant as a random effect.

Results



Players demonstrated a significant decrease in posterior corpus callosum MWF over the season compared to controls (Fig 1; $\beta = -0.013$, $p = 0.009$). Greater cumulative corpus callosum strain showed a trend toward reduced MWF in splenium region of brain ($r = -0.400$, $p = 0.053$). Higher iMG HAE counts were significantly associated with decreased

verbal fluency (r = -0.382, p = 0.034) and greater anti-saccade error rate (r = 0.469, p = 0.028). No other outcome parameters showed significant associations with HAE exposure.

Discussion

Preliminary results indicate cumulative head impact exposure was associated with a disruption in myelin structure in corpus callosum and worsening of verbal fluency and oculomotor function in hockey players across season of ice hockey. These findings highlight the importance of monitoring cumulative head impacts in contact sports and warrant further longitudinal investigations to determine whether such changes persist, accumulate, or recover across multiple seasons of play.

Estrogen Regulates Stiffness of Murine Cervical Extracellular Matrix

Ms. Serena Russell ScM[1], Mx. Bex Pendrak MS[1], Dr. Camilo Duarte PhD[1], Mr. Tobias Funk[1], Dr. Priyya Madhukaran PhD[2], Dr. Mala Mahendroo PhD[2], Prof. Kristin Myers PhD[1]

[1]Columbia University, New York, NY, United States. [2]UTSW Medical Center, Dallas, TX, United States

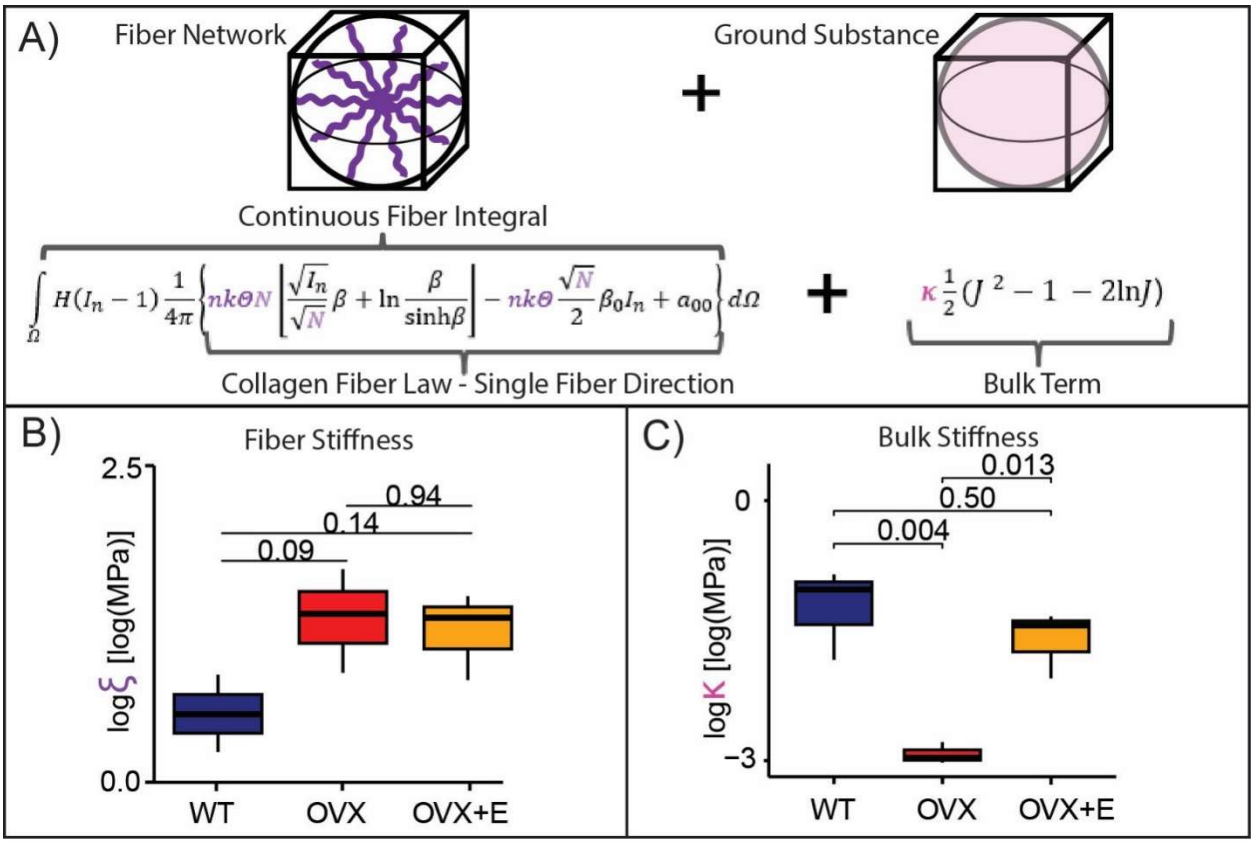
Introduction

Molecular studies have established that estrogen regulates collagen turnover in the cervix [1,2]. This study employs a ramp-hold-to-failure test to describe cervical extracellular matrix (ECM) of control (WT), ovariectomized (OVX), and estrogen treated mice (OVX+E) to elucidate estrogen's role in cervical function.

Methods

Whole cervix was collected from wildtype C57BL6/129sv mice (WT, N=3), from OVX mice (N=3), and from OVX mice that were administered 2 μg estrogen for 15 days after surgery (OVX+E, N=3). Each specimen was subjected to a tensile ramp-hold-to-break biomechanical test. The equilibrium loading behavior was characterized by a material model (Fig. 1A) in FEBio utilizing an inverse finite element modeling approach. The biomechanical parameters in this model characterize the load-bearing ECM: waviness of collagen fibers [locking stretch, LS], initial fiber network stiffness [ξ], and ground substance bulk stiffness [κ]. Rupture stress of the tissue was calculated at the point of highest stress before break. An ANOVA with post-hoc Tukey test compared the material parameters of OVX, OVX+E, and WTs.

Results



LS did not change significantly between treatment types. ξ increased in OVX and OVX+E cervix compared to WT ($p = 0.09, 0.14$, Fig. 1B). κ decreases significantly in OVX cervix compared to WT cervix, however OVX+E samples do not differ from WT ($p=0.02, 0.39$, Fig. 1C). Rupture stress was significantly lower in OVX samples than WT samples ($p=0.03$).

Discussion

Lack of estrogen negatively affects biomechanical function of the cervix. Results show that without the presence of estrogen, the initial stiffness of fibers (ξ) increases and the bulk stiffness (κ) and rupture stress decrease, leading to an overall softer cervix with less ability to stretch and handle stress. The OVX+E model recovers the lost bulk stiffness in the OVX model, displaying that estrogen regulates the bulk stiffness, while fiber stiffness may be

due to another missing factor, like progesterone. This work suggests that bulk modulus is influenced by estrogen, and replacement of missing estrogen can recover this feature.

Towards a Uterine Electromechanical Digital Twin during Late Pregnancy

Ms. Olivia Mergler, Mr. Parker Mixon, Dr. Kristin Myers, Dr. Vijay Vedula

Columbia University, New York, NY, United States

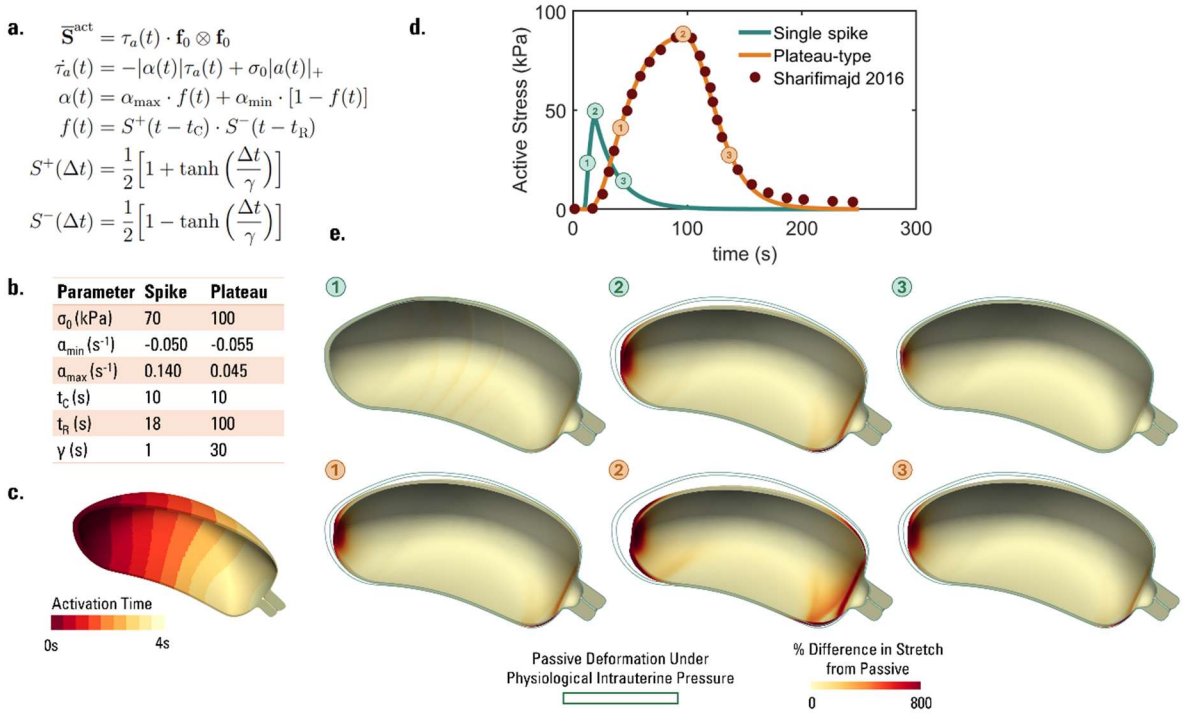
Introduction

The onset of uterine contractions is a highly regulated yet poorly understood process. Labor contractions have been found to be driven by a complex convergence of stretch-mediated inflammation and hormonal regulation. Uterine digital twins enable analyzing the sensitivity of contractions to different mechanical and electrophysiological properties and identifying the risk factors that may contribute to preterm labor.

Methods

We developed a novel digital twinning workflow for modeling uterine electromechanics. Our workflow begins with a previously developed parameterized model of the uterus and cervix, with rule-based fibers oriented longitudinally in the uterus and circumferentially in the cervix. The passive material response is characterized using the anisotropic hyperelastic GOH constitutive model, with parameters tuned to match mechanical testing data. Spatially varying Robin boundary conditions are applied to efficiently simulate interactions with the surrounding fetal membrane and abdominal organs. Active contraction is modeled using a phenomenological active stress model (Figure 1a) [1], with parameters tuned to match literature for a pre-labor single spike and plateau-type stimulus (Figure 1b) [2, 3], and spatially varying activation times based on physiological action potential propagation velocities (Figure 1c). The model is used to evaluate the effect of variable active stress waveforms on the contraction patterns (Figure 1d).

Results



Simulated uterine contractions using tuned material parameters and active stress waveforms reveal increased uterine deformations and induced stretches upon prolonged contractions. For both single spike and plateau-type stimuli, stretches were highest at the uterine fundus and lower uterine segment during maximal contraction (Figure 1e).

Discussion

Our results are consistent with physiological labor patterns and highlight the role of progressive recruitment during labor. Uterine contractions are stretch-mediated [3]; thus, stretch concentrations can inform sites of future contraction stimuli. Stretch concentrations at the lower uterine segment may impact cervical effacement and dilation,

consistent with clinical understanding. Next steps will focus on developing a coupled excitation-contraction model, enabling further investigation into the hormonal regulation of the excitation pathways that lend to the transition between different contraction patterns.

Assessing the Influence of Maternal Pelvic Geometry on Birth Simulations Using Pelvimetry-Based Models

Dr. Morgane Devismes[1], Dr. Marine Lallemant[2], Dr. Michel Cosson[1,2], Dr. Chrystèle Rubod[1,2], Dr. Olivier Mayeur[1]

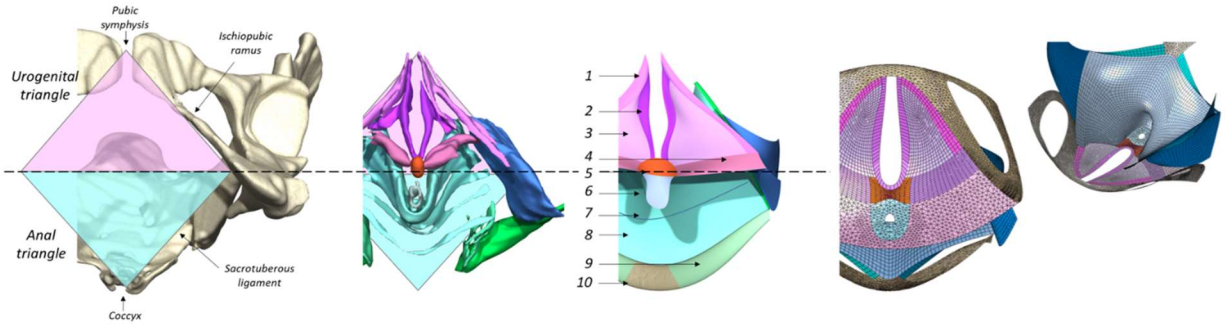
[1]Univ. Lille, CNRS, Centrale Lille, UMR 9013 LaMcube Laboratoire de Mécanique, Multiphysique, Multiéchelle, Lille, 59000, France. [2]Service de Chirurgie Gynécologique, Hôpital Jeanne-de-Flandre, Centre Hospitalo-Universitaire, Lille, 59000, France

Introduction

In France, emergency cesarean sections (C-sections) represent approximately two-thirds of all cesarean deliveries [1]. These unplanned procedures are often more challenging for patients and medical teams [2,3]. A major cause for emergency C-sections is cephalopelvic disproportion (CPD), which impedes the fetal descent. Although not used in routine, pelvimetry can help assess the risk of CPD and provides valuable input for personalized birth simulations. This study aims to use pelvimetry-based imaging to develop maternal pelvic models for birth simulations, in order to investigate how variations in pelvic geometry influence simulated delivery outcomes.

Methods

Pelvimetry scans from 63 patients (age: 34 ± 7 years; BMI: 22.5 ± 6.7) were acquired at Lille University Hospital, 2 to 36 days before delivery. Maternal and fetal geometries were segmented using 3D Slicer. Then, patient-specific soft-tissue models were automatically reconstructed, including 10 key perineal structures such as the Levator Ani Muscle and the Perineal Body (Figure 1). The fetal head was simplified to its external envelope using an alpha-shape algorithm. Maternal and fetal models were then imported into Abaqus, and vaginal delivery scenarios were simulated using a prescribed fetal trajectory.



Results

All 63 maternal pelvic models were successfully reconstructed and used to build an average maternal model suitable for generic birth simulations. At this preliminary stage, simulations were conducted using a simplified ellipsoidal parametric fetal head, allowing evaluation of the differences in simulation outcomes due to the sole variations in maternal pelvic geometry. Perineal strain magnitudes peaks up to 4 approximately, with marked variability across patients, suggesting a measurable influence of pelvic shape on mechanical response during simulated fetal descent.

Discussion

This study contributes to bridging clinical practice and computational birth simulation by grounding simulation models in pelvimetry-based anatomy. Future work will include patient-specific simulations incorporating individualized fetal head geometries and presentations, comparison of simulation results with actual clinical outcomes and expansion of the cohort for improved statistical significance.

Linking Collagen Microstructure to Uterine Mechanics Using Inflation and Inverse Finite Element Analysis

Ms. Mahmuda Arshee, Ms. Adira Safar, Dr. Ayelet Ziv-Gal, Dr. Jodi Flaws, Dr. Indrani Bagchi, Dr. Callan Luetkemeyer, Dr. Amy Wagoner Johnson

University of Illinois Urbana-Champaign, Champaign, Illinois, United States

Introduction

The uterus is a mechanically dynamic organ whose function depends on collagen microstructure, which can be altered by environmental toxicant exposures such as propylparaben [1]. While our prior work showed disrupted collagen and increased local tissue stiffness, the impact on whole-organ mechanics remains unknown. Here, we address this gap by combining physiological inflation tests with inverse finite element analysis to estimate anisotropic constitutive parameters. Our approach is novel in its use of organ-level inflation testing with simultaneous microCT-based imaging and computational modeling.

Methods

Uteri from six 6-month-old diestrus control mice were inflated ex vivo using a custom balloon-catheter setup with continuous pressure–volume recording (Fig. 1A). Samples were preconditioned through several inflation–deflation cycles to ensure repeatable mechanical response. MicroCT-segmented boundaries were used to build a symmetry-constrained quarter FE model with the Gasser-Ogden-Holzapfel (GOH) formulation, with fiber families in the circumferential and longitudinal directions. As uterine cross-sections vary in thickness, we selected a representative quarter by aligning the geometry and choosing the 90° sector whose mean thickness was closest to the overall average. Material parameters were identified by minimizing the mismatch between experimental and simulated radial displacements across pressures. Local sweeps were used to assess parameter identifiability.

Results

Inflation tests showed nonlinear stiffening, with more compliant behavior at low stretch (Fig. 1B). Variability across samples in the high-stretch region (corresponding to 0.10–0.20 mL of fluid injected into the balloon) was ~8%, indicating consistent behavior suitable for modeling. The inverse framework converged reliably with low mismatch between simulated

and experimental boundary deformations (Fig. 1C). Parameter sweeps revealed a clear low-error region around the best-fit values, suggesting that the solutions are unique. Full parameter analysis across all uteri is in progress.

Discussion

The inflation response reflects progressive collagen fiber recruitment, supporting the use of a microstructure-based model such as GOH. This framework provides a quantitative basis for evaluating how environmental exposures, ageing, or hormonal cues influence uterine mechanics.

Images (Optional)

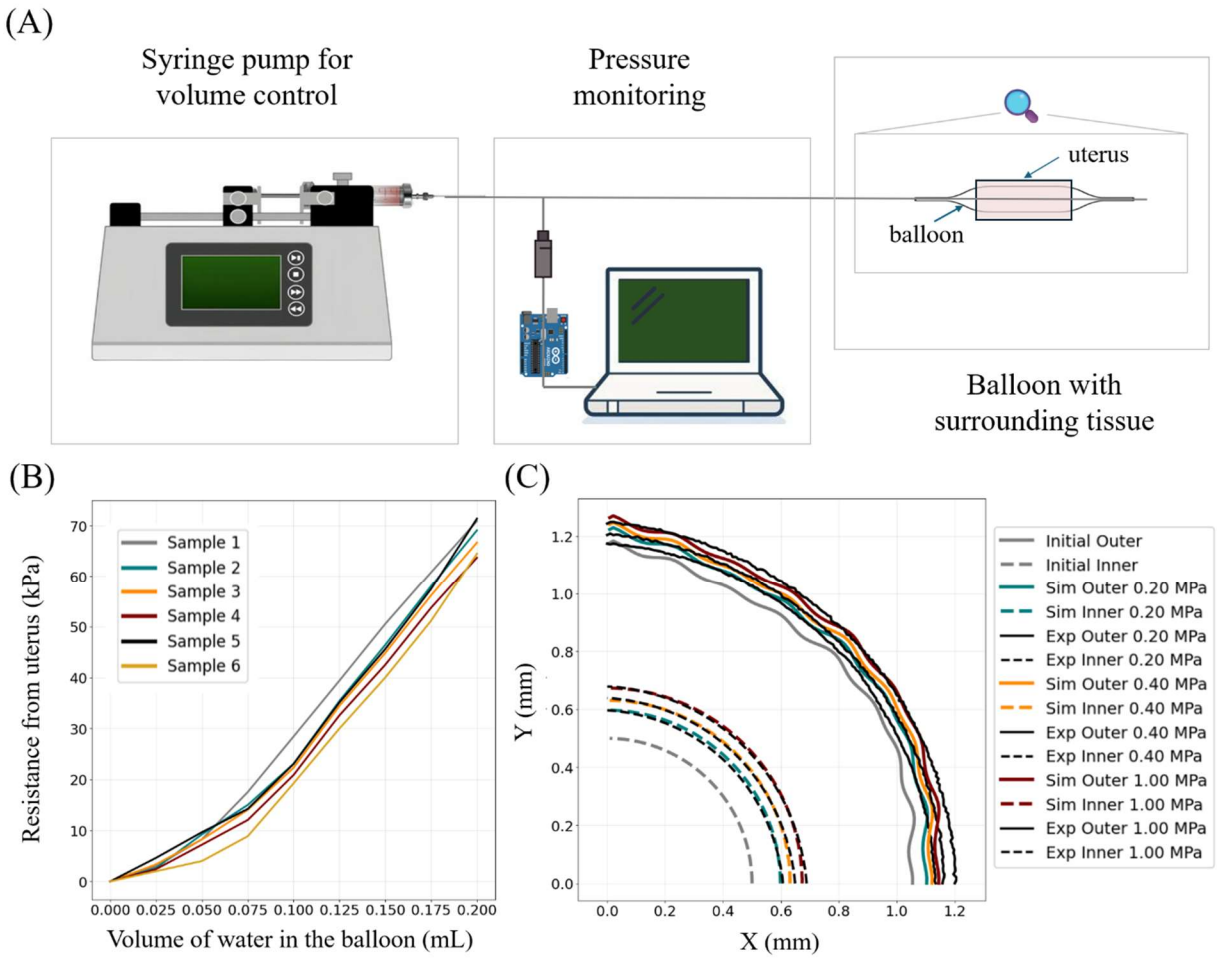

Figure 1. (A) Custom inflation apparatus consisting of a syringe pump for controlled volume input, Arduino-based pressure monitoring, and a balloon catheter positioned inside the excised uterus. (B) Measured resistance from the uterine wall as a function of balloon volume for six independent samples showing consistent nonlinear stiffening across samples. (C) Comparison of experimental and simulated inner and outer boundary profiles at multiple pressure levels, demonstrating close agreement, with <2% error between model predictions and measured deformation.

Automated MRI-Based Quantification of Femoral Growth Plate Orientation in Healthy Children

Dipl.-Ing. Kevin Kitir[1], PhD Willi Koller[1], Dipl.-Ing. Clara Egner[1], BSc Laura Rathmair[1], Assoc. Prof. Wolfgang Bogner[2], Dr. Tim Emmenegger[2], Assoz.-Prof. Janina Patsch[2], Assoc. Prof. Hans Kainz[1]

[1]Universit of Vienna, Vienna, Vienna, Austria. [2]Medical University of Vienna (Austria), Vienna, Vienna, Austria

Introduction

The orientation and morphology of femoral growth plates are key determinants of longitudinal bone development [1]. Aberrant physeal alignment contributes to atypical femoral torsion [2], yet quantitative 3D reference data in typically developing children remain scarce partly due to the impracticality of manual MRI segmentation.

This study presents an automated pipeline combining multi-contrast MRI, 3D nnU-Net–based segmentation [3], and scripted geometric analysis to characterise femoral growth plate shape and orientation in healthy children. The aim is to establish normative metrics supporting future biomechanical assessments and comparisons with pathological cohorts.

Methods

Whole-limb Dixon MRI scans of 53 healthy children (5–16 years) were analysed. Manual segmentations from 15 participants trained a four-channel 3D nnU-Net model, which subsequently generated automated femur and physis segmentations for the complete cohort.

Physeal masks were converted into surface representations using moving least squares, and a second-order polynomial surface was fitted to derive continuous geometric descriptors. Femoral shaft axes were obtained via multi-subset Principal Component Analysis (PCA).

A fully automated workflow extracted physeal surface area, normal vector orientation, curvature measures, surface irregularity (RMS deviation from the polynomial fit), and the Physeal–Diaphyseal Angle (PDA). Age-dependent patterns were evaluated across the cohort.

Results

The trained nnU-Net achieved high segmentation accuracy for femora and physes (Dice 0.86–0.96). Proximal femoral growth plates showed clear developmental trends: Surface area increased with age, reflecting expected skeletal growth. Curvature radius decreased, and surface irregularity rose, indicating greater morphological complexity. The PDA showed a modest age-related reduction, implying slightly decreasing alignment with the femoral shaft-axes during maturation.

Discussion

This automated MRI-based approach enables reliable large-scale quantification of femoral physeal geometry, with results consistent with prior observations [4]. The identified trends enhance understanding of normal physeal maturation and provide critical reference data for comparisons with pathological torsional profiles or growth disorders. The modular workflow is compatible with advanced in-silico modelling [5] and supports continued research within the INSIDE-BONE project.

Images (Optional)

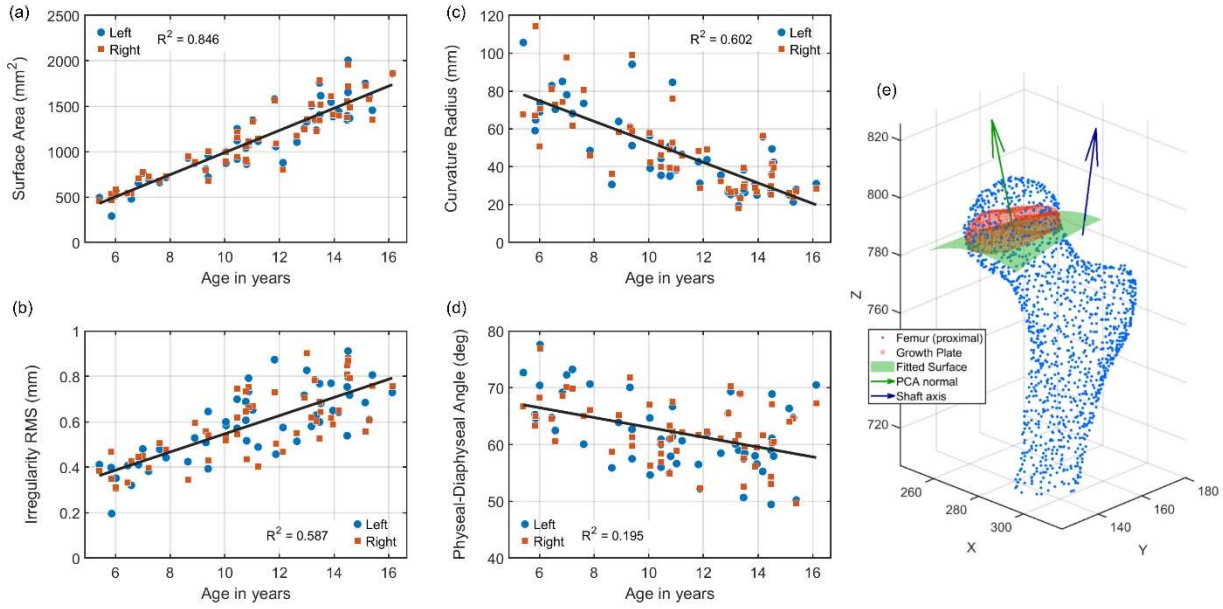

Figure 1: Left: 2×2 subplots showing an overview of growth-plate metrics over age. [1]University of Vienna, Vienna, Vienna, Austria. [2]Ostschweizer Kinderspital, St. Gallen, St. Gallen, Switzerland. [3]Orthopedic Hospital Speising, Vienna, Vienna, Austria. [4]Medical University of Vienna, Vienna, Vienna, Austria

Introduction

Lower-limb bone deformities are associated with several health conditions, often treated at a late stage, requiring extensive treatment [1]. Studying the development of deformities during growth is crucial for moving towards preventive interventions.

However, quantifying bone-shape is not straightforward: the common clinical measures for femoral geometry, Neck-Shaft-Angle (NSA) and Anteversion-Angle (AVA), have been questioned regarding inter-observer-reliability [2]. Automatic-angle-measures are available [3,4,5] but often developed on radiation-exposing CT-images or not tested on paediatric data. The aim of this study was to analyse reliability of several measurement-methods based on MRI-images.

Methods

MRIs of n=7 typically developing children were captured twice (at age 10y and 12y, 3T-T1-vibe-0.8×0.8×0.7mm). Clinical angle-measures were performed as described by Sangeux [6] by two experienced researchers (Clinical1/Clinical2). Each femur (N=28) was segmented twice (Segmentation1/Segmentation2). Difference between segmentations was calculated using dice-score (tolerance=1mm).

Three automatic angle-measures were applied to the segmented femurs: 3D-surface-model (3DSurfFCS) [3], cylinder-fitting (CylFit) [4] and a combination of MSK-staple [5], inertia-axes and refined geometry-fits (MSKsInertiaGeom). These methods are purely deterministic, leading to identical results for the same input. Therefore, robustness of such methods depends solely on segmentation.

Reliability was measured by Intraclass Correlation Coefficient (ICC).

Results

Dice-score between segmentations was 0.94±0.05. Reliability of all three automatic-angle-measures was comparable to or better than clinical measures (Fig.1). Based on MSKsInertiaGeom (overall performing best with ICC>0.8 for both angles), mean change over two years in the study population was 0.2±3.2° in NSA and -3.9±5.4° in AVA.

Discussion

While performing well compared to ICCs reported in literature [2], automatically-measured angles show maximum errors between segmentations of 10° (AVA-MSKsInertiaGeom) and 6° (NSA-MSKsInertiaGeom) - still large in relation to individual changes during growth.

Our results highlight the need for advanced automatic-MRI-segmentations, which together with consistent MRI-sequences may allow a fully reliable angle-measurement. Automatic-MRI-segmentation attempt using TotalSegmentator [7] failed for ~20% of bones for this MRI-sequence. We are currently developing an automatic-segmentation workflow using a U-Net-framework, based on a newer dataset with Dixon-decomposed MRI-images. Preliminary results are promising, indicating that fully reliable NSA- and AVA-measurements are achievable.

The Importance of Neuromusculoskeletal Model Personalisation: A Paediatric Case Example of Extreme Femoral Deformity

Miss Matilda Krywanio[1], A/Prof Nicole Williams[1,2], A/Prof Claire F. Jones[3], Prof Dominic Thewlis[1]

[1]Adelaide Medical School, The University of Adelaide, Adelaide, South Australia, Australia. [2]Department of Orthopaedic Surgery, Women's and Children's Hospital, North Adelaide, South Australia, Australia. [3]School of Electrical and Mechanical Engineering, The University of Adelaide, Adelaide, South Australia, Australia

Introduction

Developmental Dysplasia of the Hip (DDH) causes abnormalities in bone and muscle development. However, the effect of neuromusculoskeletal model personalisation for gait analysis in this condition has not been investigated. This study aimed to determine the change in estimated hip joint contact forces (JCFs) in neuromusculoskeletal models with incrementally personalised anatomy and neural solution, in one child with DDH.

Methods

The participant's affected hip (Fig. 1a) was superolaterally displaced, and the greater trochanter positioned posteriorly to the femoral head, causing abnormal muscle lever arms. Model geometry was progressively personalised: Model 1 was a linearly scaled gait2392 model. Model 2 incorporated femoral anteversion and neck shaft angles. Model 3 was fully personalised from segmented bilateral lower limb bones with magnetic resonance imaging-informed muscle pathways, in NMSBuilder [1]. For all, maximal isometric forces and musculotendon unit parameters were further scaled.

Muscle forces were estimated using static optimisation in OpenSim v4.4, or by electromyography (EMG) informed methods (Calibrated EMG-Informed NMS Modelling Toolbox v0.30.6), following which JCFs during walking were calculated. Intra-model comparisons were made using statistical parametric mapping.

Results

Compared to Model 1 with a max hip JCF of 4.5 body weight (BW), Model 2 produced higher hip JCFs (10.5BW) and Model 3, smaller (1.5BW). JCFs from EMG-informed muscles forces were not significantly different between Model 1+EMG and Model 2+EMG (5.4BW) but were lower in Model 3+EMG (2.5BW). JCFs were significantly different between Model 1 and

Model 3+EMG for 95% of stance phase ($p<0.001$, Fig. 1b). Abnormal muscle lever arms of gluteus medius in Model 3 resulted in lower forces when estimated using static optimisation, compared to Model 1 (max 0.0092BW vs. 0.77BW). When EMG signals were incorporated, the muscle force produced increased to 0.86BW, contributing to the higher JCFs estimated in Model 3+EMG compared to Model 3.

Discussion

In the presented case of significant femoral deformity, scaled generic models produced greater JCFs than the fully personalised model. Additionally, static optimisation in Model 3 misrepresented muscle forces, particularly of the gluteal muscles. With significant deformity, both personalisation of bony anatomy and incorporation of control signals should be strongly considered.

Quantification of 3D Trabecular Texture in the Femoral Head and Condyles Reveals the Locomotory Pattern in Humans and Sheep

Mr. Benjamin Zvi Rudski, Dr. Natalie Reznikov

McGill University, Montreal, Quebec, Canada

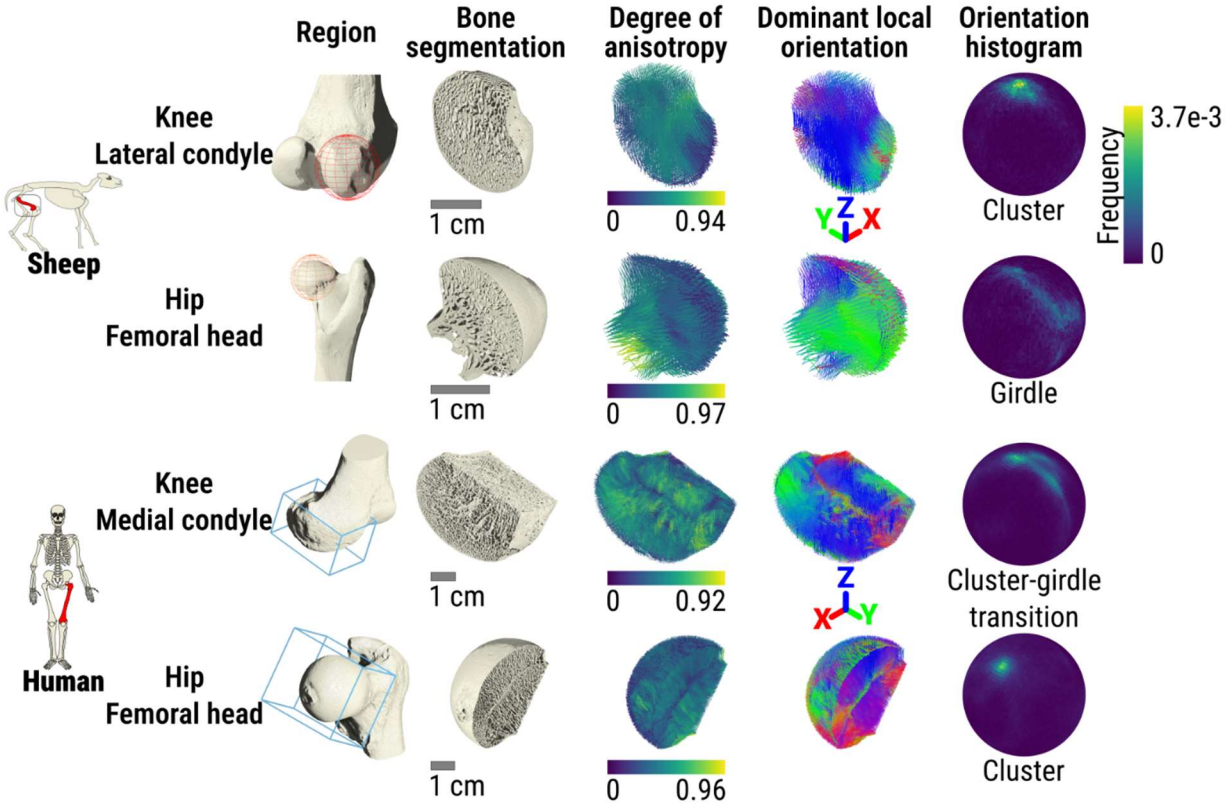
Introduction

Trabecular bone is abundant in the articulating ends of long bones. Stress trajectories observed in trabecular bone mirror mechanical forces through *functional adaptation* [1]. Thus, trabecular texture can serve as a proxy for loading history. In the hip, the femoral head articulates in a ball-and-socket joint with a broad range of movement. In the knee, the femoral condyles articulate in a hinge-like joint, moving primarily in the sagittal plane. We expected these movement ranges to be reflected in the trabecular texture of the femoral head and the condyles [2].

Methods

We examined human (n=3) and sheep (n=1) distal and proximal femora using microcomputed tomography. To visualise trabecular texture, we computed anisotropy vector fields using Dragonfly 3D World [3]. To quantify predominant trabecular textures, we constructed spherical orientation histograms and computed directional statistics using *VectoRose* [4].

Results



In the human femoral head, predominant trabecular orientations were clustered around an axis, instead of covering diverse orientations. In the human medial condyle, predominant trabecular orientations were indeed confined to the sagittal girdle. However, the angular range comprised 52%, 45% and 48% of the knee physiologic range of movement. In the sheep femoral head, predominant trabecular orientations were confined to the sagittal girdle rather than diverse orientations. In the sheep lateral condyle, predominant trabecular orientations were confined to a narrow cluster, rather than a girdle.

Discussion

In the proximal and distal femur, in humans and sheep alike, the range of predominant trabecular orientations is much narrower than the physiologically possible range of joint movement. This indicates that the range of habitual loading directions is also narrower than the physiologic range of movement. The extent of such restriction varies amongst individuals. Quantifying the extent of habitual utilisation of the maximal range of joint

movement opens new possibilities to explore the effects of loading history on trabecular adaptation in health and its maladaptation in disease.

Comparison of Ankle Muscle Activation Patterns During Self-initiated Versus Motor-induced Falls From Standing Height

Mr. Donggeon Kim PT, Dr. Kitaek Lim PT, PhD, Dr. Seyoung Lee PT, PhD, Mr. Junwoo Park PT, M.S., Mr. Sungmin chun PT, Ms. Soyeon Yoon PT, Prof. Woochel Joseph Choi PT, PhD

Injury Prevention and Biomechanics Laboratory, Yonsei University, Wonju, Gangwon-do, Korea, Republic of

Introduction

To study falls, researchers employ two laboratory approaches: having participants fall voluntarily or inducing falls through external perturbations [1,2]. These two methods create fundamentally different conditions, and the resulting biomechanical responses are therefore expected to differ. However, no study has examined the impact of fall method on these responses. In particular, no information is available on how ankle muscle activation patterns vary depending on the type of fall. This study aims to address this gap.

Methods

Eight young adults participated in falling experiments that included self-initiated falls (SIF) and motor-induced falls (MIF) in forward, sideways, and backward directions. Fall kinematics were recorded using a motion capture system at 200 Hz, and muscle activity was collected using surface electromyography (EMG) at 2,000 Hz from the lateral and medial gastrocnemius (LGCM, MGCM) and tibialis anterior (TA) muscles bilaterally. Fall initiation was defined as a 10% drop in the pelvis marker. The 200 ms preceding this point was designated as the pre-fall phase, and the subsequent descending phase until body contact was time-normalized to 100%. The outcome variable was the reference voluntary contraction (%RVC), which was compared between fall types using one-dimensional statistical parametric mapping paired t-tests (SPM{t}).

Results

During the pre-fall phase, MIF exhibited greater bilateral ankle muscle activation than SIF across all directions. Sideways falls showed significant differences in every muscle, with MIF exhibiting on average about 5.3 times greater muscle activity than SIF (Figure 1a). During the descending phase, forward falls exhibited a significant cluster only in the right MGCM. In contrast, sideways falls showed multiple distinct clusters in left TA, MGCM, and LGCM, indicating different muscle activation patterns between MIF and SIF (Figure 1b). Backward falls revealed no significant differences across all muscles.

Discussion

Differences between MIF and SIF varied by fall direction and phase, suggesting that ankle responses to unexpected perturbations rely on context-specific neuromuscular strategies. These findings imply that fall-prevention or perturbation-based training may require multidirectional and unpredictable challenges rather than single-direction, predictable tasks.

Images (Optional)

Not All Falls Result in Injury in Older Adults: Distinct Risk Factors for Falls and Fall-Related Injuries

Mr. Junwoo Park PT, MSc, Dr. Kitaek Lim PT, PhD, Ms. Soyeon Yoon PT, Mr. Donggeon Kim PT, Mr. Sungmin Chun PT, Prof. Woochol Joseph Choi PT, PhD

Injury Prevention and Biomechanics Laboratory, Department of Physical Therapy, Yonsei University, Wonju, Gangwon-do, Korea, Republic of

Introduction

Falls can be prevented by identifying risk factors and implementing proactive strategies. However, a critical limitation is that most studies have focused only on risk factors for falls, neglecting the differences between injurious versus non-injurious falls [1]. A clear understanding of these differential risk factors should help improve fall prevention strategies.

Methods

We utilized data from the National Survey of Older Koreans 2023. We extracted the comprehensive potential risk factors, including demographics, the number of chronic disease conditions (comorbidity), assistive devices (aids), required assistance for activities of daily living (ADL), and home modifications [2,3]. Binomial logistic regression with stepwise selection was used to identify risk factors for falls (non-fallers versus fallers) and fall-related injuries (non-injurious versus injurious fallers). Falls were defined by fall history within the last year, and fall-related injuries were categorized by whether the fall required medical treatment.

Results

Characteristics of participants were presented in Table 1a. Our results suggested that height, gender, drinking, cognition, comorbidity, aids, and required assistance for ADL were significant risk factors for falls (Table 1b). Whereas, age and installation of handrails in bathrooms were significant risk factors for fall-related injuries (Table 1c).

Discussion

Our results indicated that the risk factors associated with falls differed from those associated with fall-related injuries. Interestingly, age presented as a risk factor for fall-related injuries, suggesting a marginal decrease in the odds of injurious falls as age

increases. This counterintuitive finding may be attributed to our definition of injurious falls, and it is plausible that younger older adults exhibit higher injury perception or are more likely to seek medical care following a fall. Furthermore, the installation of home modifications was associated with fall-related injuries, indicating that while home modifications are effective in preventing falls, they may not sufficiently mitigate fall-related injuries. Therefore, more considerate and injury-preventive design in home modifications is needed to develop effective fall and injury prevention strategies.

Introduction

Falls are frequent among individuals with lower limb amputation (LLA), leading to reduced mobility, independence, and quality of life. Although fall prevention research has addressed prosthetic design, risk factors, and balance assessment, the ability to initiate a step in an unpredictable context—involving compensatory mechanism crucial to maintain stability and assess fall risk—remains largely underexplored in this population. The choice stepping reaction time (CSRT) test evaluates this capacity, integrating neuropsychological, sensorimotor, and musculoskeletal control, yet it remains uncharacterized in LLA. This study examines the timing of stepping phases in a CSRT test performed by individuals with LLA, comparing the prosthetic and sound limbs.

Methods

Participants stood on two force platforms and stepped as quickly as possible onto central or lateral targets following LED cues, using either the sound or prosthetic limb (Figure 1.A). Four trials were performed for each target, resulting in 16 randomized trials. From vertical Ground Reaction Force (GRF) components, three temporal phases were defined as in [1]: Reaction Time (RT), Anticipatory Postural Adjustment (APA), and Swing Phase (SP); their sum yielded the total CSRT duration (Figure 1.B). For analysis, central and lateral targets were pooled by side (sound or prosthetic). Wilcoxon tests compared outcomes between limbs.

Results

Eleven individuals with unilateral LLA (9 transtibial and 2 transfemoral) completed the CSRT test. Initiating steps with the prosthetic limb produced significantly longer total movement durations, resulting from shorter APA and longer SP duration (Figure 1.C).

Discussion

These results reveal biomechanical asymmetry in step-initiation strategies according to the stepping side. Stepping with the prosthetic side produced longer CSRT durations, comparable to values reported in older adults at risk of falling, suggesting increased susceptibility to falls. Differences in APA and SP suggest that participants use adaptation strategies to increase reliance on the sound leg, potentially to limit landing velocity and mechanical load on the prosthetic side. Overall, the CSRT test appears suitable for

assessing balance and fall risk in individuals with LLA. It ensures high participant safety, particularly compared with other balance assessments involving external perturbations, while effectively distinguishing between the sound and prosthetic limbs.

Anticipatory and Reactive Balance Control During Walking Entry and Exit on a Moving Platform

Dr Genki Hisano[1], Dr Romain Bechet[1], Dr Helene Pillet[1], Dr Raphael Dumas[2], Dr Thomas Robert[2]

[1]Institut de Biomecanique Humaine Georges Charpak, Arts et Metiers Institute of Technology, EPF Engineering School, Universite Sorbonne Paris Nord, Paris, Île-de-France, France. [2]Univ Lyon, Univ Gustave Eiffel, Univ Claude Bernard Lyon 1, LBMC UMR_T 9406, Lyon, Auvergne-Rhône-Alpes, France

Introduction

Moving platforms such as escalators and moving walkways are common in daily life. Changes in velocity during transitions onto and off these surfaces may provoke imbalance and lead to falls, yet the underlying balance control strategies remain unclear. This study investigated anticipatory and reactive balance control during walking entry and exit on a moving walkway by examining changes in antero-posterior CoM velocity (V_{ap}) and whole-body angular momentum (WBAM) [1].

Methods

Sixteen healthy adults completed three conditions at preferred speed: steady-state walking, walking from overground to a moving walkway (entry), and the opposite condition (exit). During entry and exit, the treadmill belt moved at 0.5 m/s in the walking direction. Each trial included one stride, with the transition occurring during the second step (**Fig. 1A**). A 42-marker set defined a 13-segment full-body model. Center of mass (CoM) was computed as the barycenter of segmental mass and WBAM as the sum of segmental angular momenta about the CoM. V_{ap} (relative to the fixed ground) and WBAM waveforms were compared across conditions using non-parametric, permutation-based SPM one-way ANOVA with post hoc tests where main effects occurred ($\alpha = 0.05$).

Results

V_{ap} differed significantly across the conditions (**Fig. 1B**), increasing before the transition in entry and not returning to steady-state in the post-transition step of exit. In entry, sagittal WBAM (**Fig. 1C**) was significantly lower than steady-state during pre-transition swing, then showed a larger negative (forward-rotation) peak at the transition and a positive (backward-rotation) shift after foot contact. In exit, sagittal WBAM was significantly more positive

(backward-rotation) during pre-transition swing and more negative (forward-rotation) after the transition.

Discussion

Changes in V_{ap} indicate anticipatory preparation and a need for additional post-transition steps to stabilize. During entry, V_{ap} and sagittal WBAM patterns indicate anticipatory modulation of forward WBAM to match the moving platform's belt speed, followed by a reactive braking response after foot placement. During exit, V_{ap} and sagittal WBAM adjustments suggest anticipatory deceleration before belt assistance is withdrawn and rapid re-engagement of self-generated propulsion on the stationary surface. These findings may support applications in safety guidance or gait training.

Images (Optional)

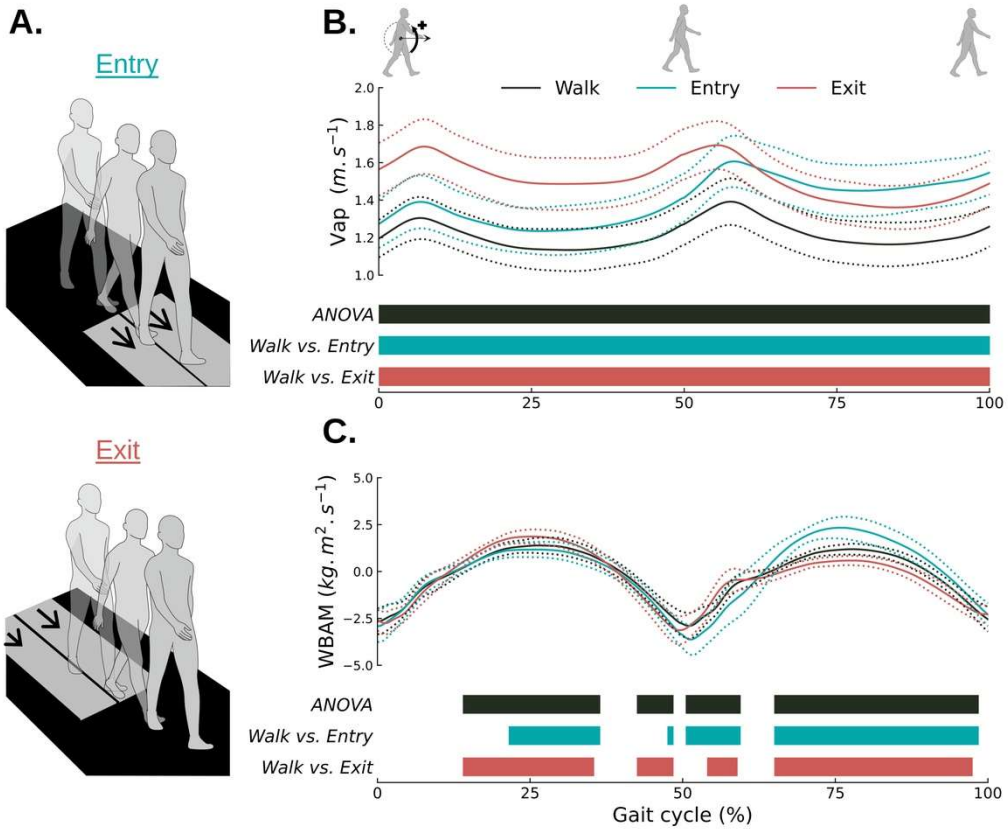

Figure 1: Task schematics for the entry and exit conditions (A.). Antero-posterior CoM velocity (V_{ap}) (B.) and sagittal whole-body angular momentum (WBAM) waveforms (C.) for three conditions: steady-state walking (black), entry (green), and exit (red). Each panel shows one stride time-normalized to 0–100%; with the transition occurring during the second step. For entry/exit conditions, the treadmill belt translated at 0.5 m/s in the walking direction. Significant one-way SPM ANOVA results ($\alpha = 0.05$) are shown by thick black bars for main effects, and by colored overlays for post hoc comparisons.

Dynamic Muscle Coordination Analysis Using Wearable Ultrasound: Advancing Biomechanical Assessment of Recovery

Dr. Erica L. King PhD, Dr. Qi Wei PhD, Dr. Siddhartha Sikdar PhD, Dr. Margaret T. Jones PhD, Dr. Parag V. Chitnis PhD

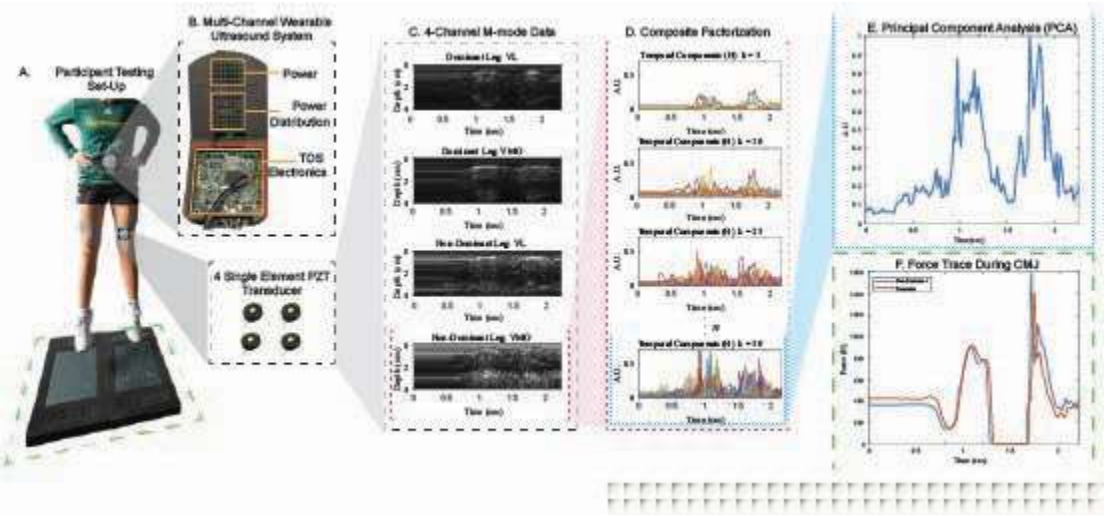
George Mason University, Fairfax, VA, United States

Introduction

Conventional musculoskeletal ultrasound provides high-resolution imaging but is limited to static, single-site assessments using handheld probes[1]. These constraints hinder dynamic biomechanical monitoring during rehabilitation, where multi-muscle coordination is critical for understanding recovery. This study introduces a compact, wearable ultrasound (WUS) system designed for real-time, multi-site imaging of muscle mechanics during movement.

Methods

A custom four-channel Time Delay Spectrometry Ultrasound (TDS-WUS) system[2] was developed to capture M-mode data during bilateral countermovement jumps (CMJs) on a split force platform. The system transmitted 20-ms frequency sweeps (3–5 MHz) and recorded echo signals at 50 lines/s from transducers placed over the vastus lateralis (VL) and vastus medialis oblique (VMO) bilaterally. Automated processing using Composite Factorization Principal Component Analysis (CF-PCA) extracted contraction dynamics without manual annotation, enabling quantification of intra-limb coordination and timing precision through cross-correlation analysis. Twenty NCAA Division I female athletes were categorized into two groups: prior knee injury (n = 8) and no injury (n = 12). Jump performance metrics (jump height and reactive strength index-modified) were compared alongside ultrasound-derived coordination indices.



Results

While CMJ performance did not differ significantly between groups, CF-PCA revealed biomechanical disparities in muscle coordination. Athletes with prior knee injuries exhibited reduced VL–VMO synchrony ($p = 0.039$) and increased activation time-lags ($p = 0.013$), indicating persistent neuromuscular adaptations despite medical clearance. These findings align with functional survey scores ($p = 0.001$), suggesting that conventional performance metrics may mask underlying deficits in muscle recruitment and timing.

Discussion

Wearable multi-site ultrasound combined with automated analysis provides a novel biomechanical approach for assessing neuromuscular recovery. By capturing real-time coordination patterns during dynamic tasks, this technology offers clinicians and researchers objective indicators of muscle function beyond traditional performance measures. Integration into rehabilitation workflows could improve readiness-to-return assessments, reduce re-injury risk, and advance individualized recovery strategies. This work highlights the importance of synchronized, multi-muscle imaging for understanding complex biomechanical adaptations in sports medicine and rehabilitation.

In-Vivo Radiation Dose During Dynamic Fluoroscopic Analysis of Knee Joint Motion

MSc Raphael Surbeck[1], Dr. Roland Zemp[1], Dr. Mirko Kaiser[1], MSc Stefan Plüss[1], Dr. Dr. Peter Cossmann[2], Prof. Dr. William R. Taylor[1]

[1]ETH Zürich, Zürich, Zürich, Switzerland. [2]MedTechConsulting, Zug, Zug, Switzerland

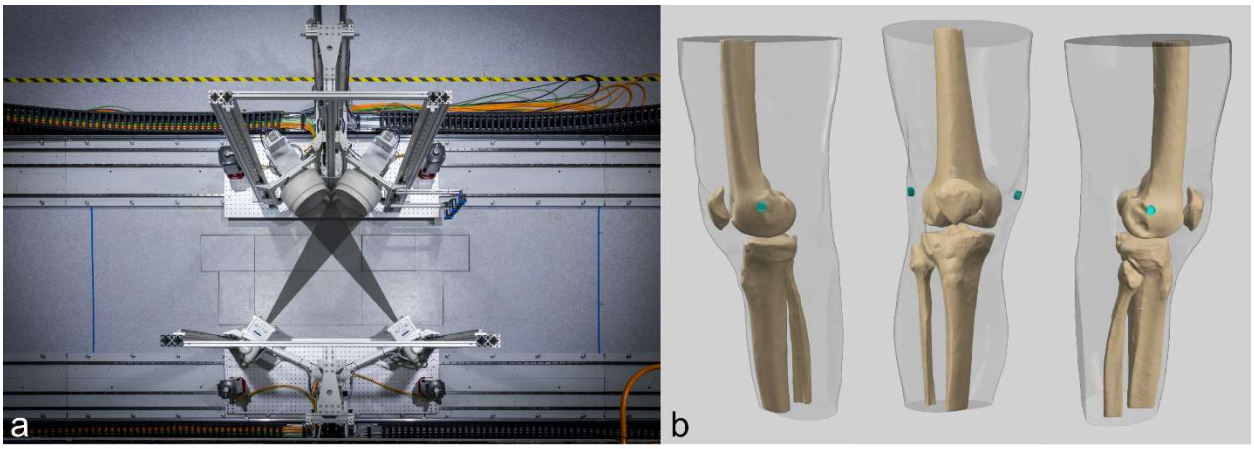
Introduction

Dynamic fluoroscopy enables high-accuracy in vivo assessment of joint kinematics by avoiding soft-tissue artefacts inherent to optical motion capture. However, participant exposure to ionizing radiation imposes ethical and practical limits on trial duration and frequency, potentially reducing the ecological validity of measured movements. Accurate quantification of effective radiation dose is therefore required to optimize imaging protocols and ensure participant safety. This study experimentally quantified in vivo X-ray dose during representative lower-limb motion tasks using a tracking biplanar fluoroscopy system.

Methods

A single participant (male, 46 years, 192cm, 103kg) diagnosed with knee osteoarthritis, scheduled for total knee arthroplasty and participating in an ongoing fluoroscopy study was included for this analysis. Imaging of the right knee was performed using a novel tracking biplanar videoradiography system (Fig. 1a) comprising two X-ray tubes (G1082, Varian Medical Systems, USA) and image intensifiers arranged at a 110° angle. X-ray acquisition parameters were 65 kV and 100 mA, using 30 Hz pulsed radiation with a pulse length of 1ms.

Radiation dose was measured during six functional activities with 3-4 repetitions each: level walking, stair ascent, stair descent, ramp ascent, ramp descent, and a forward lunge. For each task, four thermoluminescent dosimeters were placed 2 cm above the medial and lateral femoral epicondyles on both legs (Fig. 1b).



Results

A total effective dose of 0.181mSv was measured. Detailed results can be found in Fig. 1c.

Discussion

Radiation dose was substantially higher in the right (tracked) leg compared to the contralateral side for most tasks (Fig. 1c). Differences in doses between limbs and tasks could be attributed to task-specific kinematics and spatiotemporal parameters influencing the dose distribution; for example, prolonged leg crossing during stair descent increased exposure to the left leg while reducing exposure to the tracked right knee.
The cumulative dose of 0.181mSv measured during the fluoroscopic motion-analysis study was comparable to the natural background radiation accumulated over a few weeks. The estimated additional lifetime cancer risk was approximately 0.001%, indicating a negligible contribution relative to baseline population risk, consistent with ICRP Publication 103 (2007). These findings demonstrate that high-fidelity data using dynamic fluoroscopy can be obtained with minimal radiological risk.

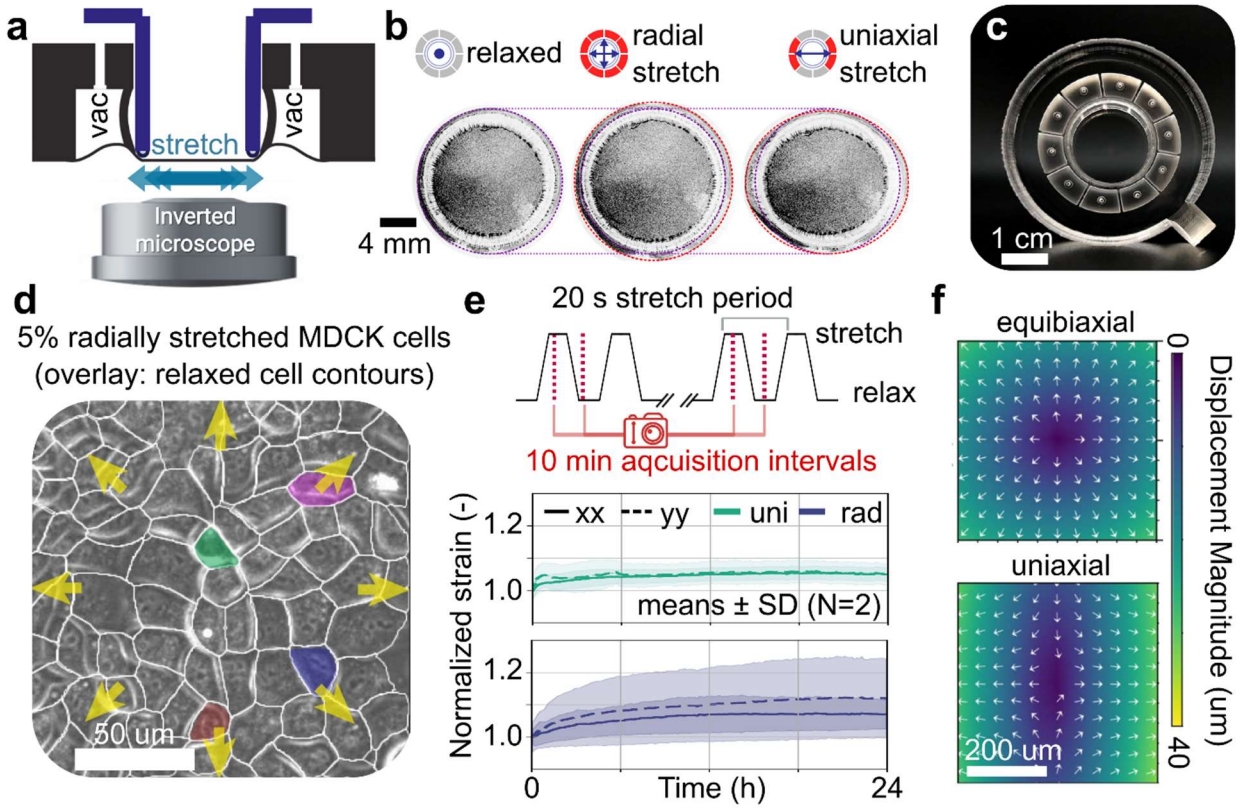
[5]Institute for Biology – Microbial Infection Biology, Humboldt-Universität zu Berlin, Berlin, Berlin, Germany

Introduction

Dynamic tissue stretching critically affects various cellular processes, from drug uptake to regeneration, and influences pathologies. The involved spatiotemporal dynamics remain largely unknown, partly due to the lack of cell stretching platforms compatible with videomicroscopy [1]. We introduce StretchView, a first-of-its-kind in vitro platform integrating cyclic cell stretching with automated, long-term videomicroscopy.

Methods

StretchView is a PDMS-based cell culture device enabling uniaxial, biaxial, or radial stretching of cells on an elastic membrane actuated by surrounding vacuum chambers. StretchView supports inverted microscopy, features a removable lid for top access, and allows automated videomicroscopy in relaxed and stretched states via an integrated ring-shaped spacer that limits vertical membrane movement to keep cells in focus (Figure a–c). As proof-of-concept, MDCK cell monolayers were grown on collagen I-coated StretchView membranes, imaged by time-lapse microscopy under radial cyclic loading (5% strain) for several hours, and analyzed for cell shape/kinematics via segmentation (Figure d) and particle image velocimetry [2]. Displacements and strains were quantified by digital image correlation for device calibration and post-experimental validation (Figure e,f).



Results

Long-term stability of focus and strain fields (6% radial, 9% uniaxial strain) was confirmed through 24 h of videomicroscopy of cyclically stretched membranes, as depicted in Figure e, with mean relative strain drift of +0.05 (uniaxial) and +0.1 (radial) compared to the baseline (t=0). Long-term imaging (12 h) of cells under stretch was shown for the first time without the need for human intervention (snapshot: Figure d, full video: Supp. Movie 2 in [2]). Remarkably, alternating stretch patterns (radial, bi-/uniaxial) were demonstrated in a single experiment [2].

Discussion

Our videomicroscopy cell-stretching experiments yielded spatiotemporal data volumes exceeding prior studies limited to manual acquisition, endpoint analysis, or static stretch. As a powerful in vitro tool, StretchView enables diverse applications: multi-cell-type cultures, biomechanical measurements, FRET-based signaling dynamics monitoring, and stretching protocols with altering directions and waveforms. In our ongoing work, we analyze stretched cells by traction force microscopy, integrate membranes with tuned substrate stiffness, and enhance throughput by a multi-well design.

A Predictive Model for Trips on a Ladder: Groundwork to Create a Ladder Climbing Safety Tool

Dr Sarah Griffin PhD[1,2], Dr. Eni Halilaj PhD[3], Dr. Mark Redfern PhD[2], Dr. Kurt Beschorner PhD[4]

[1]University of Washington, Seattle, WA, United States. [2]University of Pittsburgh, Pttsburgh, PA, United States. [3]Carnegie Mellon University, Pittsburgh, PA, United States. [4]University of Pittsburgh, Pittsburgh, PA, United States

Introduction

Falls from ladders are a common cause of serious occupational injuries. Trips, characterized by the climber's foot inadvertently contacting the rung during swing phase, contribute to these falls. Although prior laboratory studies have not characterized these events, they likely result from poor moving quality, which can be characterized by the symmetry, stability, and smoothness of their movement.

This study developed a predictive model for ladder trips using gait quality metrics collected from a single wearable sensor. This represents a first step towards a system to monitor ladder climbing safety on a jobsite.

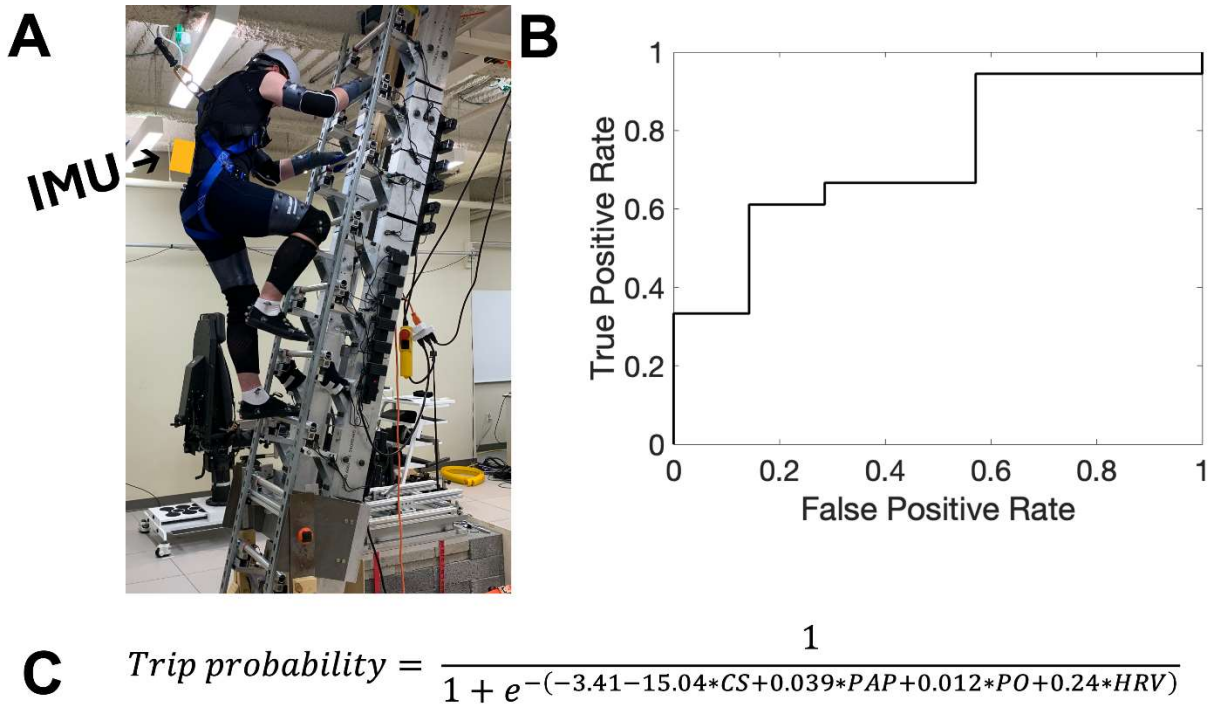
Methods

Twenty-five (16 F; 1.7 ± 0.09 m; 40.8 ± 12.7 years; 25.0 ± 3.7 kg/m^2) individuals who climb ladders regularly climbed up and down a series of ladder configurations (four rung designs at two different angles).

Optical motion capture data was used to identify trips during climbing, and participants were classified based on whether they experienced a trip.

An IMU attached to the pelvis collected acceleration data during ascending trials (Figure 1A). Root mean squared (RMS) acceleration (in three dimensions and overall magnitude) and harmonic ratio (in three dimensions) were calculated for one stride of each trial. These measures, as well as climbing speed, were regressors for the predictive model.

Least absolute shrinkage and selection operator (LASSO) regression generated a predictive model for trips. A nested leave-one-out approach tuned the model and evaluated its performance on left out data using the area under the receiver operating curve (AUC).



Results

The resulting model included the following predictors: climbing speed (*CS*), RMS acceleration in the AP direction (*PAP*) and of its overall magnitude (*PO*), and the vertical harmonic ratio (*HRV*) (Figure 1C). This model was moderately predictive with AUC = 0.73 (Figure 1B).

Discussion

This work suggest that whole body stability and smoothness are relevant to trip risk during climbing. In contrast, no single metric was predictive of trips (supplemental analysis). This work lays the groundwork for the development of a safety monitory tool using a combination of factors measured by a single sensor on their waist (e.g., smart phone in pocket).

An Opensource Toolbox for Ergonomic Analysis using Xsens Awinda

Dr. Matthew Russell Ph.D., A.E., Mr. Justin Davidson M.Sc., CSCS, Ms. Julia Li M.Sc., Mr. Jameson Vanstone, Dr. Steven Fischer Ph.D, C.C.P.E., R.Kin

University of Waterloo, Waterloo, Ontario, Canada

Introduction

Inertial Measurement Unit (IMU) based motion capture offers a balance between traditional optical systems and publicly available computer vision models. IMUs are more portable and accessible than optical systems and do not suffer sensitivity to viewing angle and occlusions like computer vision methods. These advantages have increased their use in workplace and in-field applications, including occupational assessment and virtual task design. Despite offering a portable, detailed kinematics solution, the ability to integrate such rich data into streamlined ergonomic assessment workflows is still nascent and may benefit from opensource solutions. Thus, this study aimed to (1) develop an MSD risk assessment toolbox compliant with Xsens (Movella) data formats and (2) compare MSD risk assessment measures between IMU, optical, and computer vision motion capture systems.

Methods

Twelve participants lifted a 5.4 kg box from floor to shoulder height while collecting full body kinematics using (1) Xsens Awinda IMU-based system, (2) a 11-camera optical system (Vicon, Oxford, UK), (3) an 8-camera video-capture system (Qualisys AB, Gothenburg, Sweden). IMU data were subsequently exported to Movella's .mvnx format and processed in a custom Python (Ver. 3.11.8) toolbox.

Results

Our toolbox provides both a programmatic object-oriented interface and a graphical user interface (GUI) for interfacing with Xsens kinematic data (Figure 1.A.). Lift 'start' and 'stop' markers can be set manually or custom lift-detection algorithms can be called to identify single or multiple lift start and end times, and optionally infer the lifting frequency, by locating hand displacement minima and maxima surrounding the peak vertical hand velocities during the trial (Figure 1.B.). NIOSH recommend weight limit (RWL) and Liberty Mutual maximal acceptable load (MAL) calculations [1,2] are currently supported by

extracting relevant sex (Xsens Analyze 2025 only) and kinematic data, including horizontal and vertical lift distances, and asymmetry angle.

Discussion

Presented is an opensource toolbox to streamline analysis and dashboarding of Xsens IMU-augmented MSD risk assessments. Comparisons between IMU-, optical-, and computer vision-based MSD risk assessment measurements and coefficients are forthcoming.

OA174-03

Influences of Anti-Fatigue Mat Stiffness on Self-Reported Pain During Prolonged Standing and Biomechanical Metrics of Balance Control

Ms. Alyssa M. Tondat, Mr. Taylor B. Winberg, Dr. Andrew C. Laing

University of Waterloo, Waterloo, ON, Canada

Introduction

Anti-fatigue mats (AFMs) decrease underfoot surface stiffness towards reducing musculoskeletal pain (MSK-P) [1]. However, this design principle has differential effects across competing biomechanical demands/pathways (e.g. pain, balance control). This multi-study project investigated these biomechanical pathways towards determining an optimal AFM stiffness for reducing MSK-P whilst minimizing balance impairments.

Methods

An industry partner generated AFMs (identical polyurethane foam materials and geometry) at five distinct stiffness levels characterized by CF durometer (higher CF is stiffer).

Study 1: Eleven participants completed 75-minutes prolonged standing on four separate days: three AFMs (CF 26, 34, 41), and a rigid control (RC) surface. Pain ratings were recorded for the low back (LB), shanks, and feet. Pain after 75-minutes was compared across AFM conditions. Subset analysis explored AFM effects for LB pain (LBP) developers [1].

Study 2: Ten participants completed static (standing) and dynamic (reaching, sit-to-stand) balance tasks on five AFMs (CF 24,29,32,36,40) and a RC surface. IMUs (APDM Opal) measured whole-body kinematics. Outcomes included sway velocity, RMS, and path length for standing tasks, and reach distance and trunk lean angle for dynamic tasks.

Results

Study 1: AFM stiffness effects on pain were body-part specific (Figure 1). The stiffest AFM (CF 41) decreased foot pain by 43.3% compared to RC ($p=0.022$). AFM effects were non-significant for shank pain ($p=0.403$) and LBP ($p=0.406$). For pain-developers, the stiffest AFM reduced LBP by 72.6% ($p=0.008$).

Study 2: AFMs had minimal effects on balance control. Compared to RC, there were no AFM effects on dynamic balance measures, or 4/7 static tasks (all $p>0.05$). In the three tasks with AFM effects, differences were least pronounced on the stiffest AFM (CF 40).

Discussion

This multi-study, industry-relevant project explored potentially competing demands of AFM stiffness on biomechanical outcomes. The stiffest polyurethane foam AFM produced the largest effects on MSK-P whilst minimizing effects on balance control (aligning with anecdotal reports of plywood flooring's benefits in manufacturing settings). Continued work is exploring underlying biomechanical mechanisms (muscle activation, blood oxygenation) towards developing application-specific design criteria (e.g. prolonged standing vs. impact attenuation).

Images (Optional)

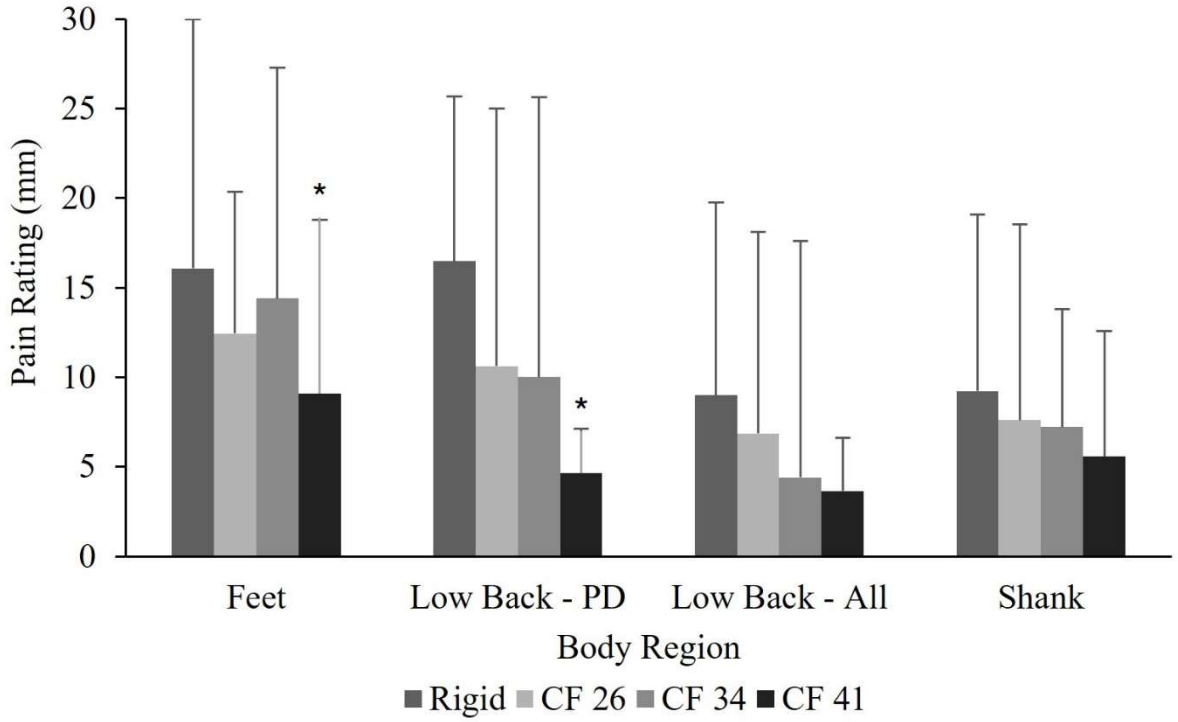

Figure 1: Pain ratings after 75-minutes of prolonged standing across body regions. PD = Pain-developer subgroup; All = all participants combined. The highest durometer AFM (CF 41) was most effective at reducing pain across all body regions. * indicates significant difference from the rigid control condition.

Concurrent Validity of Markerless Motion Capture for Assessing Manual Lifting Kinematics

Ph D Candidate Mengjie Zhang[1], Professor Mark Boocock PhD[2], Senior Lecturer Arne Nieuwenhuys PhD[1], Associate Professor Yanxin Zhang PhD[1]

[1]School of Exercise, Sport and Rehabilitation Sciences, Faculty of Science, University of Auckland, Auckland, Auckland Region, New Zealand. [2]Ergonomics and Human Factors Group, School of Allied Health, Auckland University of Technology, Auckland, Auckland Region, New Zealand

Ph D Candidate Mengjie Zhang

Professor Mark Boocock

Senior Lecturer Arne Nieuwenhuys

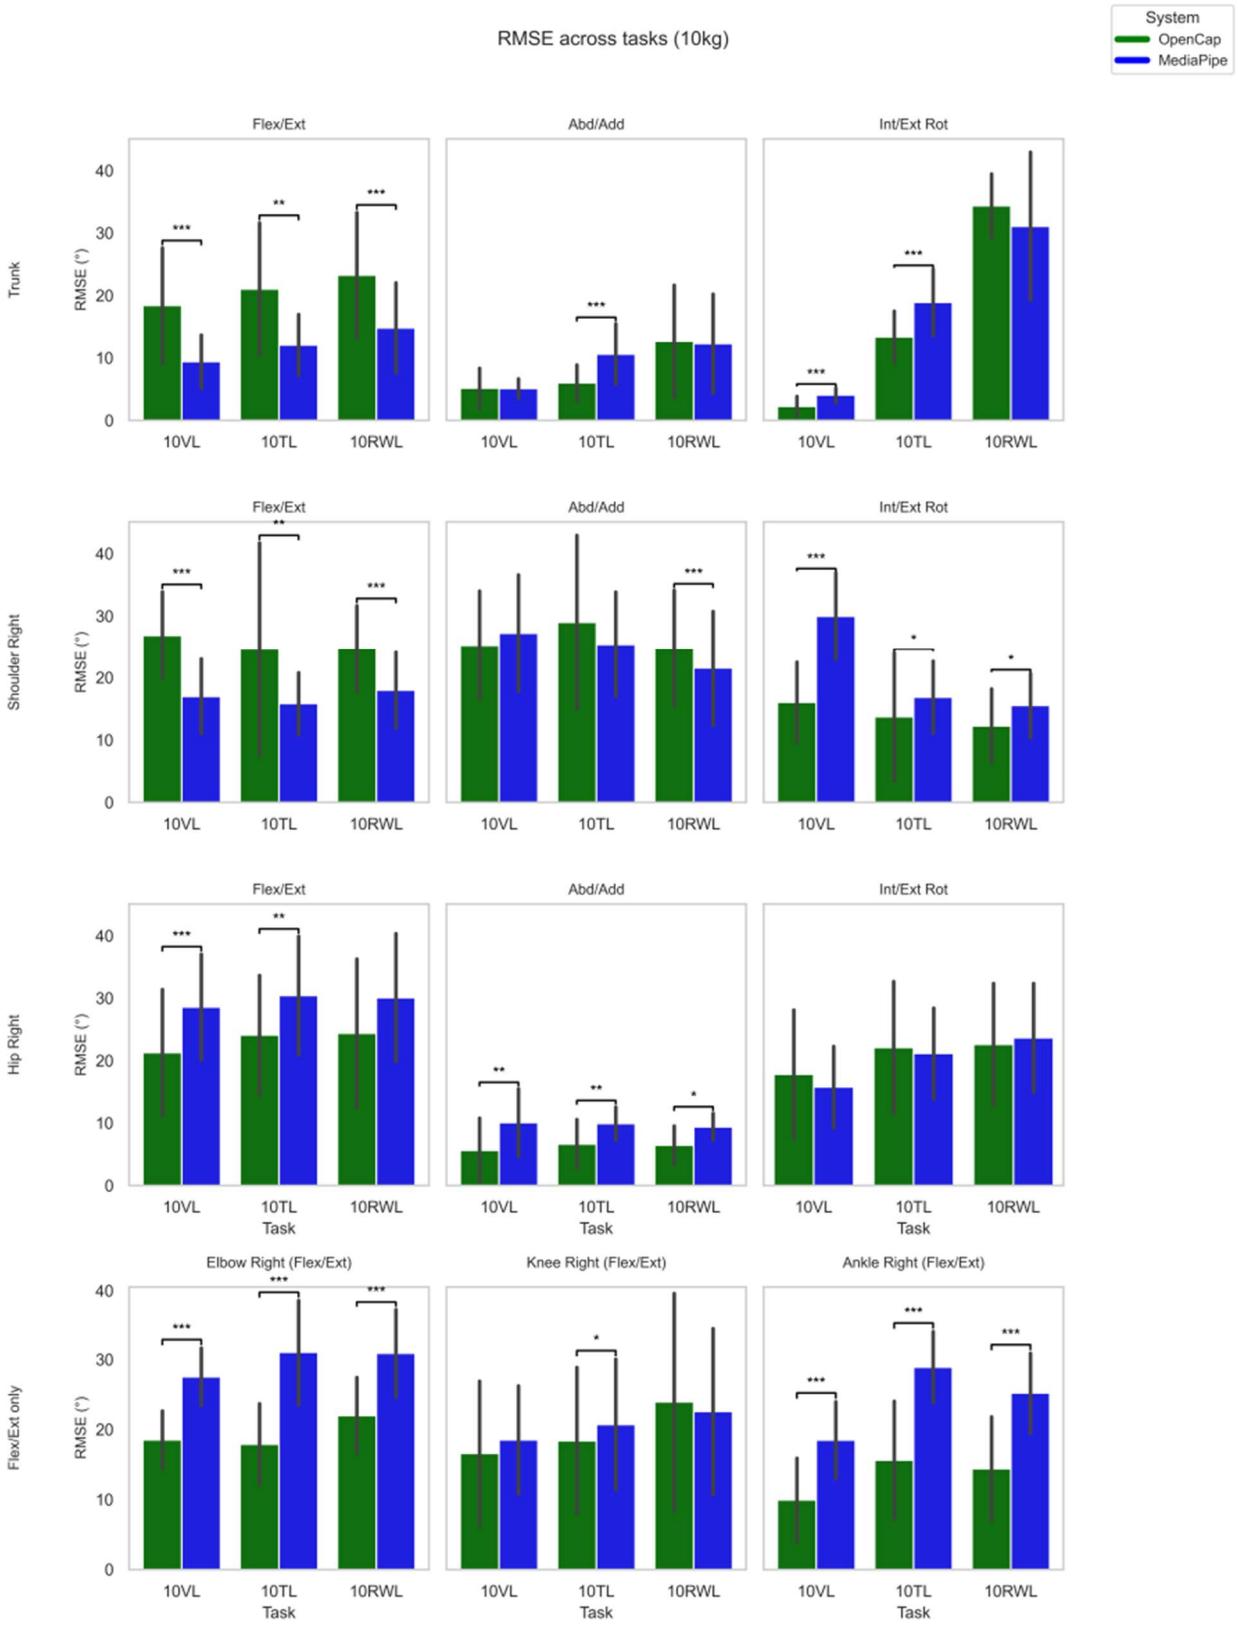
Introduction

Work-related musculoskeletal disorders (WMSDs) are a leading cause of occupational disability. Although markerless motion capture (MMC) offers low-cost, scalable alternatives to laboratory systems, validation studies have focused primarily on gait and sports, leaving complex manual handling tasks with load-induced occlusion and multi-planar movements underexplored. This study evaluated the concurrent validity of two MMC systems (OpenCap and MediaPipe) against a marker-based system (Vicon) as the gold standard for two-handed lifting tasks.

Methods

Twenty healthy participants (12 females/8 males; age 28.2 ± 2.19 years; height 1.68 ± 0.07 m; mass 60.8 ± 11.27 kg; BMI 21.43 ± 2.77) performed three tasks with increasing complexity: two-handed vertical lifting (VL), performed symmetrically in the sagittal plane; transverse lifting (TL), involving trunk rotation and frontal-plane motion; and rotational walking-and-lifting (RWL), combining lifting with short-distance walking and rotation. Full-body kinematics were captured simultaneously using Vicon (100 Hz, 39-marker Plug-in

Gait full-body model), OpenCap (60 Hz, three iOS devices), and MediaPipe (60 Hz, single-camera custom pipeline). Joint angles across all three planes were compared using Root Mean Square Error (RMSE, °), normalized RMSE% (relative to Vicon peak-to-peak range), and coefficient of determination (R^2) over the complete lifting cycle.



Results

Concurrent validity varied substantially by task, plane, and joint (Fig.1). For OpenCap, RMSE ranged from 4° to 67° (12-121%), with R^2 from 0.07 to 0.88. For MediaPipe, RMSE ranged from 6° to 60° (13-150%), with R^2 from 0.07 to 0.89. In the sagittal plane, RMSE% ranged from 12% to 42% across joints in VL tasks, with R^2 values up to 0.89. Accuracy decreased in the frontal and transverse planes with increasing task complexity, with RMSE% increasing approximately 15-30% from VL to RWL.

Discussion

MMC demonstrates potential for sagittal-dominant ergonomic assessment but remains substantially limited in frontal/transverse planes due to persistent landmark occlusion and depth ambiguity, challenges that persist even in optimized multi-view systems. Future work should address real-world occlusions, include diverse populations, enhance deep learning and optimization-based models, and validate hybrid approaches integrating biomechanical constraints or RGB-D fusion for robust WMSDs risk assessment.

A Hybrid Two-Phase Framework for Posture Prediction of Manual Material Handling Tasks

PhD Candidate Mengjie Zhang[1], Professor Mark Boocock PhD[2], Senior Lecturer Arne Nieuwenhuys PhD[1], Associate Professor Yanxin Zhang PhD[1]

[1]School of Exercise, Sport and Rehabilitation Sciences, Faculty of Science, University of Auckland, Auckland, Auckland Region, New Zealand. [2]Ergonomics and Human Factors Group, School of Allied Health, Auckland University of Technology, Auckland, Auckland Region, New Zealand

PhD Candidate Mengjie Zhang

Professor Mark Boocock

Senior Lecturer Arne Nieuwenhuys

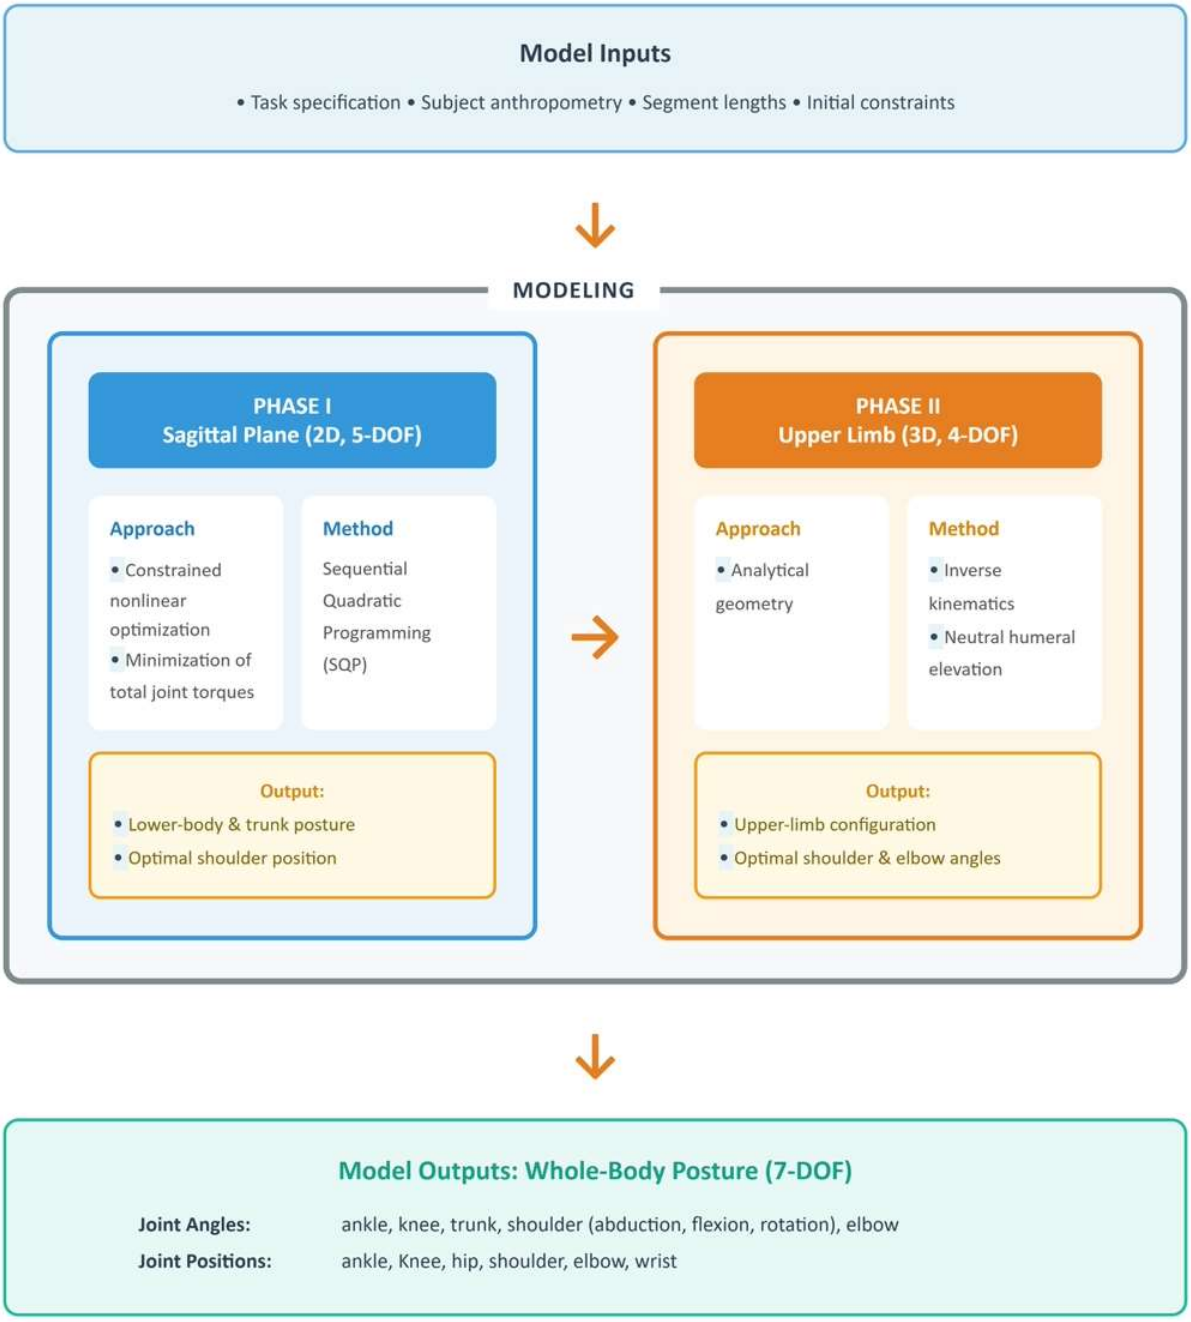
Introduction

Digital human models are efficient tools for simulating human postures and movements in specific work environments. Given the human body is a highly complex nonlinear system, predicting a virtual human's joint configurations under given tasks and constraints is a challenging task. Current 3-dimensional (3D) posture prediction models include redundant degrees of freedom (DOFs) that create a high-dimensional ill-posed optimization problem. On the other hand, 2-dimensional (2D) solution models consist of fewer DOFs in the sagittal plane, which are computationally efficient but lack DOFs in the frontal and transverse planes. This study developed a hybrid two-phase framework combining efficient 2D sagittal-plane optimization with 3D upper-limb reconstruction, delivering both accuracy and efficiency across diverse manual handling tasks.

Methods

Given fixed hand/foot positions, external load, and anthropometrics, Phase I performed constrained nonlinear optimization (5 DOFs) by minimizing joint torques subject to biomechanical constraints. Sequential Quadratic Programming was applied to solve the

optimization problem. During Phase II, the 3D upper-limb posture was predicted by applying inverse kinematics to compute the shoulder and elbow angles while adhering to biomechanical and performance criteria (Fig. 1). To validate the model, twelve participants (7 females/5 males; 28.5±2.19 years) performed two-handed vertical lifting (10 kg), shoulder-height drilling, and overhead drilling tasks. Vicon motion capture (100 Hz, 39 markers) provided ground truth, with validation performed using Root Mean Square Error (RMSE) for 7 joint angles.



Results

Across lifting and drilling tasks, the model achieved joint angle RMSEs of 4.21°-37.32° with 65-85 ms computation time per posture. The upper-limb predictions showed shoulder flexion/extension RMSE of 5.56°-7.56°, shoulder abduction/adduction RMSE of 6.97°-11.27°, and elbow flexion RMSE of 7.25°-18.63°. The lower-body and trunk flexion/extension angles showed RMSEs of 4.21°-7.06° (ankle), 6.86°-7.55° (knee), and 10.47°-12.39° (trunk).

Discussion

By combining efficient 2D optimization for the lower body and trunk with analytical 3D reconstruction for the upper limbs, the model provides a practical tool for predicting postures in diverse manual tasks. Validation confirms its reliability in simulating both reaching and lifting activities. The model has potential to be integrated into workflows for human-machine interface design.

OA174-06

Exploring the Efficacy of Different Field-Based Kinetic Measurement Approaches for the Calculation of Peak and Cumulative Low-Back Moments.

Mr. Justin Davidson MSc., Dr. Dennis Larson PhD, Ms. Julia Li MSc, Dr. Steven Fischer PhD

University of Waterloo, Waterloo, Ontario, Canada

Introduction

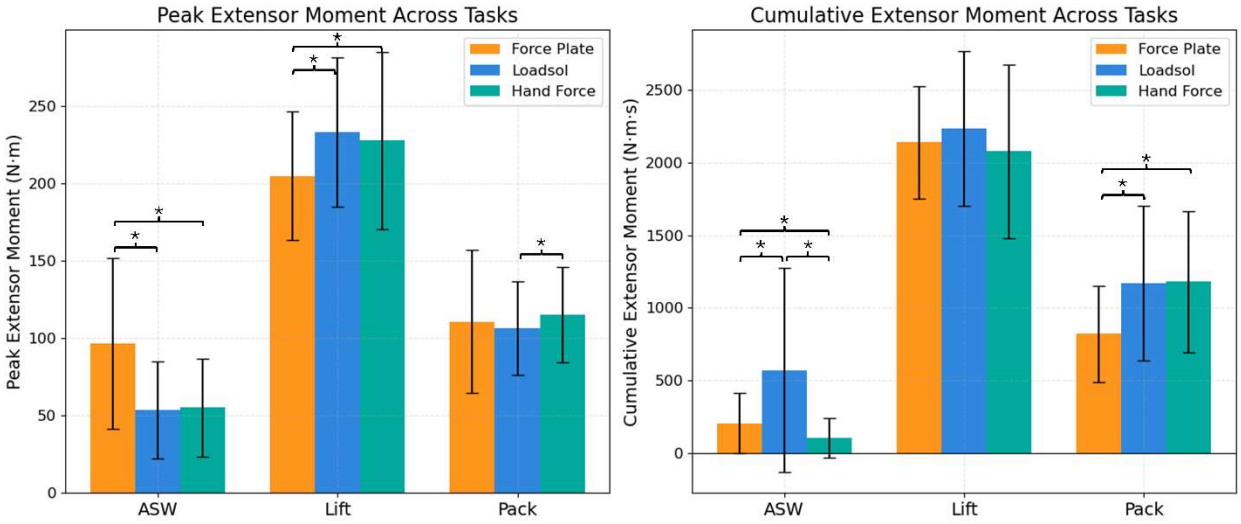
Accurately estimating peak and cumulative low-back exposures in the workplace is critical for assessing low-back injury risk [1]. In lab, force plates are the standard input for bottom-up inverse dynamics; however, their high cost and limited portability make them impractical for field measurements. Hand force estimates have been used as an alternative, but accurately measuring hand forces and identifying when to apply them to a kinematic model remains difficult. Recent innovations in force-estimating insole technology offer a potential solution [2]; however, their validity in computing low-back moments has not been evaluated. This study aimed to compare three kinetic measurement approaches for estimating peak and cumulative low-back extensor moments during occupationally relevant tasks.

Methods

Forty participants (20F, 20M) performed three occupational tasks: floor-to-shoulder lifting, box packaging, and above-shoulder work sorting. Kinematics were capturing using a Qualisys video capture system and processed through Theia3D. Kinetics were measured with force plates (gold-standard), force estimating insoles (Loadsol, Novel), and hand forces estimates derived from known weights applied at the center of mass of the hand. Peak and cumulative low-back extensor moments were computed in Visual3D for each measurement approach (bottom-up for force plate and insoles, top-down for hand force estimates). Two-way repeated measures ANOVA's evaluated differences between peak and cumulative low-back extensor moments across tasks and measurement systems.

Results

Significant interactions between measurement systems and tasks existed for both peak and cumulative moments (Figure 1). Differences in peak moments between measurement systems were most pronounced during the above-shoulder work sorting task, while cumulative moments varied most during the packaging task. Moments during lifting remained similar overall between kinetic measurement approaches.



Discussion

Estimating moments via hand force and via force-estimating insoles were comparable to estimates using gold standard force plate data. Considering the practical challenges of estimating hand forces and when they should be applied in the field, force-estimating insoles may provide a viable alternative for detailed time-series low-back moment calculations. Improving the accuracy of field-based kinetic measurement can enhance our understanding of occupational low-back injury risks and inform better prevention strategies long-term.

Images (Optional)

Figure 1

Peak and cumulative low-back extensor moments for three occupational tasks measured by three unique kinetic measurement approaches. Significant interactions of task and measurement approaches were found for peak and cumulative moments. Post-hoc pairwise comparison revealed significance is indicated by an *.

Monitoring Longitudinal Healing in Ovine Large Defect Reconstruction using Virtual Mechanical Testing

Ms. Kylie Frew[1], Dr. Madeline Boyes[2], Dr. Thomas Schaer[2], Dr. Hannah Dailey[1]

[1]Lehigh University, Bethlehem, Pennsylvania, United States. [2]University of Pennsylvania, Department of Clinical Studies New Bolton Center, School of Veterinary Medicine, Kennet Square, Pennsylvania, United States

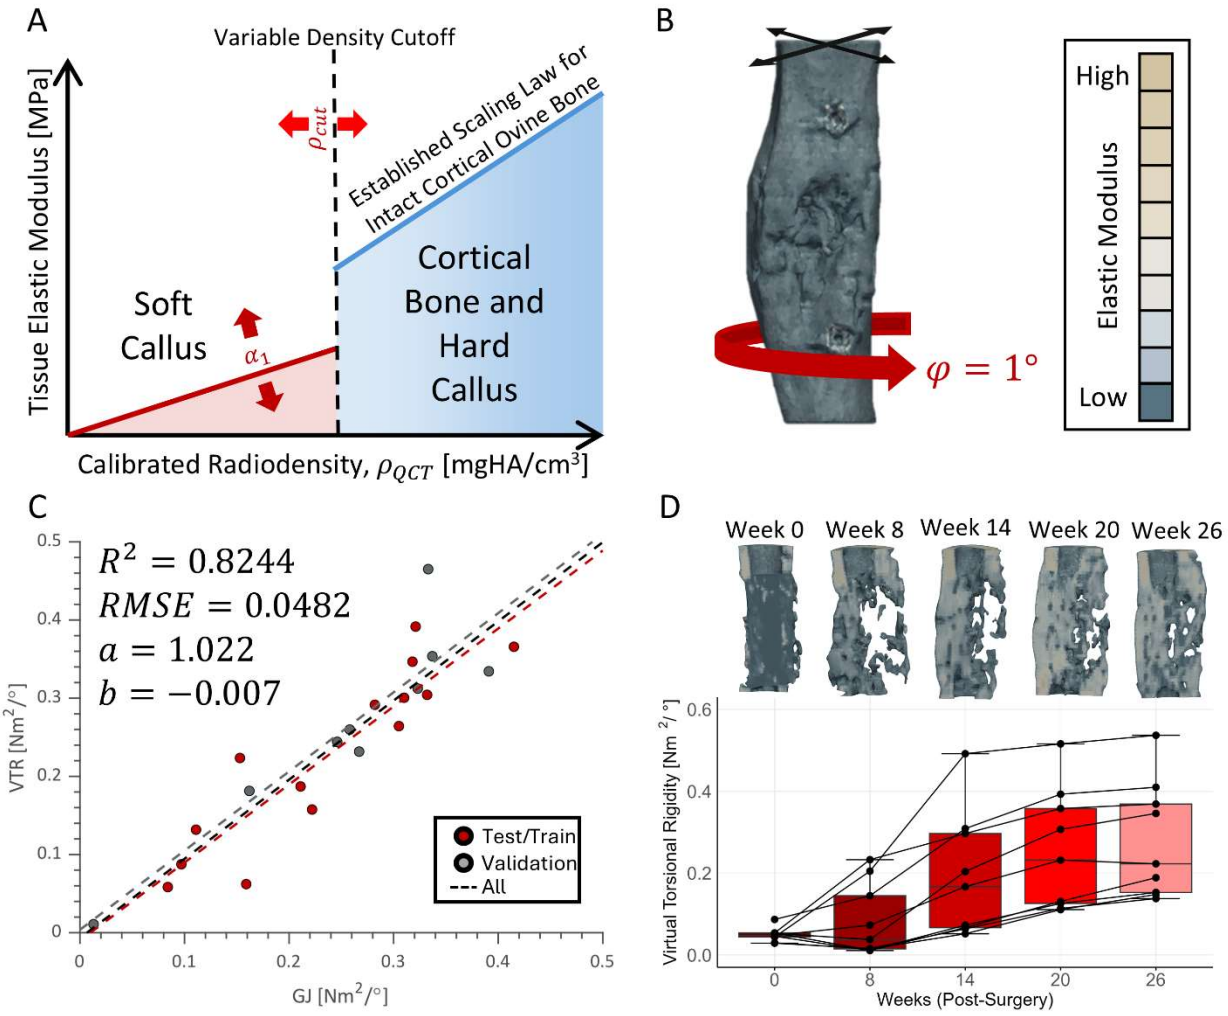
Introduction

Virtual mechanical testing is an image-based, noninvasive *in vivo* approach for evaluating bone rigidity. This study focused on monitoring healing in an ovine model of large-defect limb salvage. The objective of this study was to validate a new approach methodology (NAM) that can capture mechanical healing progression over time using longitudinal *in vivo* scans – data that cannot be obtained any other way – and thereby support the reduction, refinement, and replacement (3Rs) of animal use.

Methods

Thirty-three adult female sheep received either 30-mm (N=24) or 50-mm (N=9) tibial defects with autograft. *In vivo* computed tomography scans were obtained at sacrifice (18 weeks for the 30-mm, 26 weeks with 4-weekly scans for 50-mm). *Ex vivo* torsion testing was performed on the 30-mm cohort and was used to validate the virtual mechanical test. Models created from the scans in Materialize Mimics were assigned elementwise materials using a piecewise function (Fig 1A) and virtual torsional rigidity (VTR) was analyzed in ANSYS (Fig 1B). A repeated k-fold cross-validation (k = 4) procedure encompassing ~1700 simulations was used to optimize the material model parameters for the piecewise function of Fig 1A using the 30-mm cohort (N = 14 test/train, N = 10 validation). The objective of the optimization was to match VTR to physical torsional rigidity (GJ). The optimized material model was then applied to the 50-mm cohort for longitudinal healing analysis. Statistical analysis was performed in R.

Results



The optimized material model yielded strong, significant agreement between VTR and GJ for all optimization animals (N = 24) (Fig 1C). For the longitudinal scans in the 50-mm cohort, rigidity began to substantially increase after week 8 (significant differences vs. weeks 14, 20, 26) with callus formation plateauing around 20 weeks (non-significant

difference vs. week 26) (Fig 1D). Substantial within-week VTR variability emerged after 8 weeks, suggesting individual divergence in healing trajectories between animals.

Discussion

Virtual mechanical testing reliably quantified mechanical healing and is a validated surrogate for postmortem physical testing in this large-defect model. This method also provided nondestructive longitudinal outcomes assessment leading to clinically relevant insights that are unobtainable by other means.

OA175-03

Efficient and Validated Finite Element Analysis for Quantitative Assessment of Fracture Healing

Dr. Peter Schwarzenberg, Ms Giulia Minikus, Dr. Peter Varga

AO Research Institute Davos, Davos, Grisons, Switzerland

Introduction

Fracture-healing decisions currently rely on qualitative radiographs that potentially miss subtle mechanical deficits, contributing to tibial shaft nonunion rates near 15%. CT-based finite element (FE) modeling can quantify virtual torsional rigidity (VTR), yet current workflows involve demanding meshing and solver tools (Abaqus) and expertise that limit throughput [1]. We evaluated whether a simplified voxel-based FE pipeline involving a parallel multigrid solver (ParOSol) maintains diagnostic alignment with a high-fidelity reference model and *in vivo* strain-sensor measurements while enabling rapid, automation-ready analyses.

Methods

Data from eight sheep with tibial osteotomies fixed with locked plates including the implantable AO Fracture Monitor sensor and CT scans at eight timepoints were used. The cohort included a delayed-healing and a nonunion case. FE simulations were performed at 4 levels of sequential simplifications: L0 utilized whole-bone quadratic tetrahedral meshes with kinematic couplings solved in Abaqus; L1 simplified embedded boundary conditions; L2 used linear hexahedral mesh; L3 exchanged coupling to direct node-based displacements; L4 solved in ParOSol. Virtual torsion tests yielded VTR. Healing was determined from longitudinal VTR data using a threshold and a plateau. Strain-sensor-based relative implant load (RIL) provided ground truth. Agreement was evaluated using correlation analysis.

Results

All FE-levels reproduced the monotonically advancing healing trend for healers and identified the delayed-healing and nonunion cases seen by sensors. Cross-level VTR comparisons showed excellent correlation between L4 versus L0 ($R^2 \geq 0.980$; Figure 1A). L4 achieved similar accuracy as L0 ($R^2 = 0.769$ versus $R^2 = 0.788$; Figure 1B,C) in predicting sensor-based healing time. L4 was solved three times faster versus L0.

Discussion

Voxel FE modeling derived directly from segmented CT volumes retained diagnostic fidelity despite stepwise simplifications to geometry, mesh, loading, and solver choice. Concordance with both the reference model and the sensor-based ground truth indicates that longitudinal VTR consistency, not intricate meshing, governs clinical usefulness. The accelerated solver workflow and standardized load application reduced manual labor and positions the pipeline for automation once segmentation is scripted. Next steps include automated segmentation, extension beyond torsion, and validation in clinical fracture cohorts.

A Tissue-Differentiation Framework to Predict Bone Formation Following Lumbar Interbody Fusion

Mr. Davide Ninarello MSc.Eng.[1], Professor Hanna Isaksson PhD[2], Associate Professor Luigi La Barbera PhD[1]

[1]Deptartment of Chemistry, Materials and Chemical Engineering “G. Natta”, Politecnico di Milano, Milan, Italy, Italy. [2]Department of Biomedical Engineering, Lund University, Lund, Sweden, Sweden

Introduction

Pseudoarthrosis after lumbar interbody fusion (LIF) is often linked to inadequate mechanical stimulus of tissues around the intervertebral cage. LIF technique, implant stiffness and biological factors strongly influence the surgical outcome. This study applied a tissue-differentiation algorithm to enable objective assessment of postoperative LIF biomechanics and healing process over time, across various scenarios.

Methods

An iterative ABAQUS-Python framework was implemented, where cell activity and tissue formation occurred under suitable mechanical stimuli [1], following Claes & Heigele’s theory [2]. A validated thoraco-lumbar model [3] was reduced to T12–S1, and two surgical techniques (namely, XLIF and PLIF) were simulated at L4–L5 with long posterior fixation (titanium pedicle screws and 5.5 mm rods, Fig.1A). Both Ti (E=110 GPa) and PEEK (E=4.5 GPa) cages were modelled, accounting for PEEK hydrophobicity by down-scaling parameters linked to osteoblast-specific activity.

Results

Most of bone formation occurred in the posterior disc region for both LIF techniques, independent of cage material. XLIF and PLIF showed comparable mean bone concentrations in the posterior region (38% vs 36%), though only XLIF achieved bony bridging through the cage holes (Fig.1B). Regarding cage materials, Ti produced up to 42% higher bone concentration than PEEK at day 25, a difference that fell to 3% by day 100 (Fig.1C). Ti also prevented bridging within the cage holes, whereas the more compliant PEEK cage supported a continuous bridge.

Discussion

Minor differences in bone formation were seen between XLIF and PLIF, consistent with retrospective clinical findings [4]. PEEK's hydrophobicity reduced osteoblast activity and limited bone formation near the cage (Fig.1D), potentially increasing the risk of micro-movements, in line with clinical observations [5]. Future analyses will include longer follow-ups and alternative fixation and fusion strategies. This study demonstrates the potential of tissue-differentiation algorithms to evaluate long-term outcomes of complex LIF approaches while providing relevant clinical insights.

Optimal Strength for Mandibular Reconstruction With Low Bone Stock

Dr Hans Gray[1], Mr Adrian De Angelis[2], Mr Anand Ramakrishnan[1,2], Dr Peter Lee[1]

[1]The University of Melbourne, Melbourne, Victoria, Australia. [2]The Royal Melbourne Hospital, Melbourne, Victoria, Australia

Introduction

Surgical resection of the mandible may be required as treatment for tumours involving the lower jaw. When the resection leads to a defect in continuity, reconstruction with a bony flap held together with a reconstruction plate and screws is required. When the available proximal bone stock is limited to only the mandibular condyle and neck, there may be insufficient bone for attaching a standard reconstruction plate. To design a plate for situations with low bone stock, the current study aimed to determine the optimum screw positions on the condylar neck for maximum fixation strength.

Methods

A geometric model comprising the mandibular condyle and neck was resected from a mean model of a mandible created using statistical shape modelling. The geometry represented a typical low bone stock case (Fig. 1A). A genetic optimisation algorithm coupled with finite element modelling was used to find the optimum number and positions of screws to provide maximum fixture strength. Failure envelopes were used to evaluate the efficacy of the optimised solution. A failure envelope was constructed considering 1536 unique force directions spread out in 3D space applied on the condylar head (see [1] for details on failure envelopes). A second similar failure envelope was constructed for a case with adequate bone stock and typical screw positioning (Fig. 1B) as per the current practice using existing reconstruction plates.

Results

The low bone stock case with four optimally placed screws resulted in a failure envelope (Fig.1, red envelope) that almost entirely encapsulated the failure envelope representing the current practice when sufficient bone stock is available (Fig. 1, green envelope). Only in 24 of the 1536 directions was the predicted fracture load greater for the current practice than for the optimised fixture proposed for the low bone stock case.

Discussion

The results demonstrated that the optimised solution for the low bone stock case was superior in strength to the typical current practice in mandibular reconstruction surgery when sufficient bone stock is available. Further work is underway using patient-specific models derived from CT data to understand if the results are consistent across patients.

Images (Optional)

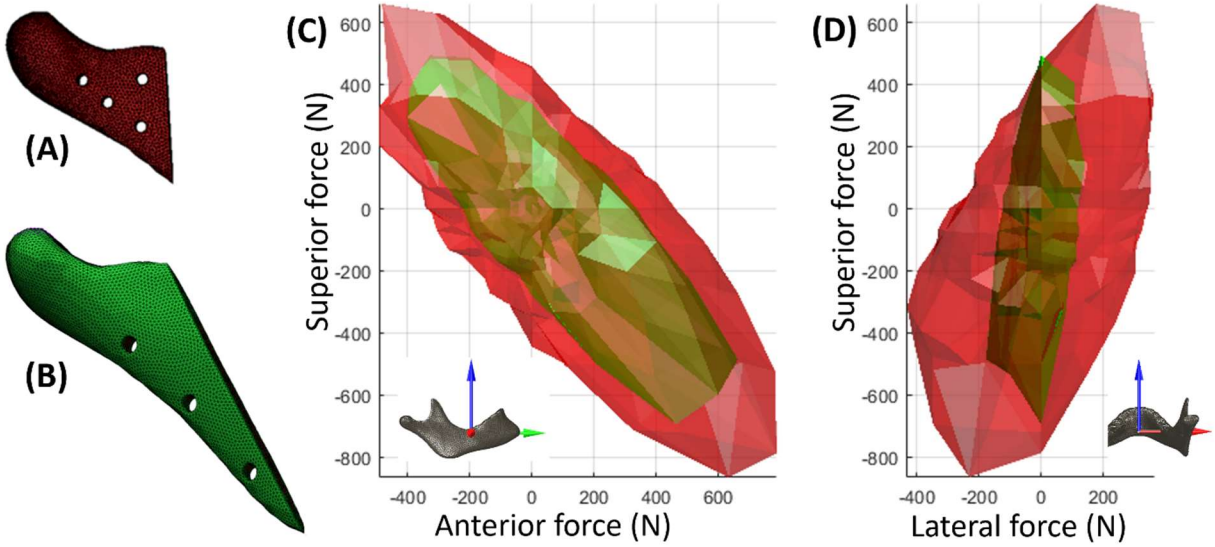

Figure 1: (A) Optimum screw configuration for low bone stock case. (B) Current practice with adequate bone stock. (C) Lateral view and (D) posterior view, of force envelopes for low bone stock (red) and current practice with adequate bone stock (green). The green envelope was almost entirely encapsulated by the red envelope, indicating the superior strength of the optimised solution compared to the typical current practice.

[3]the Department of Mechanical Engineering, KAIST, Yuseong-gu, Daejeon, Korea, Republic of

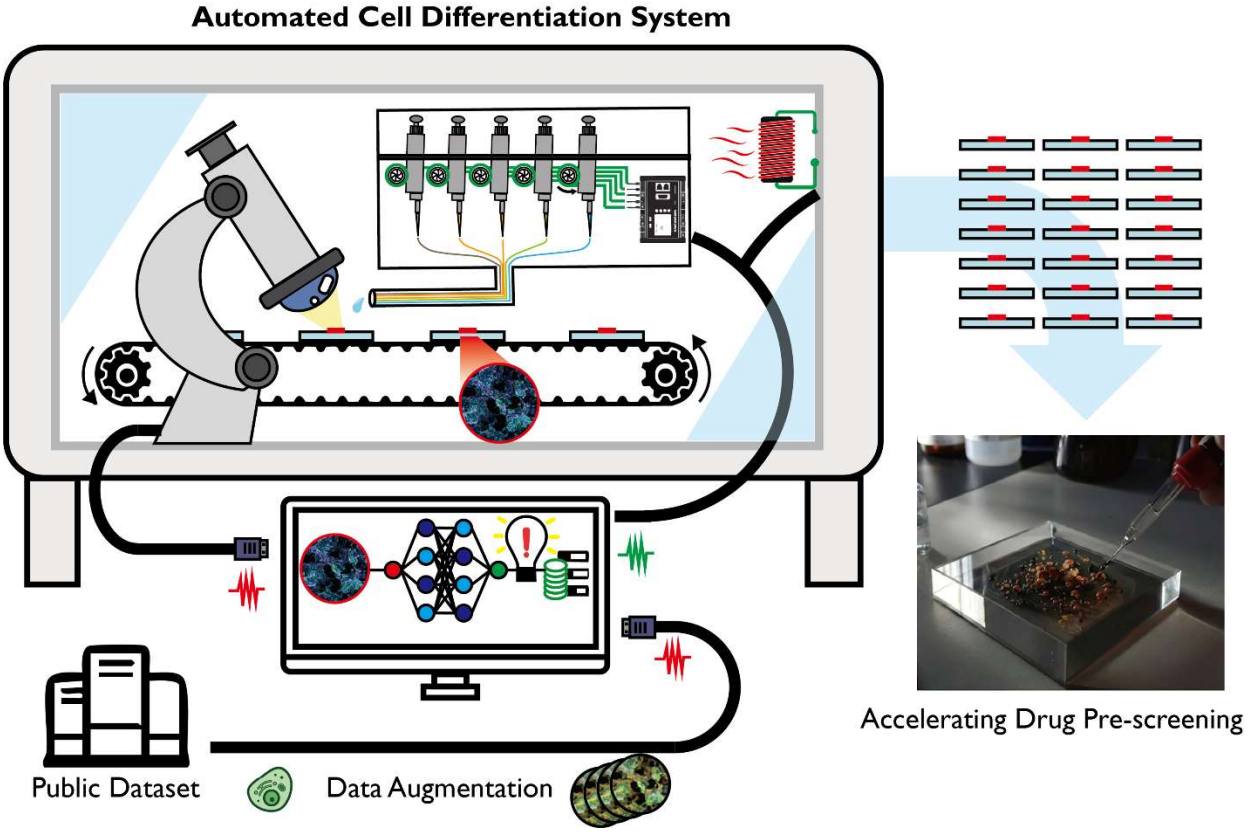
Introduction

Stem cell-derived neuronal in-vitro models serve as essential tools for pre-clinical screening of neurological drug candidates. These systems are gaining significance for their potential to replace animal testing and improve clinical trial success rates. While basic differentiation protocols are well established, subtle variables that protocols alone cannot control inevitably arise during differentiation. Assessing cell density heterogeneity, morphological changes, and batch variations still relies on skilled researchers' experience and intuition, resulting in low reproducibility and labor and time costs limiting mass production scalability. To overcome these limitations, we propose an AI-based automated differentiation system that recognizes cellular states in real-time and adaptively controls the culture environment. As an initial step, we established a robot-based culture system with precise environmental control and developed a preliminary deep learning model using public datasets.

Methods

For environmental control, we developed a microfluidic robot driven by a stepper motor and ball screw mechanism, incorporating a Peltier cooling system, an environmental chamber, and a high-resolution microscope. For state recognition, we trained an Xception classifier on a public neuronal dataset (~100,000 images). An augmentation pipeline reflecting differentiation-associated morphological changes was also developed for future application with in-house data.

Results



The microfluidic delivery robot was designed to achieve a fluid injection resolution of 0.05 μL. The Peltier cooling system maintained 4°C, while the integrated chamber enabled precise regulation of temperature, humidity, and gas concentrations, facilitating real-time

image acquisition. In validation on the public dataset, the Xception model achieved an overall accuracy of 98.3%. Astrocytes had the highest recognition rate (99.4%), and neurons achieved 99.0% despite being the largest sample group. Oligodendrocytes showed relatively lower accuracy (92.5%); misclassification as neurons were attributed to morphological similarities shared during specific differentiation stages.

Discussion

This study established a precision environmental control robot and a high-accuracy cell state recognition AI as an initial framework for automated cell differentiation systems. Future work will implement a real-time AI-robot feedback loop through transfer learning with in-house data and time-series-based state prediction models. This automated system is expected to enable mass production and quality standardization of brain cells, ultimately contributing to a high-throughput screening platform for neurological disease therapeutics.

Synchronized and Metachronal Coordination in Macro-Scale Physical Models of Coupled, Autonomously Beating Cilia

Ms Naomi Hsieh, Ms Jeslyn Gao, Ms Alexis Rivera BS, MS, Dr. Louis Woodhams PhD, Dr. Philip Bayly PhD

Washington University in St. Louis, St. Louis, Missouri, United States

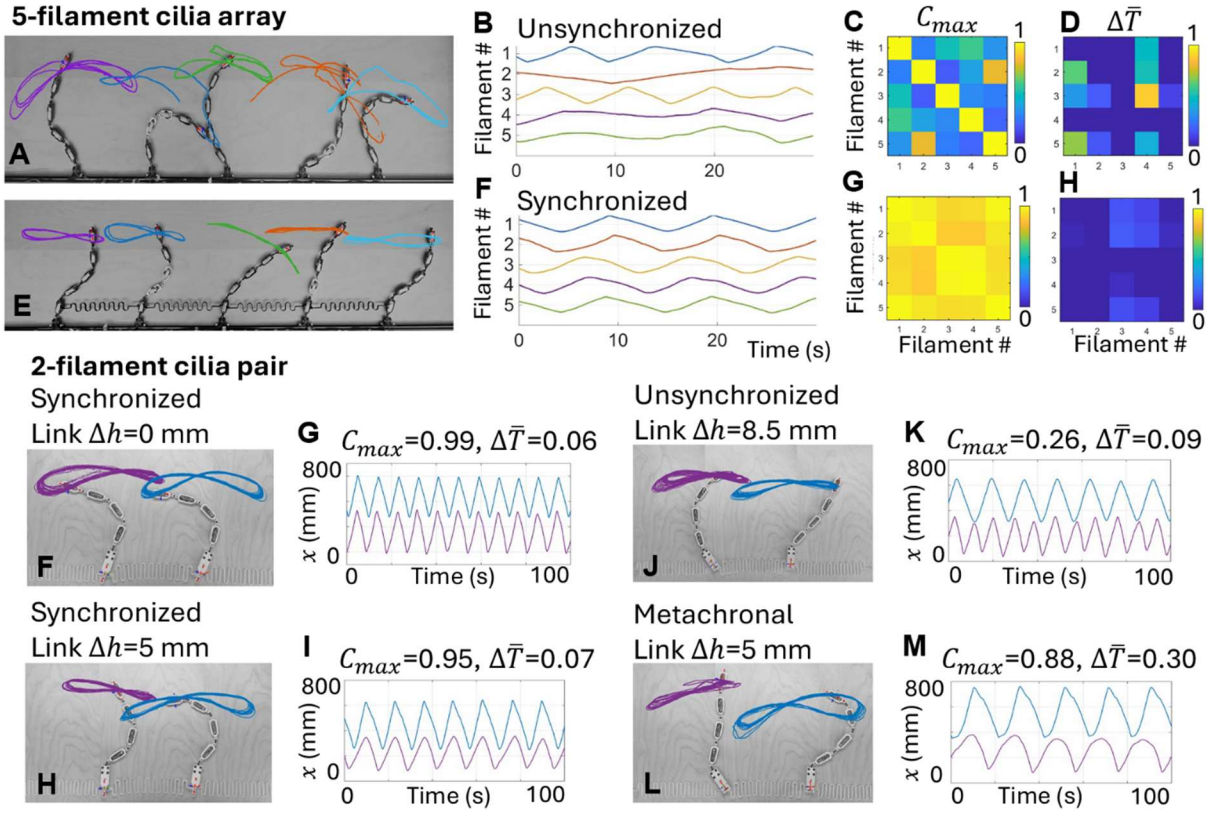
Introduction

Motile cilia are slender organelles that project from cells and beat rhythmically to propel the cell or move fluid. In multiciliated cells or microorganisms, arrays of cilia can enhance their propulsive efficacy via metachronal coordination, in which adjacent cilia beat with a consistent phase difference. The mechanisms responsible for establishing metachronal beating are not clear. In theory, hydrodynamic coupling is sufficient to produce metachronal waves in arrays of autonomously beating cilia [1]. However, experiments in *Tetrahymena* [2] show that altering intracellular connections between cilia basal bodies disrupts metachrony. To explore the effects of mechanical coupling on cilia coordination we built physical models of autonomously beating filaments and quantified the similarity and phase of their oscillations.

Methods

Filaments exhibiting spontaneous, base-to-tip, oscillatory waveforms were constructed by connecting Hexbug™ vibrating toys (hexbug.com) by short segments of flexible rubber (Fig.1A). Each “cilium” beat autonomously with a period between 10-20 sec. Video recordings (30 fps) of arrays (5-cilia) or pairs (2-cilia) were analyzed using a custom optical flow-based tracking algorithm to measure tip displacement. Coupling was introduced by attaching 3D-printed elastic “spring” elements between basal links (Fig.1E,F,H); in some cases “free-play” nonlinearity was added by introducing a slot in the link (Fig.1J,L). Coordination was characterized by the maximum cross-covariance (C_{max}) and phase lag (ΔT, cycle fraction) between tip displacements.

Results



Arrays of 5 cilia were uncoordinated ($C_{max}<0.5$; Fig.1A-D) when uncoupled and synchronized ($C_{max}>0.9$, $\Delta T<0.1$; Fig.1E-H) with spring coupling. Pairs of cilia were synchronized ($C_{max}>0.9$, $\Delta T<0.1$; Fig.1F-I) with spring coupling, but when free-play was introduced, cilia were uncoordinated when intrinsic frequencies differed ($C_{max}<0.5$; Fig.1J-

K) or metachronal, beating out-of-phase (C_{max}~0.9, ΔT=0.3; Fig.1L-M) when intrinsically similar.

Discussion

Physical models of autonomously beating cilia arrays exhibited varying levels of coordination when coupled elastically at their bases. The coupling elements in these macro-scale models are analogous to intracellular links such as striated fibers that connect basal bodies of adjacent cilia in *Tetrahymena*. Experimental investigations in these physical models, including quantitative measurements of metachronal coordination, can illuminate the behavior of cilia on cells and microorganisms.

A Mechano-Osmotic Coupling Drives Stress-Dependent Growth in Breast Cancer Spheroids Revealed Through AI-Accelerated Discrete Cell Modelling

Mr Irish Senthilkumar[1], Mr Jef Vangheel[2], Dr Vatsal Kumar[1], Prof Laoise McNamara[1], Dr Bart Smeets[2], Dr Enda Howley[1], Dr Eoin McEvoy[1]

[1]University of Galway, Galway, Galway, Ireland. [2]KU Leuven, Leuven, Leuven, Belgium

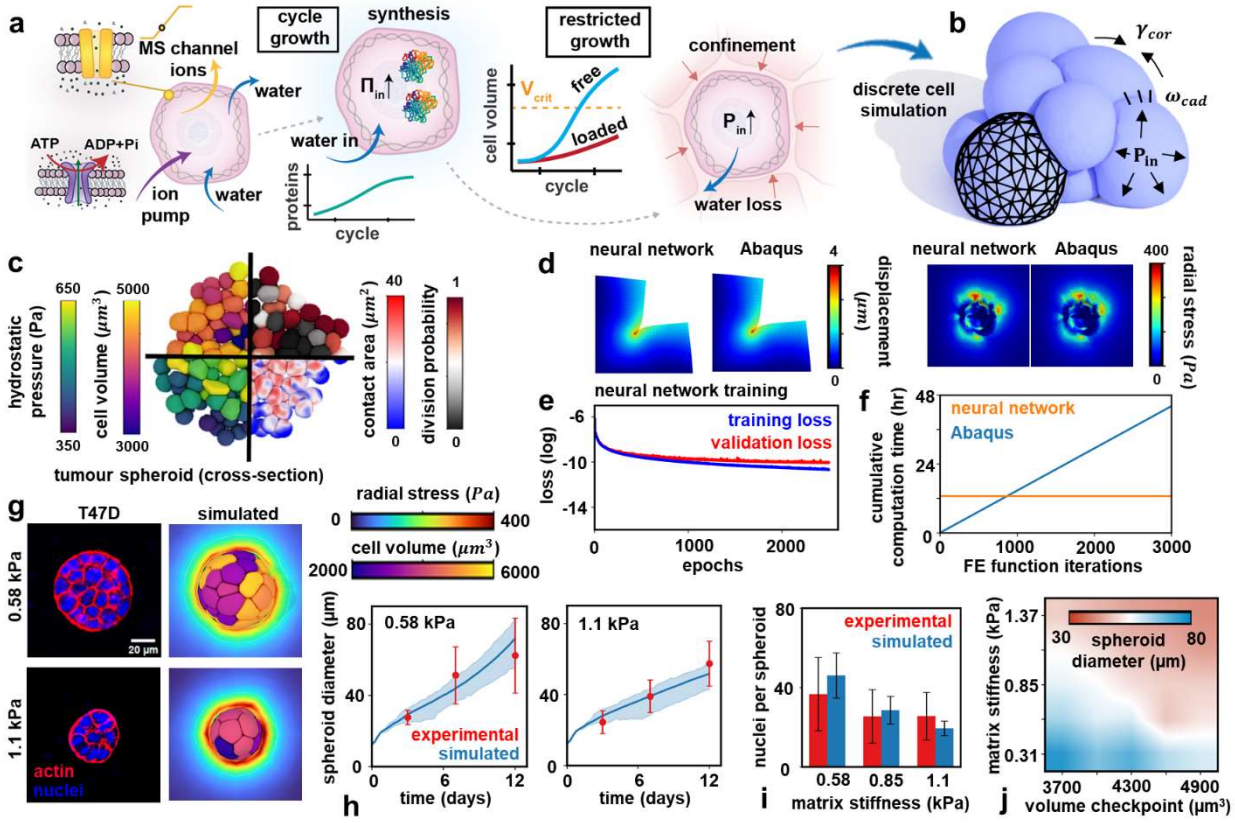
Introduction

Mechanoresponsive cell proliferation is a feature of growing tumours, despite the suppression of other regulatory checkpoints in cancer, but the underlying cell-scale mechanisms driving this behaviour remain unclear. We propose a biophysical model for cell growth as governed by actively controlled osmolarity, integrated with a discrete particle framework to simulate growth and remodelling of breast cancer spheroids.

Methods

We describe volumetric growth as dependent on biosynthesis-driven increases in osmolarity, which promotes water intake, and hydrostatic pressure generated by cortical tension and matrix-induced compression [1] (Fig1A). This formulation is implemented within MPacts (Fig1B) [2], where each cell is described as a deformable, pressurised viscoelastic shell that may divide subject to surpassing a recently identified sizing checkpoint [3]. Mechanical feedback from the extracellular matrix is implemented through a custom neural network (NN) surrogate finite element (FE) model.

Results



Simulations demonstrate that biosynthesis increases intracellular osmotic pressure, promoting volumetric growth, while confinement increases hydrostatic pressure to limit cell division (Fig1C). The NN-FE surrogate accurately predicts ECM deformation in both 2D and 3D (Fig1D-E) while enabling a substantial reduction in computational cost at a higher number of FE iterations (Fig1F). Extending this model to cell-matrix interactions reveals an ECM stiffness-dependent response: spheroids in softer hydrogels attain larger volumes with a higher cell division probability, while stiff hydrogels impose sufficient growth-induced stress to limit expansion (Fig1G-I) as per our experimental measurements. Increasing the volume checkpoint or matrix stiffness promotes smaller spheroids (Fig1J).

Discussion

Our models and experiments identify a mechano-osmotic mechanism for stress-dependent growth in which synthesis-driven cell swelling competes with confinement-mediated increases in intracellular pressure. This computationally efficient tool could readily be extended for analysis of patient-derived tumouroids and mechanoresistance.

Full-Field Elastography of the Cell Nucleus Reveals Peripheral Stiffening in Response to Strain

Mr. Kurt Winkler, Dr. Stephanie Schneider, Dr. Emily Miller, Dr. Corey Neu

University of Colorado Boulder, Boulder, CO, United States

Introduction

The cell nucleus senses and responds to mechanical stimuli, making nuclear mechanics important for understanding how cells interact with and respond to their mechanical environment. While methods such as AFM and micropipette aspiration measure bulk nuclear stiffness, subnuclear stiffness resolution has remained largely unknown. Here, we introduce an image-based full-field elastography pipeline that utilizes deformable image registration and inverse modeling to determine nuclear stiffness. We demonstrate its accuracy with forward models and apply it to live cells subjected to mechanical strain.

Methods

Finite element forward models were generated from microscopy images of DAPI- and H2B-eGFP-labeled nuclei, with element stiffness correlated to pixel intensity. Equiaxial strains were applied to these models in FEBio (4.5.0) [1] to produce pairs of undeformed and deformed images. These images were registered using MATLAB's imregdemons algorithm [2] to generate displacement fields which served as inputs to an iterative inverse solver to determine full-field relative stiffness maps. To generate real data, mouse embryonic fibroblasts (MEFs) were subjected to biaxial strains of 5% or 10% for 30 minutes followed by 30 minutes of recovery. Microscopy images of cell nuclei were acquired at various timepoints to track temporal stiffness changes.

Results

Our elastography method accurately reconstructed ground truth stiffness maps in DAPI- and GFP-based forward models, achieving correlation coefficients >0.8 for physiologically relevant strains. Case examples of MEF's subjected to 5% or 10% biaxial strain showed localized hot spots of increased stiffness in the nuclear periphery, with recovery toward baseline stiffness within 20min of unloading, demonstrating dynamic and reversible alterations in nuclear stiffness.

Discussion

Our elastography method is an effective tool for mapping full-field nuclear stiffness, addressing a significant methodological gap in mechanobiology research. The ability to

measure relative stiffness under controlled strain reveals that the nucleus experiences load-dependent and region-specific changes in stiffness, highlighting its sensitivity to external stimuli. This method could be further used to study how nuclear stiffness influences cell mechanics, mechanotransduction pathways, and mechanical adaptation of cells to their environment.

Images (Optional)

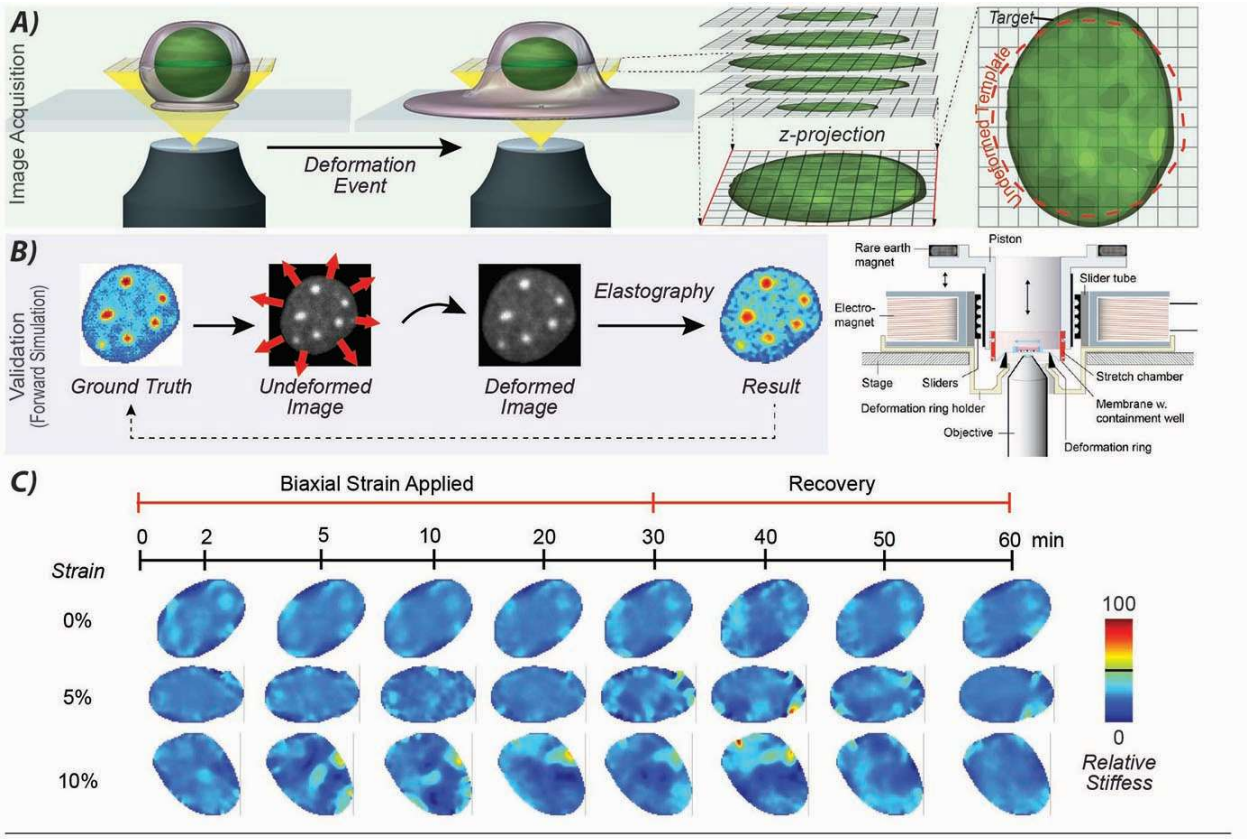

Figure 1. Intra-nuclear elastography, using image-based mechanics, enables measurement of the time-evolving stiffness in stretched cells. *(A-B)* Optical acquistion of nucleus images is used in combination with deformable image registration and inverse modeling to reveal intra-nuclear stiffness patterns. Forward simulations confirm our ability to reconstruct ground truth patterns. *(C)* Mechanical stretch of mouse embryonic fibroblasts shows a strain-dependent peripheral enrichment and recovery of stiffness over time.

Effects of Running-Related Fatigue on Hip and Knee Muscle Synergies Among Male and Female Endurance Runners

Ms Cinthuja Pathmanathan PhD candidate[1], Dr Leonardo Gizzi[2], Professor Deborah Falla[3], Professor Caroline Paquette[1], Professor Julie N Côté[4]

[1]1Department of Kinesiology and Physical Education, McGill University, Montreal, Quebec, Canada. [2]Department of Biomechatronic Systems, Fraunhofer Institute for Manufacturing Engineering and Automation, Stuttgart, Baden-Württemberg, Germany. [3]Centre of Precision Rehabilitation for Spinal Pain (CPR Spine), School of Sport, Exercise and Rehabilitation Sciences, University of Birmingham, Birmingham, England, United Kingdom. [4]School of Human Kinetics, University of Ottawa, Ottawa, Ontario, Canada

Introduction

Previous studies have shown that muscle fatigue affects some indicators of multi-muscle coordination in runners, such as the relative contributions of leg muscles. Muscle activation coefficients and areas are measures used in synergy analysis to assess motor control strategies. However, little is known about whether these fatigue-related changes are the same or different between males and females during Running Induced Fatigue (RIF). We aimed to quantify sex-specific effects of RIF on patterns of lower limb synergies.

Methods

Twenty-one healthy endurance runners (12 males, 25.0±6 years; 9 females, 23±2 years) were recruited. The activity of 10 hip and knee muscles was measured bilaterally using surface electromyography (EMG) before and after an incremental fatigue protocol performed until exhaustion (confirmed via the Borg 6-20 scale). A tridimensional motion capture system was used to measure lower limb kinematics and partition the EMG data. Non-negative matrix factorisation was applied to muscle activities to extract synergies. The best matched pairs of synergies, determined using cross-correlation, were compared between trials. Statistical parametric mapping (SPM) and generalised estimating equations were performed.

Results

Five synergies (Variance accounted for [VAF] global = 0.97±0.01) during pre-fatigue and six synergies (VAF global = 0.99±0.02) during post-fatigue status explained the neuromuscular control in both sexes. RIF resulted in a significant reduction in the activation area of all synergies (p <0.001, coefficient (β) ranges from -0.481 to 2.805) in both sexes. However, in synergy 6, which explained pelvic stability, the activation area showed a sex × fatigue

interaction effect (p <0.001, β=4.758), with the RIF-related reduction being higher in females compared to males. Sex-specific SPM analysis showed that there was no statistical difference in activation coefficients in pre- and post-fatigue statuses in all five synergies (p >0.05).

Discussion

Results suggest that runners adapt to RIF by decreasing voluntary activation of some muscles and reallocating load to other muscles (i.e. 6th synergy). A higher synergy 6 reduction in females suggests less efficiency in coordinating pelvic stabilizing muscles with fatigue, and that they may benefit from coordination training of pelvic muscles to prevent RIF-induced injuries.

Older Adults Exhibit Savings of Adapted Motor Patterns from Repeated Exposure to Virtually-Induced Fall-Related Anxiety

Dr. Kelly Poretti[1], Dr. Toby Ellmers[2], Dr. Quentin Sanders[3], Dr. Nathalia Peixoto[3], Dr. Christopher Rhea[4], Dr. Tiphanie Raffegeau[1]

[1]George Mason University, Manassas, VA, United States. [2]Imperial College London, London, London, United Kingdom. [3]George Mason University, Fairfax, VA, United States. [4]Old Dominion University, Norfolk, VA, United States

Introduction

Evidence-based interventions that use virtual reality (VR) to administer 'exposure therapy' for anxiety disorders combined with laboratory-based methods of inducing a postural threat that elicits fall-related anxiety may serve as a multi-dimensional fall intervention for older adults. However, it remains unknown how older adults might adapt differently to repeated immersion to postural threat compared to young adults. The purpose of this study is to determine age-related differences to gait habituation in response to repeated immersion in virtual anxiety-inducing settings.

Methods

Participants (N = 30, 14 older adults) experienced two five-minute immersions in anxiety-inducing VR settings (i.e., high elevation), with a one-minute washout period walking at ground level. Visualization of the absolute distance between the headset and ankle trackers (HTC Vive Pro Eye) was used to extract and calculate steady state gait parameters (speed, step length and width, percent double support). To determine gait habituation across trial time and immersion the first (T1) and last (T2) six steady state steps were extracted for the first (I1) and second (I2) immersion. Linear mixed-effect regression compared gait across Age (2 levels: Older vs. Young Adults), Time (2 levels: T1 vs. T2), and Immersion (2 levels: I1 vs. I2).

Results

In the first immersion, young and older adults walked with longer steps ($F = 15.50$, $p < .001$), and faster speeds ($F = 7.05$, $p = .013$) at T2 compared to T1 at I1. Demonstrating savings between immersions, young and older adults walked with longer ($F = 21.17$, $p < .001$), and faster ($F = 16.50$, $p < .001$) steps at T1 of I2 compared to T1 of I1. No savings were observed in step width or double support.

Discussion

Young and older adults preserve locomotor balance, not altering step width or double support time, while demonstrating savings of step length and increasing gait speed, likely due to the constrained walkway width. Across immersions, participants appear to gain confidence in their ability to preserve locomotor balance at high VR settings, saving habituated motor patterns. Our results provide evidence to support the potential use of the VR paradigm as a habituation intervention to reduce fall-related anxiety in older adults.

Images (Optional)

OA177-03

Eliminating the Distal-to-Proximal Redistribution in Older Adult Joint Mechanics Improves Walking Economy

Ms. Ningzhen Zhao[1], Dr. Ross Miller[2], Dr. Lisa Griffin[1], Dr. Owen Beck[1]

[1]University of Texas at Austin, Austin, TX, United States. [2]University of Maryland College Park, College Park, Maryland, United States

Introduction

During walking, older adults push-off the ground less with their ankles than young adults, compensating by producing more work at their hip. The implications of this age-related redistribution in joint mechanics are strictly hypothetical because no intervention has restored youthful, preferred walking mechanics in older adults – until now. Here, we temporarily restored youthful joint mechanics in older adults following a brief functional electrical stimulation (FES) paradigm, uncovering the metabolic consequence of walking like an older adult.

Methods

Twenty adults (10 young: 5 F; 21 ± 2 yrs; 10 older: 5 F; 77 ± 5 yrs; Avg ± SD) performed treadmill walking trials at 1.25 m/s. Five minutes after a familiarization trial, participants performed a 5-minute baseline walking trial. Next, participants walked for 10 minutes with FES applied bilaterally over user soleus muscles during late stance [1]. Following a 20-minute rest, participants performed a final 5-minute walking trials *sans* stimulation.

Results

At baseline, older adults exhibited a greater ratio of hip-to-ankle work versus young adults ($p=0.042$). After walking with FES, older adult preferred ankle mechanical output increased versus baseline (peak power: $p=0.013$; work: $p<0.001$), with a concomitant 22% reduction in hip work ($p=0.035$). After walking with FES, older adults walked with a 21% decrease in their baseline hip-to-ankle ratio of mechanical work ($p=0.004$), yielding nearly identical relative joint work production compared to young adult at during baseline walking ($p=0.788$). Moreover, post-FES walking elicited a 4% lower gross metabolic power compared to baseline in older adults ($p=0.021$).

Discussion

The short-term carry-over effects of pairing FES with voluntary drive eliminated the distal-to-proximal redistribution in older adult preferred walking mechanics. The findings further suggest that the age-related distal-to-proximal redistribution contribute to the greater

metabolic cost of walking in older versus young adults. Overall, intervening on the nervous system is sufficient to restore youthful, preferred walking joint mechanics in older adults and reduce whole-body metabolic rate.

Images (Optional)

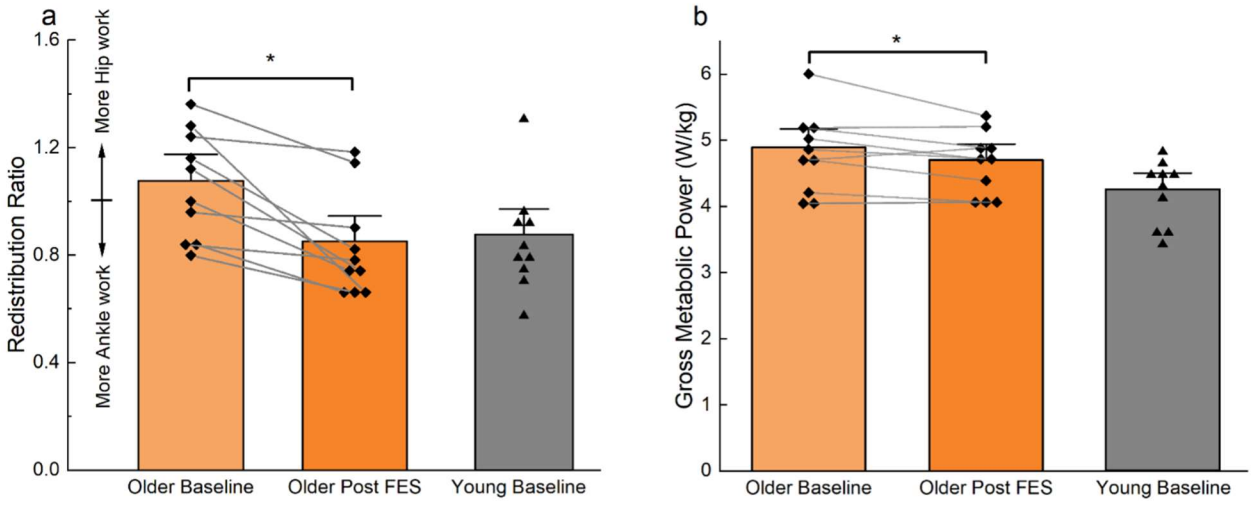

Figure 1. Redistribution ratio and metabolic power at baseline and post-FES conditions. Bar graphs represent group average (±SE) with individual data represented for each participant. a) Redistribution ratio and b) gross metabolic power. Data represents older adults baseline (light orange), older adults post-FES (dark orange), and young adults baseline (gray). Asterisks (*) indicates that p value < 0.05.

Changes in Duty Factor in Response to Three Running Retraining Cues in Military Runners

MAJ Jennah Bulen PT[1], MAJ Gregory Freisinger PhD[1,2], Dr. Mikel Joachim PhD[3], Dr. Erin Florkiewicz PhD[4,1], LTC Jamie Morris PT, DSc[1]

[1]Baylor University - Keller Army Community Hospital Division 1 Sports Physical Therapy Fellowship, West Point, NY, United States. [2]United States Military Academy, West Point, NY, United States. [3]University of Wisconsin-Madison, Madison, WI, United States. [4]Rocky Mountain University of Health Professions, Provo, UT, United States

Introduction

Duty factor (DF) represents the proportion of ground contact time (GCT) within the step cycle and serves as a key temporal descriptor of running mechanics, capturing how runners distribute stance and flight time across each step [1–3]. Although gait retraining can modify step rate and GCT, components of DF, it remains unclear whether different cueing strategies produce distinct DF adaptations. This study examined how verbal, metronome, and visual cues independently influence DF in military runners.

Methods

Twenty-nine military runners (21 men, 8 women; mean age 25 ± 6.9 years) completed treadmill running at a consistent self-selected speed under four conditions: baseline, metronome cue set at 10% above their baseline step rate, verbal cue of pulling the foot off the ground as quickly as possible, and a visual cue set at 5% below their baseline contact time. Step rate and GCT were collected using RunScribe inertial measurement units. DF was calculated as GCT divided by stride time, with stride time estimated from step rate using established wearable-sensor methods [3]. A one-way repeated-measures ANOVA assessed cue effects on DF, with Bonferroni-adjusted pairwise comparisons.

Results

Cue type significantly affected DF ($p < .001$, partial $\eta^2 = .28$). The verbal cue produced the lowest DF, significantly lower than baseline ($p = .011$), metronome ($p < .001$), and visual cues ($p = .009$). Metronome feedback produced a small but significant increase in DF compared with baseline ($p = .039$). Visual feedback did not differ from baseline or metronome ($p = 1.000$).

Discussion

The cueing strategies produced distinct effects on DF. The verbal cue elicited the greatest reduction, the metronome produced a small but significant increase, and the visual cue showed no significant change. Overall, the verbal cue produced the most substantial shift in stride timing. Assessing DF using wearables may help clinicians monitor retraining responses and identify cues that most effectively target temporal adjustments to reduce running-related injury risk in military runners.

The Effects of Carbon Fiber Insoles on Plantar Intrinsic Foot Muscle Fatigability During Prolonged Walking

Ms Megan Spencer BS[1], Ms Sydney Menendez[1], Dr Ross Smith PhD[2], Dr Kota Takahashi PhD[3], Dr Jason Franz PhD[1]

[1]University of North Carolina and North Carolina State University, Chapel Hill, NC, United States. [2]University of Memphis, Memphis, TN, United States. [3]University of Utah, Salt Lake City, UT, United States

Introduction

The plantar intrinsic muscles (PIMs) function as a coordinated unit to support the medial longitudinal arch and regulate foot mechanics during locomotor activities such as walking. However, no studies to date have examined how PIM excitation changes during prolonged walking, an important requisite to understanding the onset and progression of walking-related fatigue ability. Further, carbon fiber insoles (CFIs) have the potential to offload PIMs and may promote fatigue resistance. Here, we used indwelling EMG time-frequency analyses to quantify intrinsic foot muscle fatiguability and the modifying influence of increased footwear bending stiffness via CFIs. We hypothesized that PIM excitations would shift toward slower frequencies with prolonged walking, indicative of fatigability, which would be mitigated when wearing CFIs.

Methods

16 young adults (9M/7, age:23.6±3.1 years) completed a two-day protocol in randomized order, each involving 30 minutes of prolonged walking at 20% faster than preferred speed. On one day, participants wore standardized shoes; on the other day, they wore the same shoes with 1.6-mm CFIs. We recorded continuous right leg indwelling electromyography (EMG) signals from the abductor muscles (AH, n=16 analyzed) and the flexor digitorum brevis (FDB, n=12 analyzed). EMG mean frequency and EMG time-frequency analyses examined spectral shifts in those muscle excitations across time.

Results

Independent of footwear condition, AH and FDB both exhibited time-dependent decreases in EMG mean frequency across time ($p<0.001$). Time-frequency analyses added that a shift toward slower-frequency excitations over time for both muscles occurred particularly during mid-to-late stance – a change indicative of fatigability that was mitigated when walking with CFIs (Fig. 1) and that would have been otherwise missed using mean frequency alone, which did not differ significantly between conditions.

Discussion

Supporting our hypothesis, prolonged walking elicited measurable changes in PIM excitations (i.e., slower mean frequencies) indicative of fatiguability. We also find evidence that CFIs promoted fatigue resistance for both AH and FDB; these PIMs exhibited a lesser shift towards slower-frequency excitations compared to walking in standardized footwear. Cumulative findings suggest that increasing footwear bending stiffness may mitigate PIM fatigue, likely by offloading the biological structures, with implications that include preserving gait function among older adults.

Physiological, Biomechanical, and Perceptual Effects of Mass Placed Anteriorly vs Laterally on the Shank to Inform the Design of Powered Footwear Systems

Ms Kristin Quah, Ms Kristin DeHart, Dr Julia Butterfield, Dr Alison Sheets-Singer

Nike, Inc., Beaverton, Oregon, United States

Introduction

Nike is creating a powered footwear system (PFS) for running and walking. The PFS structure can introduce penalties that actuation must offset to provide athletes with enjoyable experiences. While physiological penalties from total system mass have been modeled [1,2] and can be overcome when powered [3], the biomechanical and perceptual effects of mass placement are less known. Therefore, this experiment simulates the effects of PFS mass distributions on athletes' metabolic cost, biomechanics, and perception of running by placing 1kg masses anteriorly or laterally on the proximal shank.

Methods

Fourteen athletes gave informed consent and completed familiarization and testing visits. In familiarization, athletes ran for 10 minutes with each mass location. Testing visits included six, 5.5-minute submaximal trials. The three conditions (shoes, shoes+1kg lateral mass, shoes+1kg anterior mass) were pseudo-randomized and tested in ABCCBA order. Metabolic data (COSMED K5), RPE (9-point scale), "ease of running" (100-point scale), and heel-mounted IMU data (Vicon Blue Trident) were measured. Metabolic cost (Brockway equation) and biomechanical differences (sum of angular velocity differences squared in 30–100% of stride) were compared between shoes and mass conditions in the final 1.5 minutes of each trial. Significant differences were identified using linear mixed effects models (fixed effect: condition, random effect: participant) with Tukey's post-hoc tests.

Results

While there were no metabolic differences between running with lateral and anterior masses (Figure 1A), and both increased metabolic power compared to shoes ($p<1e-6$), athletes perceived the lateral condition to be more difficult than anterior. Lateral RPE values were larger, "ease of running" scores were lower ($p<0.001$, Figures 1B/C), and all athletes preferred the anterior placement. Biomechanical differences from shoes were also larger when mass was placed laterally ($p=0.03393$, Figure 1D).

Discussion

Although the metabolic cost of adding lateral and anterior mass were not significantly different, athletes universally preferred the anterior placement and had the smallest biomechanical changes. This suggests that anterior mass distributions should be used in future PFS designs to minimize penalties introduced by the structure.

Images (Optional)

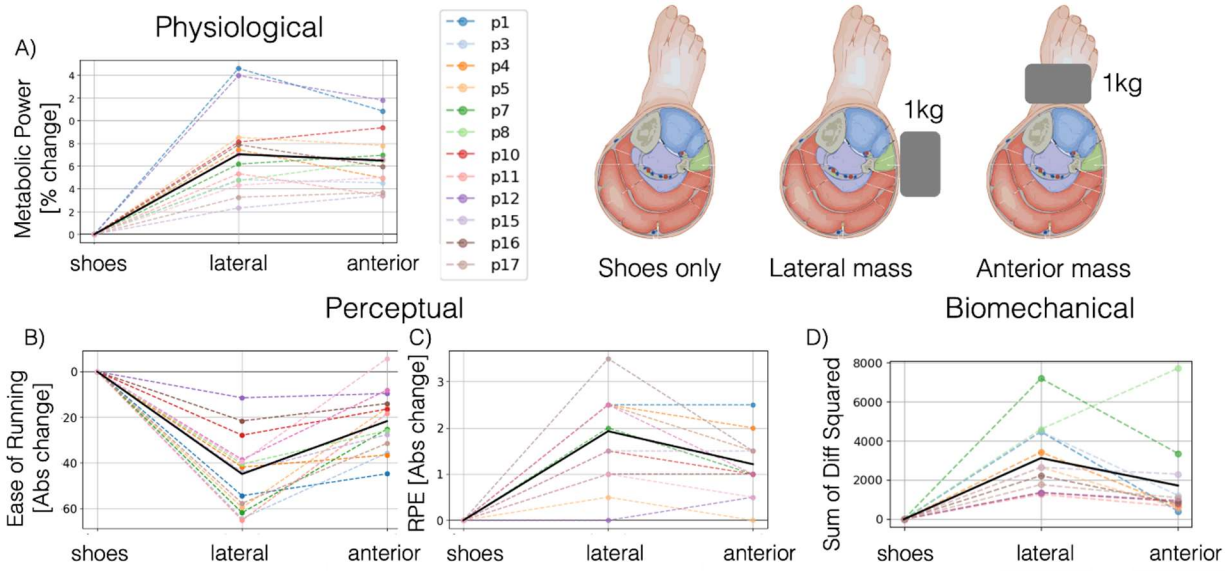

Figure 1: (A) While participants' metabolic power were larger when running in both mass conditions compared with shoes, there was no significant difference between the lateral and anterior positions. (B) Using a sliding scale of 0 (hardest) to 100 (easiest), athletes perceived running in the lateral condition to be more difficult than the anterior position. (C) Using a 9-point RPE scale, athletes perceived the lateral condition to require more effort to run in compared to the anterior position. (D) The lateral condition had a significantly larger sum of difference squared metric from the shoe condition compared to the anterior condition. Each colored point and dotted line represents data from a single athlete while the thick black line represents the mean across all athletes.

Spatiotemporal Plantar Pressure Differences Between Individuals with CMT and Healthy Controls

Mr. Tyce Marquez MS, Mrs. Lauren Crowe BS, Dr. Bopha Chrea MD, Dr. Jason Wilken PT, PhD, Dr. Donald Anderson PhD

University of Iowa, Iowa City, Iowa, United States

Introduction

Charcot-Marie-Tooth (CMT) disease is the most common inherited neuromuscular disease [1]. It is characterized by progressive distal muscle imbalance and often results in pes cavus feet [2], contributing to altered gait mechanics and abnormal pressures on the plantar foot surface [3]. Altered plantar pressures have been demonstrated along the lateral column in CMT patients using discrete region-of-interest analysis, an approach that fails to capture differences in load progression. This study evaluated spatiotemporal plantar pressure differences between individuals with CMT and healthy controls.

Methods

Twenty-six individuals with CMT (14M/12F, 47.2±19.9 years) and 26 healthy controls (12M/14F, 41.8±12.4 years) each completed three walking trials per foot across a Novel-EMED plantar pressure platform [4]. Time series plantar pressures sampled at 10 ms intervals were linearly interpolated to 5% intervals over stance and rotated based upon the foot progression angle [5]. Values within a bounding box defined by the maximum pressure distribution were extracted and scaled to a standard size for sensor-level comparisons. Sensor-level plantar pressure mean differences were compared between CMT and control participants.

Results

During the loading response phase of stance, CMT participants experienced decreased loading in the hindfoot relative to controls (Figure 1). In mid- and terminal stance, CMT participants had increased loading in the lateral hindfoot and midfoot, with minimal forefoot loading. During pre-swing, CMT participants had limited load progression through the toes while experiencing increased pressures at the first/fifth metatarsal heads.

Discussion

Individuals with CMT were unable to propel load progression from the hindfoot through the forefoot. This led to minimal toe loading, limiting toe-off power. Altered spatiotemporal plantar pressures were most prominent along the lateral column, potentially increasing injury risk in that region. Utilizing spatiotemporal plantar pressure assessment between healthy and deformed feet provided insight into loading features associated with pes cavus deformity. This knowledge can inform surgical interventions aimed at restoring the foot tripod to effectively reduce loading deficits.

Images (Optional)

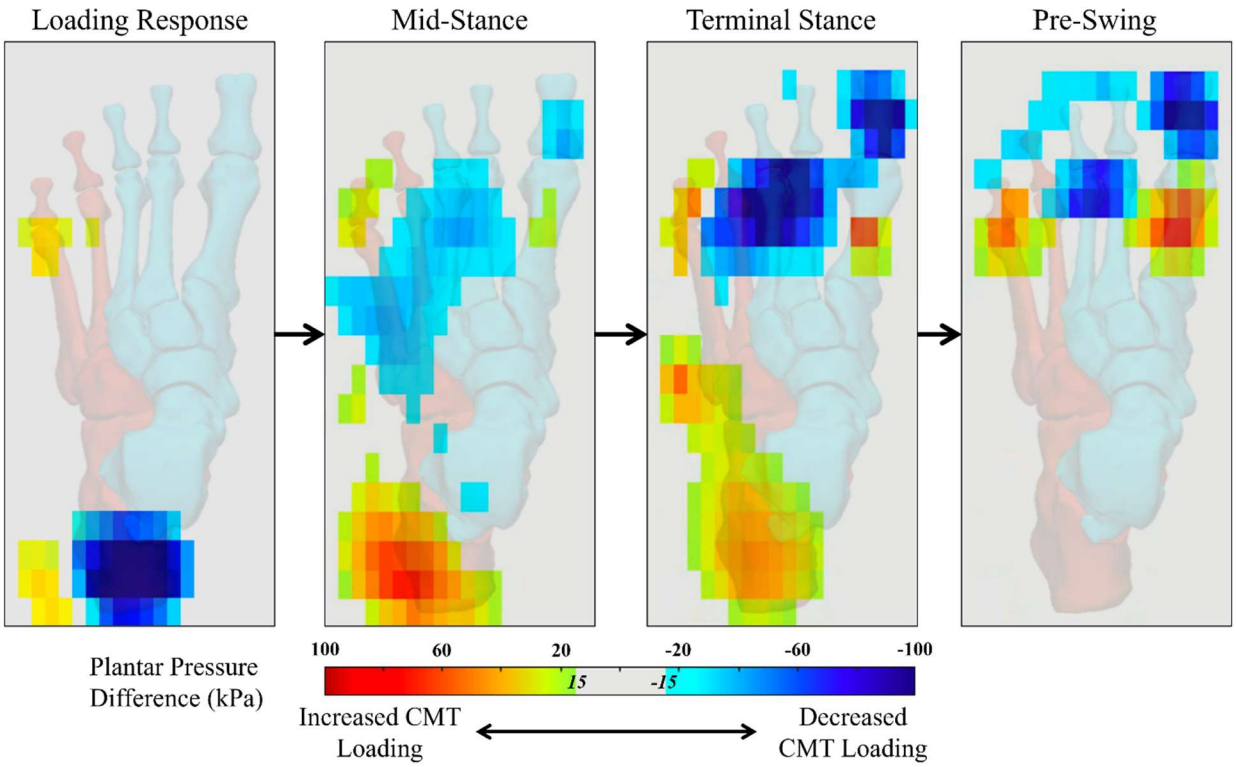

Figure 1: Mean plantar pressure differences (kPa) on a sensor-level between CMT and healthy control participants at the four phases of stance are shown here as representative distributions selected from each phase. Bony foot model is overlaid for anatomical reference with red bones representing the lateral column.

The Terrain Not Taken: The Effects of Trail and Road Running on Ankle Injury Predictors

Dr Key Nahan BPodMed, MSc, PhD[1], Mr Malicki Diallo BSc[1], Mr Adam Grimmitt MSc[1], Mr Aidan Watts[2], Dr Wouter Hoogkamer BSc, MSc, PhD[1]

[1]University of Massachusetts Amherst, Amherst, Massachusetts, United States. [2]SUNY College of Environmental Science and Forestry, Syracuse, New York, United States

Introduction

Trail running introduces unique mechanical challenges (e.g., uneven surfaces), which may increase the risk of ankle injuries as compared to road running. While trail running is difficult to study in a laboratory, inertial measurement units (IMUs) can overcome this barrier. IMUs can measure peak eversion velocity, which has been used assess shin splints risk [1], and peak inversion velocity, which has been used to assess ankle sprain risk [2]. Based on the uneven terrain, we hypothesize that trail running will be associated with greater peak eversion and inversion velocities during the loading phase as compared to road running.

Methods

Six participants (4M, 2F) ran on a flat road and an uneven trail at their easy pace. We collected vertical acceleration and frontal-plane angular velocity data using bilateral heel-mounted IMUs (1125 Hz; Blue Trident, IMeasureU, NZ). We segmented strides using the peak jerk squared and extracted maximum and minimum angular velocities during the loading phase (first 20% of each stride). We concatenated left and right strides and matched stride number across terrains. We used LMEMs to assess maxima and minima over all strides (dependant variable~Terrain+(1|Participant). We classified strides with inversion velocities below −300°/s as at risk for an ankle sprain [2]. The number of risky strides was assessed with a one-tailed Wilcoxon signed-rank test.

Results

Maximum angular velocity was lower on the trail (341°/s [195,488]; EMM [95%CI]) than the road (459°/s [312,605]; Δ=-117°/s [-211,-24]; p=0.021). Minimum velocity did not differ between terrains (trail:-73°/s [-121,-25], road :-50°/s [-98,-2]; Δ=-23°/s [-61,15]; p=0.201). Participants took 683±130 (mean±SD) strides, with more risky strides on the trail (18±30) than the road (1±2; Δ=17±29; p=0.016).

Discussion

Due to the higher maximum angular velocities, road running may increase eversion-related injury risk as compared to trail running. Minimum angular velocity did not differ between terrains, yet trail running had more risky strides, suggesting a higher risk of inversion ankle sprains. This may guide terrain specific footwear design.

Images (Optional)

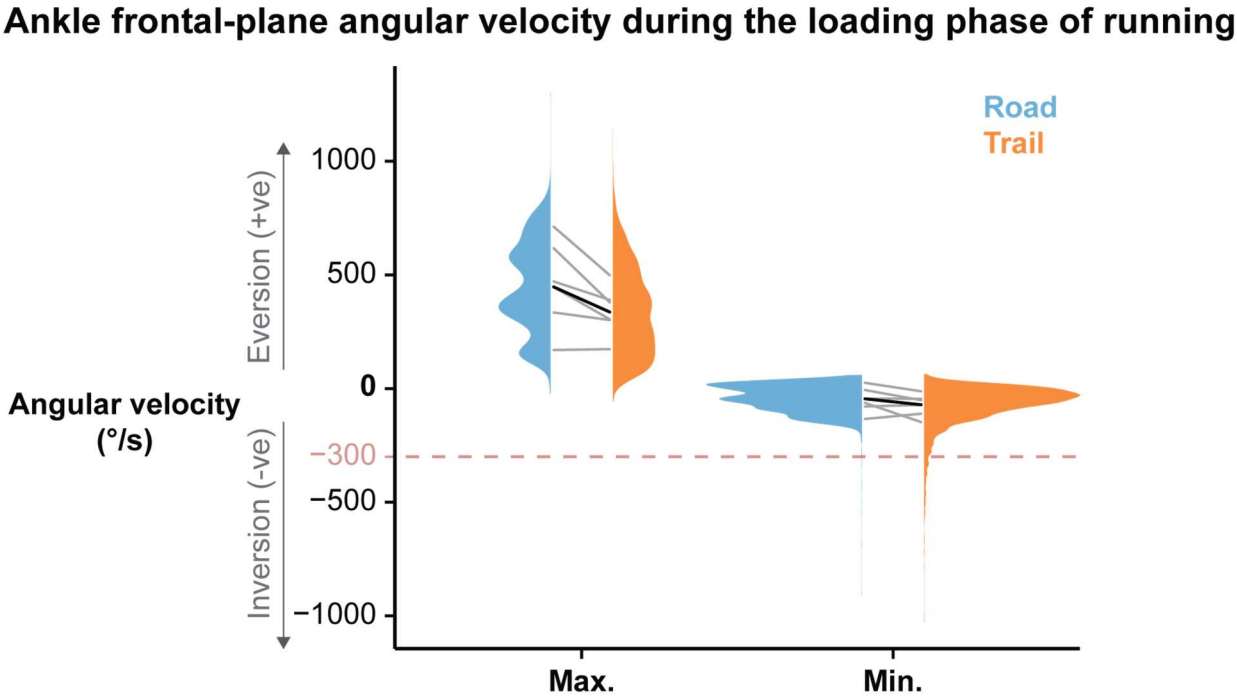

Figure 1. Ankle frontal-plane angular velocity maxima and minima during the loading phase (first 20% of a stride) of road and trail running. Black bars are group means, grey bars are participant means, and the red dotted line is the ankle sprain risk threshold.

Mass Distributions of Powered Footwear Systems Affect Swing Leg Biomechanics

Dr. Julia Butterfield, Ms. Kristin Quah, Ms. Kristin DeHart, Ms. Hannah Frame, Dr. Alison Sheets-Singer

Nike, Inc., Beaverton, Oregon, United States

Introduction

Nike is creating a powered footwear system (PFS) for walking and running. Previous Nike research [1] demonstrated that mass added laterally to the shank could induce biomechanical changes during swing that were associated with negative sensations and higher perceived effort. This suggests that metabolic benefits would be harder to perceive in a PFS that changes swing-phase kinematics. In this meta-analysis, we compared swing-phase biomechanics when running in shoes and three unpowered PFS prototypes with different mass distributions.

Methods

During three experiments, 3-6 athletes gave informed consent and ran at least two 90-second 6-mph trials on a Bertec treadmill: in shoes, and an unpowered PFS. Toe position in the pelvis reference frame (VICON) and heel angular velocity (VICON Blue Trident) during swing were compared to shoes across three systems and within a system with an anterior or lateral battery placement. Metrics to compare systems included the difference in concavity of the toe position in the PFS and shoes, and the sum of the differences from shoes squared of angular velocity about the heel's vertical axes (internal/external rotation).

Results

In System 1 with primarily lateral mass, the swing-phase concavity of the toe position was significantly different than running in shoes (Figure 1), and athletes described negative sensations. Moving System 2's battery anteriorly resulted in the toe position becoming more like running in shoes. In System 3 with both an anterior battery and a smaller motor located closer to the leg, toe position was closest to running in shoes and athletes did not describe negative swing-phase sensations. Angular velocity differences about the heel's vertical axis exhibited a similar trend to the toe position concavity, demonstrating the promise of IMUs to capture this phenomenon without motion capture.

Discussion

Kinematic changes in the swing phase of running can produce negative sensations and higher perceived efforts [1] for athletes. When navigating the myriad of design goals for a

PFS, both total mass and mass distribution should be considered. Moving mass anteriorly or bringing mass closer to the leg can improve the athlete experience during straight-line locomotion by allowing natural swing-phase motion.

Images (Optional)

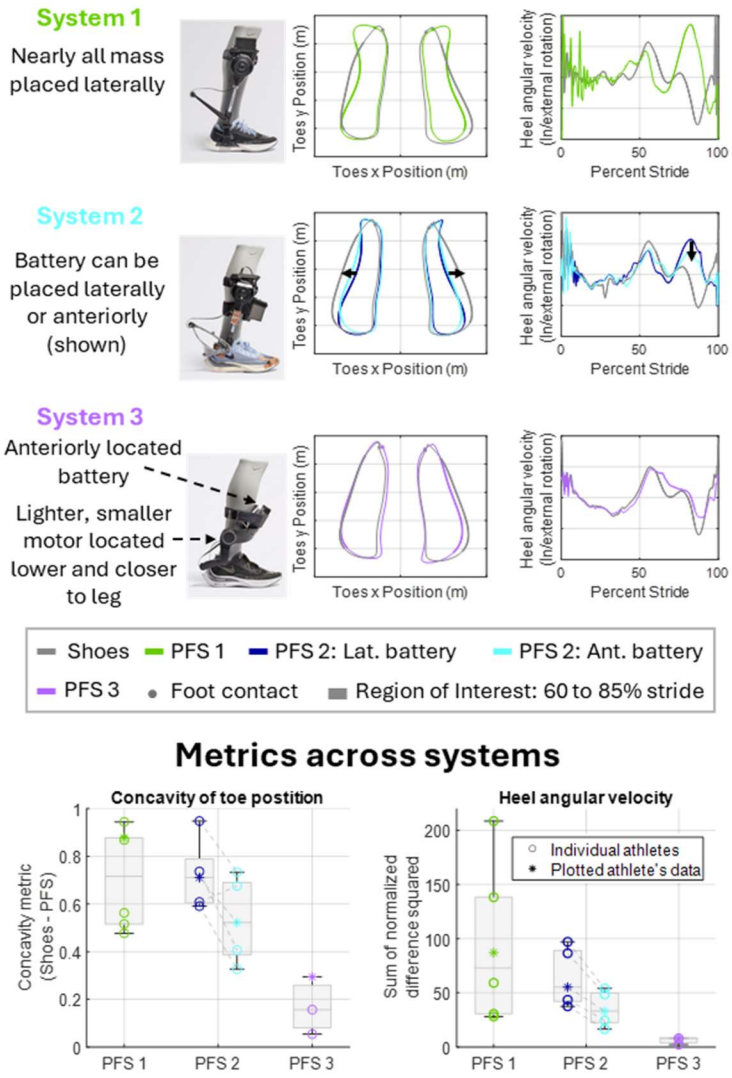

Figure 1. In System 1 (top row), nearly all of the mass is placed laterally on the leg. Toe position in the pelvis reference frame during swing (middle column, thick line corresponds to 60-85% stride) exhibits a different shape when running in the PFS (colors) compared to running in shoes (gray). Similarly, angular velocity about the heel vertical axis (foot internal/external rotation) differs between the PFS and shoe conditions during swing (right column, approximately 40% stride and later). In System 2 (second row), the battery (~250 g) can be placed on top of the motor in a lateral position, or anteriorly as shown. Moving the battery from lateral to anterior made the toe position curve of the PFS more like running in shoes. In System 3 (third row), the battery (~200g) was placed anteriorly, and the motor was lower and closer to the leg. Toe position during swing with System 3 is most like running in shoes, and heel angular velocity matches that of shoes throughout most of stride. Plots are shown for a representative athlete in each study, and all lines indicate the average across the final 20 seconds of each 90-second trial. Toe position differences were compared across athletes and prototypes using the difference in concavity during swing (bottom left). Angular velocity differences were compared using the sum of the squared differences from shoes during swing (bottom right). Stars represent metrics from the athletes whose individual data are plotted in the first three rows. Dashed lines for System 2 connect the lateral-battery and anterior-battery trials for each athlete.

Influence of Textured Insoles on Footstrike Characteristics and Joint Moments During Running

Mr. Nicolas Silon[1], Mr. Ryan Evans[1], Ms. Kelly Robb[2], Mr. Micheal Ryan[2], Mr. Derek Pamukoff[1]

[1]Western University, London, Ontario, Canada. [2]Kintec Footlabs Inc., Surrey, British Colombia, Canada

Introduction

Forefoot compared with rearfoot striking contributes to lower knee loading during running. Heel-textured insoles provide a tactile cue to shift the center of pressure anteriorly, which may influence footstrike pattern and lower extremity joint loading. We investigated the influence of a textured insole on footstrike characteristics and lower limb joint moments.

Methods

48 healthy recreational rearfoot strike runners participated (25 Males, 23 Females, Age: 22.8±3.7 yrs, weekly running amount: 37±20.4km). Gait biomechanics were recorded at a self-selected speed using a split-belt force-instrumented treadmill (2000Hz) and 8-camera motion capture system (200Hz). Participants were instrumented with laboratory standard footwear and reflective markers. Participants completed three running conditions (**Fig 1**): textured insole (INS), non-textured insole (SHAM), standard footwear (CON) in a random order for 10 minutes each at the same speed (average running speed: 2.92±0.38m/s). The peak internal knee extension moment (KEM), peak internal ankle plantar flexor moment (PFM), and footstrike angle (FSA) were extracted and averaged across all footstrikes. A repeated measures ANOVA compared peak KEM, peak PFM, and footstrike angle between conditions, and a Bonferroni adjustment was used for post hoc comparisons.

Results

There was an effect of condition for KEM ($F_{2,94}$=7.451, p<0.001, partial η^2=0.137) and PFM ($F_{2,94}$=5.789, p=0.004, partial η^2= 0.110). Peak KEM was lower in CON (171.5±44.5 Nm) compared to INS (175±44.8 Nm, p <0.001) and SHAM (174.3±45.2 Nm, p = 0.009). Similarly, the peak PFM was higher in CON (-172.9±42.2 Nm) compared to INS (-171±40.6 Nm, p=0.019) and SHAM (-170.5±41.3 Nm, p=0.003). No difference was found in FSA between conditions ($F_{2,94}$=0.839, p=0.436, partial η^2=0.18).

Discussion

The textured insole did not alter footstrike angle. The peak KEM was higher but the peak PFM was lower in both insole conditions compared with standard running footwear. Insoles may contribute to differences in spatiotemporal parameters of running gait, such as step length or step frequency that are known to influence net joint moments. Similarly, insoles may influence proximal muscle activation patterns that contribute to differences between conditions in net joint moments.

CoronaryFlow-Diffusion: A Physics-informed Conditional Diffusion Model for High-fidelity 3D Coronary Flow Field Reconstruction

Ms. Yang Yang PhD Candidate[1,2], Prof. Bao Li Ph.D.[1], Prof. Liyuan Zhang Ph.D.[1], Prof. Leo Hwa Liang Ph.D.[2], Prof. Mingai Li Ph.D.[1], Prof. Youjun Liu Ph.D.[1]

[1]Beijing University of Technology, Beijing, Chaoyang District, China. [2]National University of Singapore, Singapore, Singapore, Singapore

Introduction

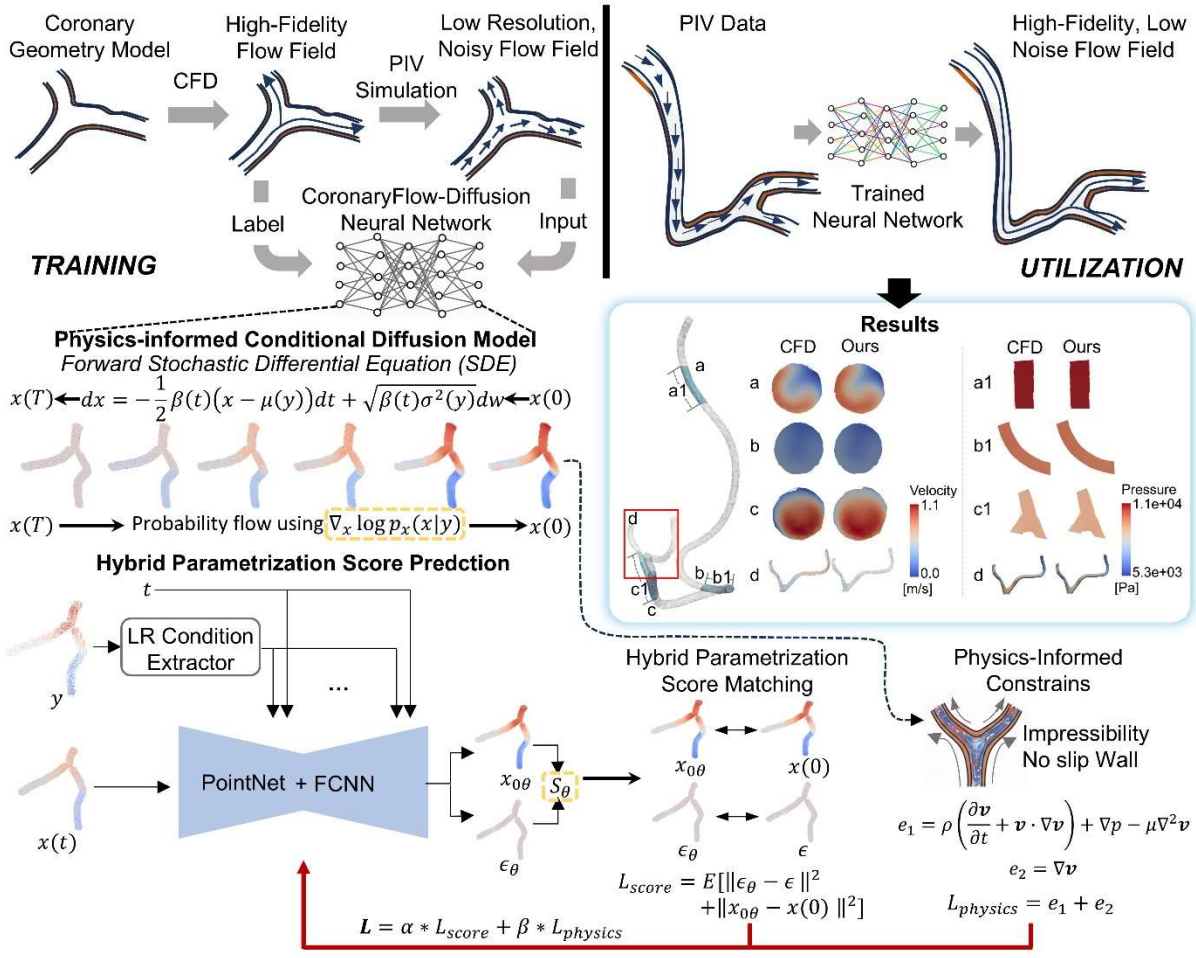
Experimental blood-flow measurement techniques play a critical role in understanding cardiovascular diseases. Particle image velocimetry (PIV) is widely regarded as the gold standard for blood-flow assessment. However, it remains limited in medium-sized coronary arteries due to the small vessel diameters and the intrinsic spatial resolution constraints of PIV. Consequently, the resulting velocity fields tend to be sparse, noisy, and subject to missing data, making high-fidelity flow-field reconstruction a key challenge for advancing coronary hemodynamic analysis.

Methods

In this study, we propose CoronaryFlow-Diffusion, a physics-informed conditional diffusion model built within a stochastic differential equation (SDE) framework. It employs a PointNet-based architecture to reconstruct high-fidelity 3D coronary flow fields. Meanwhile, we constructed a dataset of 1,311 coronary computational fluid dynamics (CFD) simulation samples. Each sample includes low-resolution inputs, simulating PIV measurements, along with the corresponding high-fidelity velocity and pressure fields. By embedding the Navier–Stokes equations into the diffusion process, the model enforces physical consistency while reconstructing high-fidelity coronary flow fields.

Results

The proposed method enables high-fidelity reconstruction of flow fields in medium-sized coronary arteries and accurately captures local hemodynamic features. Quantitative evaluation on the test set shows a mean relative error of 3% in the reconstructed pressure fields and a mean squared error (MSE) of 2% in the velocity fields, indicating that the model can reliably and faithfully reconstruct coronary flow fields.



Discussion

The CoronaryFlow-Diffusion model enhances experimental flow measurements (e.g., PIV) by providing high-fidelity coronary hemodynamic information. Through the incorporation of physical equations, the method ensures physical consistency while achieving accurate flow-field reconstruction. This framework offers a promising tool for cardiovascular research and contributes to a more comprehensive understanding of coronary hemodynamics.

Modeling the Evolution of Constitutive Response of Vein Grafts in Coronary Artery Bypass Graft Procedure Using Constitutive Artificial Neural Networks

Ms. Divya Adil[1], Dr. Marisa Bazzi[1], Dr. Ruizhi Wang[2], Prof. Ellen Kuhl[1], Prof. Jay Humphrey[2], Prof. Alison Marsden[1]

[1]Stanford University, Stanford, CA, United States. [2]Yale University, New Haven, CT, United States

Introduction

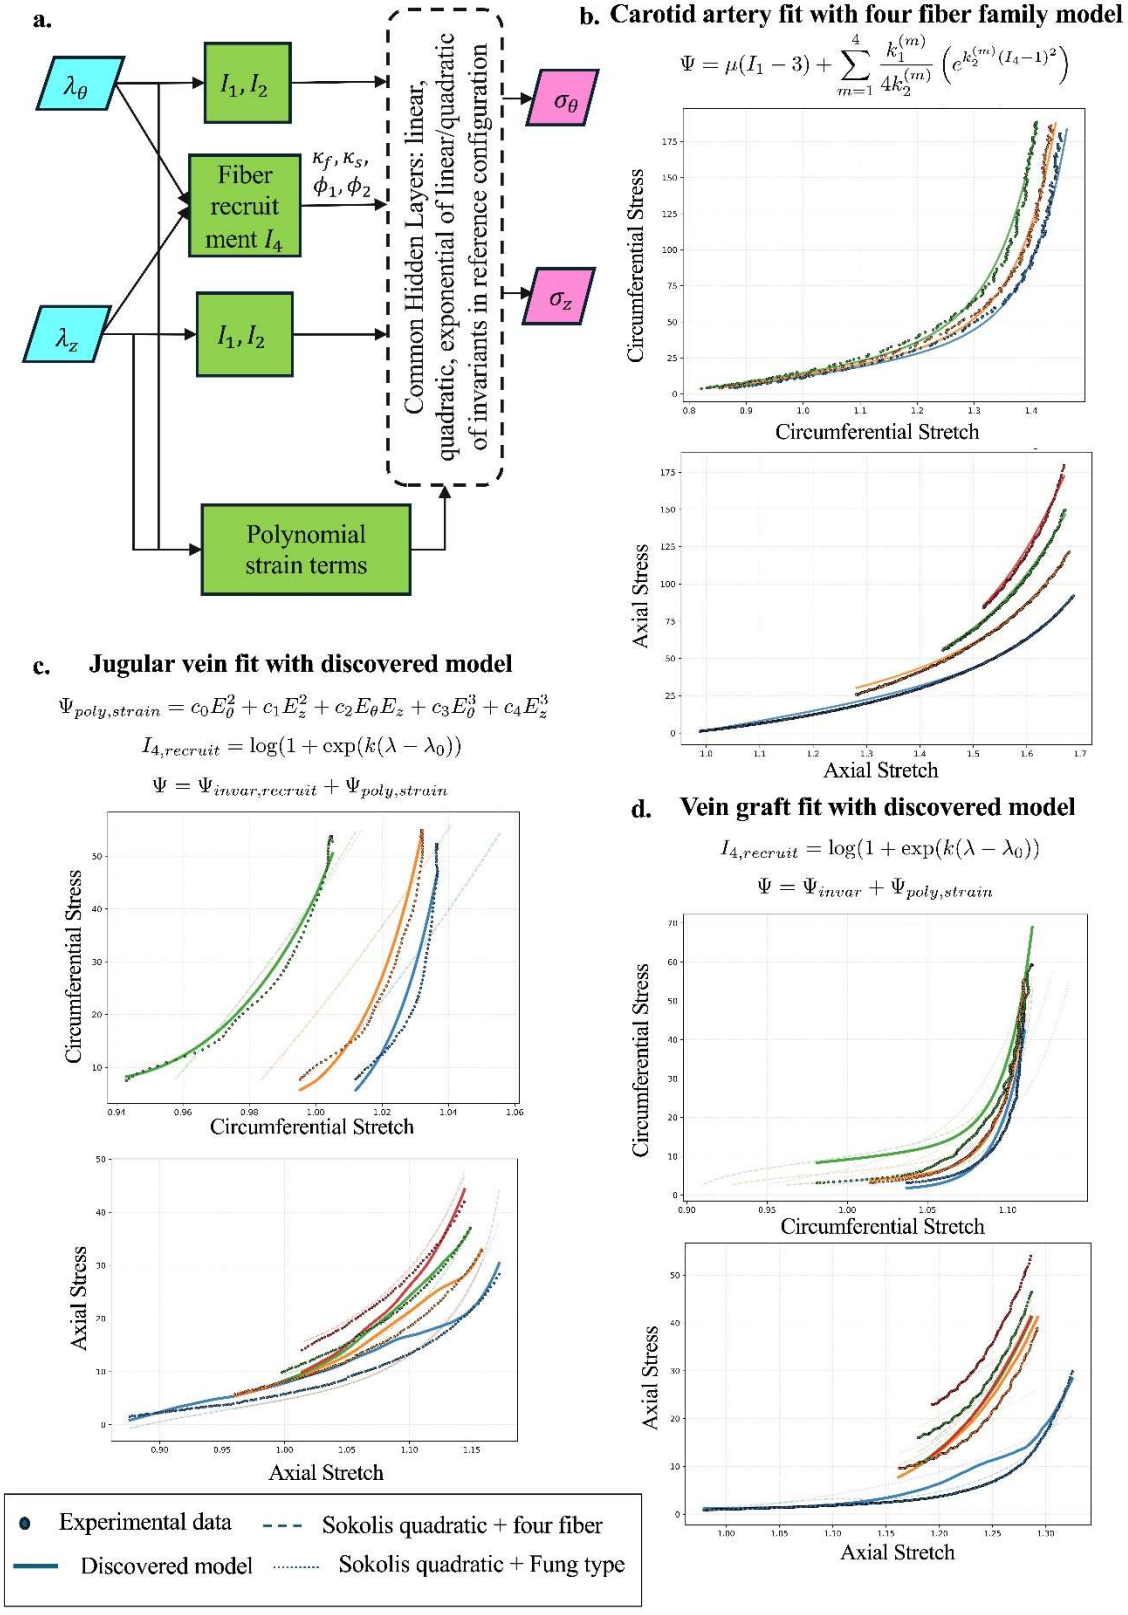
Coronary artery disease affects >315 million people globally and can cause myocardial infarction. Coronary artery bypass grafting commonly uses a saphenous vein graft, which experiences a venous-to-arterial pressure shift that triggers remodeling and contributes to high graft failure rates. Better characterization of graft mechanics is needed for developing failure-mitigation strategies.

Vessel walls are typically modeled as hyperelastic using a strain energy function (SEF). Arteries have been well characterized, whereas veins are structurally distinct and understudied[1], and vascular graft studies remain scarce. Constitutive artificial neural networks (CANN) provide a compact framework to discover interpretable hyperelastic constitutive laws from experiments while embedding prior knowledge[2].

Here, we perform inflation-biaxial testing on vessels explanted from a rabbit jugular-to-carotid graft model at multiple post-grafting time points to quantify evolving mechanics, and apply CANNs to discover control-vein and vein graft constitutive models from the biaxial data.

Methods

Pressure-diameter tests were run at fixed axial stretches (95%,100%,105%) of in-vivo length (veins: 5-30mmHg; grafts/arteries: 10-140mmHg)[3]. Force-length tests measured axial response at fixed pressures (veins: 10-15-20-25mmHg; grafts/arteries: 10-60-100-140mmHg). Arteries were fit using a 4-fiber family; veins were fit using quadratic 4-fiber or Fung-type models for comparison. Circumferential and axial stretches served as CANN inputs. The architecture contains invariant, fiber-recruitment, and strain-polynomial branches that can be selectively activated, and outputs an SEF. Training minimizes bi-directional RMS stress error, normalized by max stress.



Results

The vein SEF uses a fiber-recruitment gate plus strain-polynomial terms, reducing RMSE to 0.106, > 50% improvement vs. quadratic 4-fiber and Fung models (0.223). The week-6 graft SEF incorporates the gate on a base invariant model (0.245), improving on 4-fiber (0.275,11%) and Fung (0.338,27%).

Discussion

The four-fiber model fits arteries well (RMSE 0.060072), consistent with organized collagen structure. CANN-discovered models for veins and grafts incorporate fiber-recruitment gating and additional strain terms, capturing behaviors absent in prior formulations. The week-6 graft shows intermediate mechanics between veins and arteries, indicating partial arterial adaptation. Future work will scale model discovery to multiple samples and time points.

AI-Based Ensemble Approaches to Anticipate Symptom Progression in Patients with an Abdominal Aortic Aneurysm

Ph.D. Candidate Juan Restrepo[1], B.Sc. Archer French[1], Ph.D. Amanda Fernandez[1], M.D. Satish Muluk[2], M.D. Mark Eskandari[3], M.D. Vikram Kashyap[4], Ph.D. Ender Finol[1]

[1]The University of Texas at San Antonio, San Antonio, Texas, United States. [2]Allegheny General Hospital, Pittsburgh, Pennsylvania, United States. [3]Northwestern University, Chicago, Illinois, United States. [4]Corewell Health, Grand Rapids, Michigan, United States

Introduction

When an Abdominal Aortic Aneurysm (AAA) shows symptoms of impending rupture, the mortality rate can be as high as 90%. Early predictions of symptom onset could allow clinicians to intervene before a catastrophic event, thereby improving patient outcomes. This work evaluates tree-based ensemble machine learning models trained on hierarchical clinical, biomechanical, and morphological data to predict future symptom onset within a 6-month interval.

Methods

We trained three tree-based models-Random Forest, AdaBoost and XGBoost-on hierarchical datasets, combined with three pre-processing strategies, namely Principal Component Analysis (PCA), Recursive Feature Elimination (RFE), and no pre-processing, which yielded 93 different combinations. Biomechanical (B) features were generated using finite element analysis simulations that estimated wall stress and rupture potential index (RPI), while morphological (M) features were derived from established geometry quantification procedures. We used a sample of 200 patients (100 asymptomatic and 100 symptomatic within 6 months of imaging) from which CTA exams and clinical (C) records were collected. Model performance was evaluated using area under the curve (AUC), and false-positive and false-negative ratios for fair comparisons.

Results

The ensemble models achieved an average AUC = 0.87. Key predictors included C and B features consistently present for the nine top-performing models. Integrating all data hierarchies produced the best model: XGBoost [C + B (RFE) + M (PCA)], AUC = 0.95. Feature-importance analyses identified RPI, smoking status, and systolic blood pressure

as significantly associated with symptom progression. The second-best model, Random Forest [C + B (PCA)], minimized both false positives and false negatives (F1 = 0.93).

Discussion

Ensemble methods can meaningfully improve short-term prediction of symptom onset in AAA patients, offering a potential tool for preemptive clinical decision making. By integrating biomechanical, clinical and morphological features, the models capture complementary information beyond maximum diameter alone, consistent with reported literature. Notably, the Random Forest model shows clinical translation potential, as minimizing missed early-progression cases is critical for individualized surveillance and timely intervention planning. However, generalizability remains limited by the modest sample size. Future work should validate these models in larger, globally representative cohorts including broader demographics and assess their real-time utility within routine clinical workflows.

AI-Driven Estimation of Patient-Specific Aortic Wall Mechanical Properties for Improved Biomechanical Simulation

Ms. Ione Ianniruberto MSc[1,2], Mr. Davide Astori MSc[1], Dr. Jonathan Weinsaft[3], Prof. Emiliano Votta PhD[1], Prof. Alberto Redaelli PhD[1]

[1]Politecnico di Milano, Milano, Italy, Italy. [2]European Society of Biomechanics (ESB), Milano, Italy, Italy. [3]Weill Cornell College, New York, New York, United States

Introduction

Finite element analysis (FEA) is widely used to estimate aortic wall stress in pathological conditions, with the main goal of assessing rupture or dissection risk[1]. However, patient-specific FEA is still hindered by the lack of non-invasive measurements of aortic wall mechanical properties. Because these properties can only be obtained from excised tissue, most simulations rely on generic material parameters derived from literature data, despite pronounced inter-patient variability[2].

To address this, we introduce a new framework that estimates patient-specific material behaviour by leveraging a database of human aortic tissue mechanics and a generative AI model, a conditional variational autoencoder (CVA).

Methods

Through a literature review, we assembled 100 equibiaxial tensile tests on human aortic samples processed under consistent preservation protocols. This dataset includes paired circumferential and axial stress–stretch curves categorized according to four clinical factors: i) anatomical region, ii) pathology (thoracic aneurysm, dissection, Marfan syndrome, or healthy control), iii) valve morphology, and iv) age group (young, middle, old).

For a given patient, the method first extracts the appropriate subgroup of the database based on these factors. Within this tailored subset, the curve that best matches the patient's circumferential mechanical behaviour, estimated from systolic/diastolic pressures and aortic compliance, is selected. Once the closest circumferential curve is identified, the corresponding paired axial curve from the same tissue sample is automatically included, ensuring a consistent biaxial representation. To automate this process, we trained a CVA capable of generating stress–strain curves conditioned on patient-specific attributes.

Results

Validation was performed using tissue samples from 10 patients for whom both clinical data and ex vivo equibiaxial tests were available. A permutation test based on the L2 norm showed no significant difference between predicted and experimental curves in 8 out of 10 cases ($p < 0.001$). Preliminary analysis further demonstrates that the CVA successfully learns and reproduces the statistical characteristics inherent to each clinical subgroup.

Discussion

This approach offers a promising pathway toward integrating patient-specific mechanical surrogates into aortic biomechanics simulations, potentially improving risk stratification and personalized treatment planning.

C57BL/6N Mouse as a Model of the Age-Related Decline in the Matrix Quality of Bone

Ms. Emily Berestesky BS[1], Mr. Sasidhar Uppuganti MS[2], Ms. Elizabeth Hennen BS[1], Dr. Jeff Nyman PhD[2]

[1]Vanderbilt University, Nashville, TN, United States. [2]Vanderbilt University Medical Center, Nashville, TN, United States

Ms. Emily Berestesky

Introduction

To validate a model of aging for treatment strategies that target the bone matrix as way to prevent age-related declines in the fracture resistance of bone, we hypothesized that both post-yield displacement, a marker of brittleness, and fracture toughness of cortical bone are lower in aged female mice than in adult female mice because of age-related declines in bone matrix hydration.

Methods

Six- and 24-month-old, female, C57BL/6N mice from the US National Institute on Aging were euthanized to collect both femurs. We measured bone matrix hydration as bound water per bone volume (BW/BV) of the right femur using ^{1}H nuclear magnetic resonance relaxometry [1]. Next, we measured crack initiation toughness ($K_{Ic,ult}$) based on the ultimate force from monotonic, three-point bending tests and linear fracture mechanics for a micro-notch on the posterior surface of the mid-diaphysis [2]. Following μCT scans of the left femur to determine cortical tissue mineral density (Ct.TMD) and structural parameters, we loaded these hydrated bones to failure in three-point bending to determine ultimate moment (M_u), post-yield displacement (PYD), and work-to-fracture (W_f) per cross-sectional bone area (Ct.Ar from μCT) [1]. Significant differences in properties between age groups were determined based on $p<0.05$ from unpaired t-test, Welch's t-test, or Mann-Whitney U test.

Results

From 6-months to 24-months of age, bound water and cortical thickness (Ct.Th) decreased while Ct.TMD and polar moment of inertia (J) increased (Table). The ultimate stress ($\sigma_S = M_u \times c_{min} / I_{min}$), PYD, and toughness ($W_f$/Ct.Ar), experienced by the un-notched femur were

lower with age, while ultimate moment did not significantly differ between the age groups. For a given section modulus however, the ultimate moment was less in young than old mice (Fig). Lastly, crack initiation toughness significantly decreased with age.

Discussion

The effect of aging on the mechanical properties of cortical bone in C57BL/6N female is more than just a decline in strength; it involves a loss in the ability to resist post-yield crack formation with less bound water. Thus, this aging model can be used to test treatments that target the matrix.

Activity-Dependent Cortical Stress and Proximal Femur Stress Recovery After Total Hip Replacement

Dr. Wissal Mesfar, Dr. Mohamed Z. Bendjaballah

King Saud University, Riyadh, Riyadh, Saudi Arabia

Introduction

Preventing stress shielding after total hip replacement (THR) requires accurately predicting how cortical stresses evolve locally along the femoral shaft. Yet, most evaluations remain limited to regional averages, masking critical site-specific stress decay. This study introduces a multi-path cortical stress-tracking methodology, enabling direct comparison of pre- and post-THR stresses along anatomically matched ventral, medial, dorsal, and lateral tracks during both walking and stair climbing.

Methods

A 3D FE model of an intact femur was reconstructed from CT data and used to generate a prosthetic model hosting a cementless Ti–6Al–4V stem. Both models were meshed with hexahedral elements and assigned orthotropic/isotropic bone properties. Musculoskeletal loading for walking and stair climbing followed Heller et al. (2001). Muscle and joint loads were scaled to a 700N body weight. Twelve cortical paths— inner, middle, and outer layers at four cardinal sites lateral, ventral, medial, dorsal— were sampled for nodal von Mises stresses.

Results

Across all conditions, stresses peaked on the outer cortex, reaching ~40–50MPa during walking and ~60–80MPa during stair climbing, representing a 20–50% stress amplification depending on location. Stair climbing increased distal stresses by 35–60% relative to walking, particularly ventrally (Figure 1) and dorsally. Proximally, however, THR induced substantial stress decay—most notably on the medial path , where post-THR stresses dropped by 45–65%. Importantly, stair climbing did not reverse proximal stress loss on the medial track.

Discussion

Results reveal a clear dichotomy: stair climbing enhances distal cortical loading but fails to restore proximal stress transmission, especially medially where shielding risk is highest.

Medial proximal stress deficits exceeding 50% indicate that stem design, fixation, and stiffness—not activity modulation—govern the shielding mechanism in this region. Conversely, pronounced distal stress gains during stair climbing (up to +60%) highlight the influence of hip muscle recruitment, suggesting targeted rehabilitation strategies could exploit muscle-driven loading to stimulate regions unaffected by the prosthesis. Overall, this multi-path approach exposes highly localized stress-transfer patterns that traditional regional analyses overlook, offering a more precise framework for evaluating implant performance and optimizing post-THR rehabilitation.

Prediction of Bone Loss Due to Altered Mechanical Stimulation in Transfemoral and Through-Knee Amputees

Dr Andrew Phillips[1], Dr Linjie Wang[2], Dr Louise McMenemy[3], Prof Alison McGregor[4]

[1]Structural Biomechanics, Department of Civil and Environmental Engineering, Imperial College London, London, London, United Kingdom. [2]Institute of Medical and Biological Engineering, School of Mechanical Engineering, University of Leeds, Leeds, West Yorkshire, United Kingdom. [3]Academic Department of Military Surgery and Trauma, The Royal Centre for Defence Medicine, Birmingham, West Midlands, United Kingdom. [4]Department of Surgery and Cancer, Imperial College London, London, London, United Kingdom

Introduction

Bone mineral density (BMD) reduction occurs in the femur of lower limb amputees, observed in an active military veteran cohort [1], with transfemoral amputees more severely affected than transtibial and through-knee amputees. We propose localised osteopenia is due to reduced mechanical stimulation. We used a combined musculoskeletal and finite element bone adaptation framework [2] to compare the mechanical stimulation of the femur for a body matched control subject (CS), unilateral transfemoral (TFA), and through-knee (knee disarticulation) (TKA) amputees.

Methods

Musculoskeletal models were developed to derive joint contact and muscle forces for walking, stair-ascent, stair-descent, sit-to-stand, and stand-to-sit, for control and amputee subjects. Corresponding finite element models were developed, and forces derived from the musculoskeletal models used as input, with the resulting mechanical stimulus (strain) in the femur compared between subjects. Bone adaptation simulations were run using a strain-based algorithm for CS to establish a baseline model, and for amputees to predict BMD changes.

Results

Compared to CS, BMD reduction of 32% for TFA and 8% for TKA was predicted in the proximal femur (Figure 1). For CS stair-ascent and stair-descent provided the highest levels of stimulation. For TFA reduced stimulation was observed for all activities, while for TKA stair-descent provided stimulation close to that for CS. Both amputees descended stairs using a reciprocal motion. Both amputees favoured their intact leg in sit-to-stand. Maximum hip joint contact force (HJCF) was similar between CS and both amputees, suggesting HJCF is not a suitable proxy indicator of bone health.

Discussion

Physiological load transfer was not achieved between prosthetic socket and distal femur for either amputee. Retention of the cortex in TKA resulted in a more physiological mechanical environment in the proximal femur than in TFA, suggesting knee disarticulation compared to femoral resection is beneficial for maintaining bone health. Insights as to the most beneficial activities to maintain bone health in the CS as well as amputees were established. Further work will assess the role of novel exercise regimes, socket design, and direct fixation for TFA, in maintaining and improving amputee bone health.

A Bone Remodeling Model Integrating Calcium–Phosphate Homeostasis and Mechanical Loading

Prof. DDr. Gudrun Schappacher-Tilp[1], Dr. Peter Kotanko[2,3]

[1]FH JOANNEUM - University of Applied Sciences, Graz, Styria, Austria. [2]Renal Research Institute, New York City, NY, United States. [3]Icahn School of Medicine at Mount Sinai, New York City, NY, United States

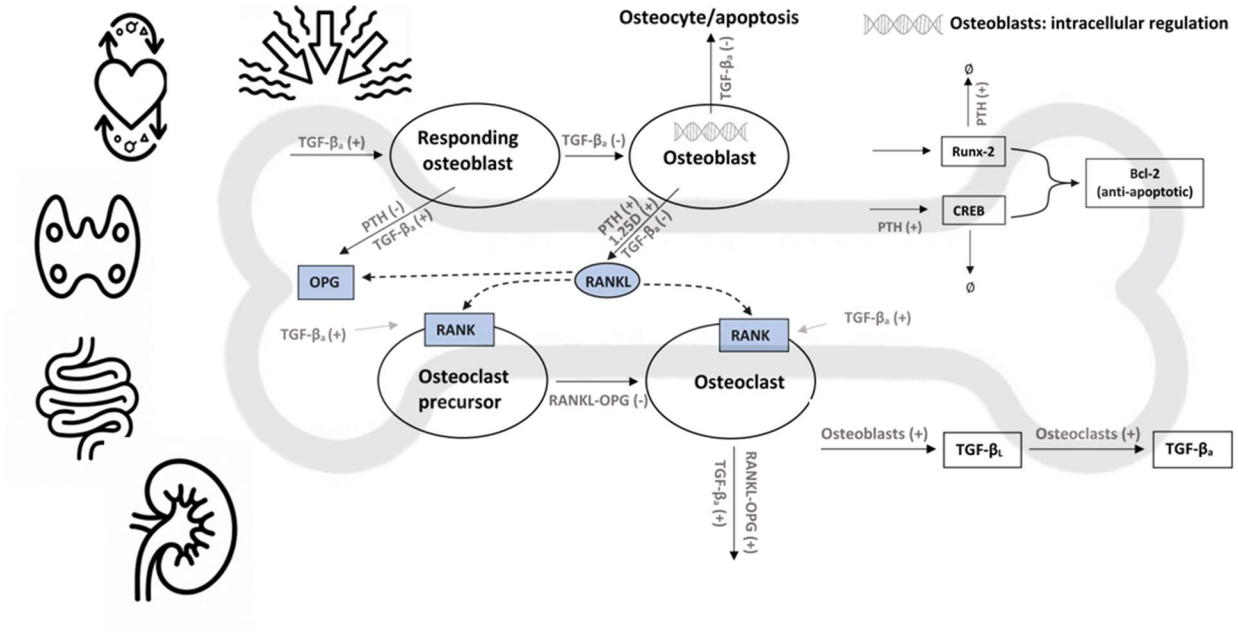
Introduction

Bone adaptation is governed by the interaction of mechanical loading, cellular remodeling processes, and systemic calcium–phosphate homeostasis. Existing models typically address these components separately, limiting the ability to study their combined effects on bone behavior. The aim of the study is to develop a unified, open-source computational framework that integrates mineral balance, osteoblast–osteoclast dynamics, biochemical regulation, and mechanical stimulus into a single extensible formulation. The platform is intended as a flexible exploration environment in which users can adjust loading histories, biochemical inputs, and parameter sets to examine how systemic and local factors jointly shape bone adaptation.

Methods

The model couples population-based osteoblast and osteoclast dynamics with whole-body calcium and phosphate mass balances and a general biochemical regulatory input. Mechanical loading enters via a lumped daily strain stimulus that modulates formation and resorption rates using a lazy-zone mechanoregulation law. Bone formation/resorption fluxes are directly linked to systemic mineral concentrations, ensuring consistent mineral exchange. Apparent mechanical properties (e.g., stiffness) are derived from bone volume fraction through a standard structure–property relationship. All governing equations, parameterizations, and simulation scripts are publicly available in a dedicated GitHub repository, enabling complete reproducibility and interactive experimentation.

Results



The framework is demonstrated using several qualitative validation examples. The model captures the contrasting skeletal outcomes of continuous versus intermittent PTH input: continuous exposure produces net bone loss, whereas intermittent pulses generate a net anabolic response under identical mechanical loading. The model also reproduces the expected increase in bone formation following vitamin D supplementation through its mineral-homeostasis pathways. In addition, the system naturally expresses qualitative

Wolff's-law behavior, with reduced mechanical loading leading to progressive decreases in bone volume and stiffness.

Discussion

The proposed framework consolidates mechanoregulation, cellular remodeling dynamics, and whole-body calcium–phosphate homeostasis into a single open-source computational platform. By providing a reproducible and extensible codebase, it offers a general tool for examining how mechanical loading and systemic biochemical signals interact to determine bone adaptation and mechanical competence.

Doctoral student Tsuyoshi Muto

Introduction

Bone remodels its structure to adapt to the mechanical environment. When assessing bone strength, the current clinical indicator—bone mineral density—reflects only bone quantity, underscoring the need for metrics capturing bone quality. In cancellous bone, trabecular architecture and microdamage, both influencing bone quality, interact to alter mechanical behavior [1]. This study aims to develop a mathematical model that simultaneously incorporates bone adaptation and damage repair via remodeling, and to investigate how trabecular arrangements influence damage evolution.

Methods

The complex cancellous structure was modeled as a series or parallel trabecular arrangement composed of two elastic cylindrical elements (Fig. 1), each assigned a time-varying radius and a damage variable. A damage-evolution equation incorporating damage accumulation, damage repair, and bone adaptation was formulated by considering continuum damage mechanics [2] and mechanoregulation of remodeling. The initial damage values and remodeling rates were systematically perturbed. For each parameter set, trajectories of the damage variables (D_1–D_2) were analyzed in phase space to characterize failure and non-failure regions.

Results

In the series arrangement (Fig. (a)), non-failure trajectories converged toward homogenized damage states, whereas highly damaged elements exhibited transient recovery followed by rapid damage progression to failure (Fig. (b)). Increasing the remodeling rate enhanced the contribution of the repair term and expanded the non-failure region. The parallel arrangement (Fig. (c)) exhibited cyclic alternation of damage between elements (Fig. (d)), indicating a complementary damage-evolution mechanism associated with stress redistribution.

Discussion

This study demonstrates that damage-evolution mechanisms differ essentially between structural arrangements. Damage behavior is governed primarily by the local balance between accumulation and repair in each element. In the parallel arrangement, damage is additionally influenced by stress redistribution, generating complementary alternation of damage evolution. Future work will extend this framework to complex trabecular models to develop next-generation indicators of bone quality.

OA180-06

Improved Trabecular Microarchitecture Representation in a Whole Bone Adaptation Model: A Preliminary Study Using a Voronoi Network With Beam and Shell Elements

Mr. Muhammad Yusril Sulaiman, Dr. Andrew Phillips

Structural Biomechanics, Department of Civil and Environmental Engineering, Imperial College London, London, England, United Kingdom

Introduction

Accurate representation of trabecular bone is crucial in bone adaptation studies seeking to understand its role resisting forces during daily living and extreme activities, investigating mechanical origins of osteoporosis and osteoarthritis, and in long-term outcomes following orthopaedic surgery. A previous predictive approach modelled trabecular bone as a high-connectivity truss network (HCT) within a model of the femur, with results corroborated by trajectory identification [1] and fracture load prediction [2]. However, imaging studies suggest trabecular topology is closer to a low-connectivity Voronoi network [3], and inclusion of plates (shells) alongside rods (beams) is important [4]. In the present study, the predictive structural approach [1] is extended for a model of the femur by incorporating a Voronoi network comprised of beam and shell elements representing trabecular microarchitecture.

Methods

We implemented a rod-to-plate transformation algorithm, where beam elements forming the edges of Voronoi faces with a final diameter-to-length ratio exceeding a threshold are converted into shell elements forming the faces. A beam model (VB) is adapted, prior to the diameter-to-length ratio being used to define a beam-and-shell model (VBS) which is further adapted. Bone adaptation was driven by a target strain, adjusting either beam diameter or shell thickness. Investigated output includes predicted trabecular topology and bone mineral density (BMD).

Results

All models predicted the five main trabecular trajectories in the proximal femur (Figure 1). Plates in the VBS model were localised in the femoral head and the region where principal tensile and secondary compressive trajectories intersect, with an overall plate-to-rod ratio of 0.265:1. For BMD, the VBS model was closest to reported values [5], while other models overpredicted in the femoral head.

Discussion

The results indicate the Voronoi network and rod-to-plate algorithm provide an improved representation of trabecular bone, although the HCT model predicted clearer trabecular trajectories. Future work will focus on model calibration, mesh adaptation, and application of multiple load cases from a range of activities.

A Microstructure-Based Material and Failure Model for Finite Element Simulation of Skin Lacerations Under Blunt Impact

Dipl.-Ing. Felicitas Lanzl[1], Prof. André Berger[2], M.Sc. Matthias Clermont[3], M.Sc. Jan Zimmermann[3], Prof. Steffen Peldschus[1]

[1]Biomechanics and Accident Analysis, LMU Munich, Munich, Bavaria, Germany. [2]School of Mechanical Engineering, University of Applied Sciences Stralsund, Stralsund, Mecklenburg-Western Pomerania, Germany. [3]Institute for Occupational Safety and Health of the German Social Accident Insurance (IFA), Sankt Augustin, North Rhine-Westphalia, Germany

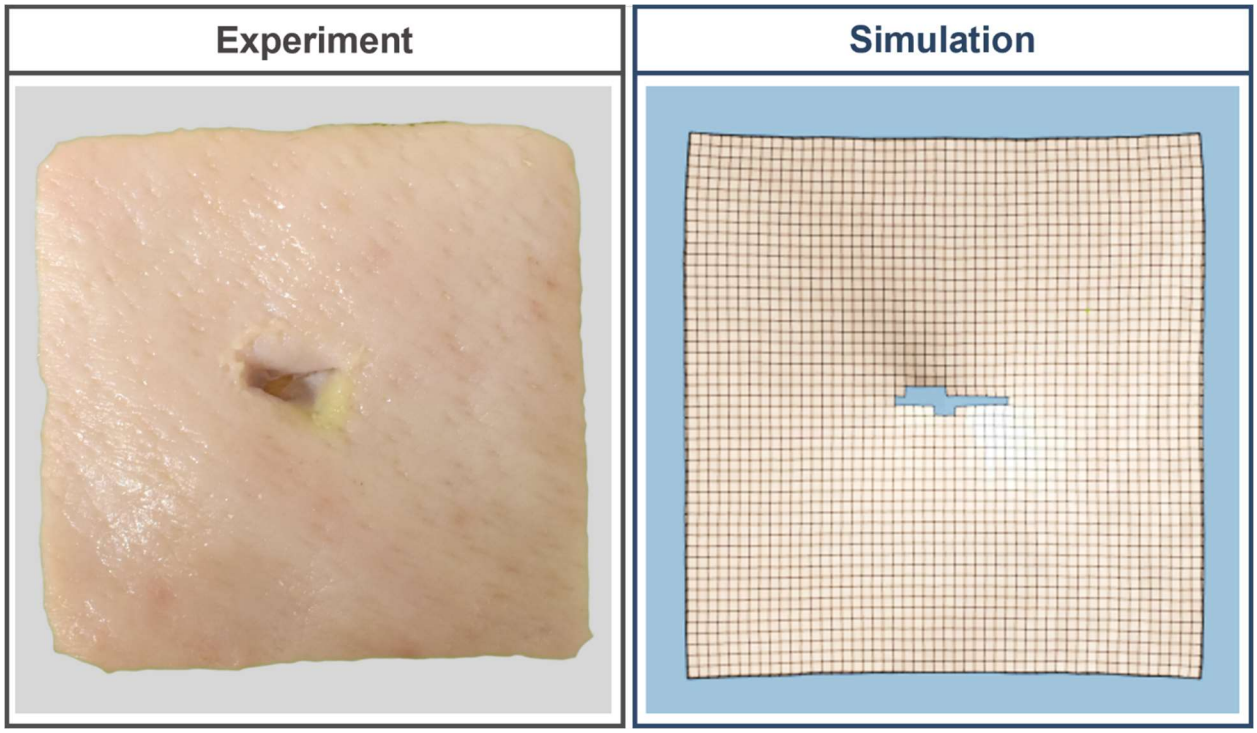
Introduction

Despite its relevance in injury biomechanics, the onset of lacerations under blunt impact remains insufficiently understood. Experimental evidence indicates that lacerations initiate parallel to Langer's Lines (LL), reflecting the underlying collagen fibre orientation in the dermis. To capture this behaviour, this work presents a microstructure-based anisotropic material and failure model for finite element simulation of skin lacerations under blunt impact.

Methods

Skin was modelled using the anisotropic microstructure-based Gasser-Ogden-Holzapfel formulation in LS-DYNA. Failure was incorporated through a threshold in the first principal strain. Model development and validation were performed using experimental data across different loading scenarios: uniaxial compression [1], uniaxial tension parallel and perpendicular to LLs [2], and in-house drop-tower experiments. A sensitivity analysis was conducted for both the material parameters and the failure threshold. The material model was first validated for all setups, followed by a second validation of the coupled material-failure model for each setup.

Results



The model reproduced the experimental stress-deformation response in compression and tension, as well as the impactor acceleration in the drop-tower tests. Incorporating failure yielded consistent behaviour across the loading scenarios: no premature rupture occurred in compression, and failure characteristics in tension along the LLs agreed with the experimental values. In tension perpendicular to the LLs, failure occurred earlier than

experimentally, although the resulting failure pattern was comparable. Under blunt impact, the model predicted direction-dependent laceration formation at similar energy levels to the drop-tower tests. Thickness-dependent variability in injury onset and differences in injury shape for two impactor geometries were also qualitatively reproduced.

Discussion

The developed material-failure model captured both the onset and qualitative shape of lacerations under blunt impact (see Figure 1). These results suggest that microstructure-based modelling can contribute to a more realistic representation of injury mechanisms. Remaining discrepancies, particularly in tension perpendicular to the LLs, indicate the need to extend the approach with a damage model. As validation was limited to isolated porcine skin samples, further validation – especially against data on human tissue and tests involving intact anatomical structures – is required.

Lung Injury Risk Curves for Behind Armor Blunt Trauma

Professor Narayan Yoganandan[1], Professor Lewis Somberg[1], Mr Jared Koser[2], Mr Alok Shah[2], Professor Brian Stemper[3], Dr. Valeta Chancey[4], Mr. Joseph McEntire[4]

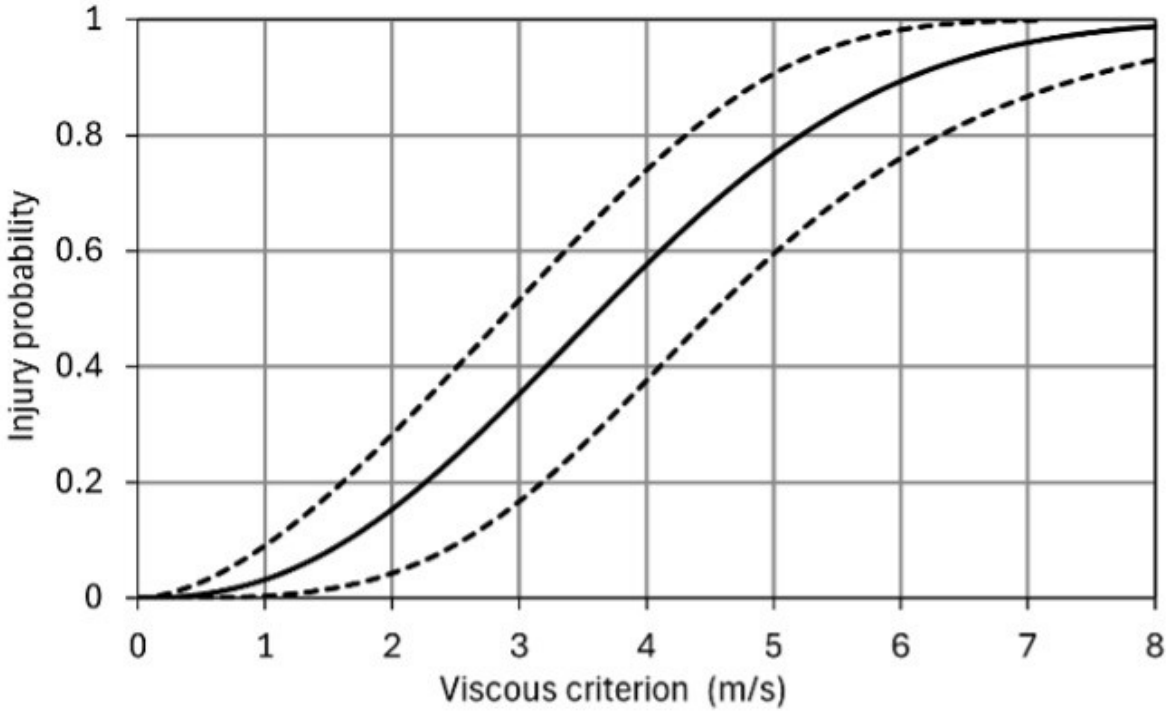
[1]Medical College of Wisconsin, MIlwaukee, WI, United States. [2]Medical College of Wisconsin, MIlwaukee, wi, United States. [3]Medical College of Wisconsin, MIlwaukee, Wi, United States. [4]USAARL, Fort Rucker, AL, United States

Introduction

The Abbreviated Injury Scale (AIS) is used to score injuries i and testing standards i. While studies have been conducted to determine the biomechanics of lung injuries for behind armor blunt trauma (BABT) applications, AIS-based injury risk curves are not available. Establishing these curves is the objective of the present study.

Methods

Impact loading was applied to the lung region of live swine using a custom indenter. The design of the indenter was based on backface deformations from human cadaver tests with hard body armor [1]. The animal was positioned supine on the laboratory table to accept the indenter-induced BABT impact to the lung region. An accelerometer (model Slice Pro, Diversified Technical Systems, Inc., Seal Beach, CA) was attached to the indenter on its back face to record acceleration signals. The viscous response was calculated from the velocity and normalized deflection signals, and peak magnitude was obtained. This was termed as the viscous criterion [2]. Parametric survival analysis was used to develop risk curves [3].



Results

There were 19 AIS2+ and 12 AIS3+ injuries, and 5 animals has no injuries. Viscous criterion at 10, 25, and 50% risks for AIS2+: 1.6, 2.5, and 3.7 m/s. For AIS3+: 2.9, 3.8, and 4.7 m/s. AIS2+ risk curves are shown (Figure 1).

Discussion

The Weibull distribution best fit the biomechanical results at AIS2+ and ASI3+ levels. Risk curves form a set of preliminary data for advancing safety from lung injuries in combat environments.

Computational Model of Shock Tube Loading on the Mouse Eye

Ms. Kelly A. Clingo BS[1], Dr. JiangYue Zhang PhD[2], Dr. Thao D. Nguyen PhD[1]

[1]Johns Hopkins University, Baltimore, MD, United States. [2]Johns Hopkins University Applied Physics Laboratory, Laurel, MD, United States

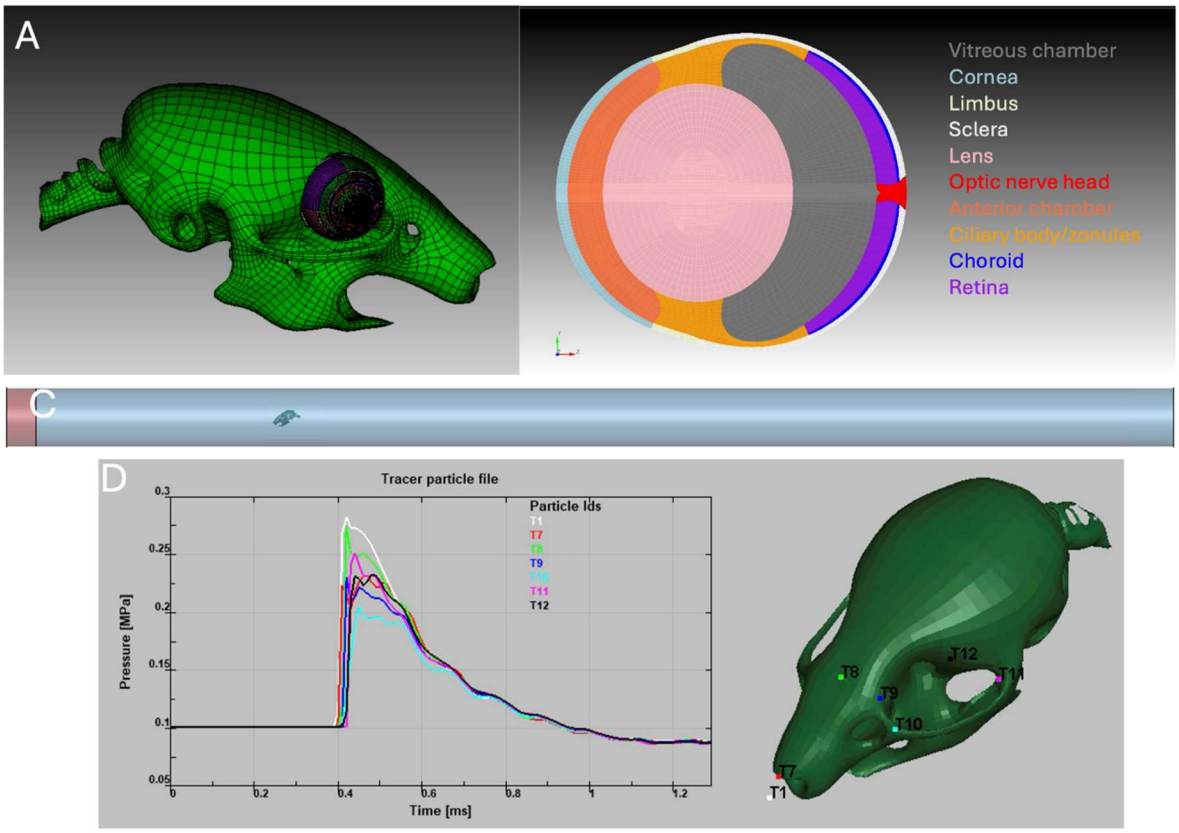
Introduction

This study developed a three-dimensional finite element model of a mouse head with deformable eyes, orbital tissues, and brain, and a shock tube to simulate blast-wave interaction and characterize the elastodynamic stress and deformation fields in the ocular tissues and brain.

Methods

The 25-mm-radius cylindrical shock tube, consisting of a 25-mm-long driver and 975-mm-long driven section, had a closed boundary condition on all walls except the driven section end, which was non-reflecting. An ideal gas equation of state described the air in the shock tube, which was discretized using an Arbitrary Lagrangian-Eulerian (ALE) mesh. A deformable eye was constructed from measurements for a 3-month-old C57BL/6 mouse found in the literature and included the following structures: cornea, limbus, sclera, choroid, retina, lens, anterior and vitreous chambers, optic nerve head, and extraocular tissue, all meshed using linear brick elements and placed within a rigid skull shell model created using the 3D Digimouse Atlas [1] and meshed using quadrilateral elements (Fig. 1A-B). The ALE shock tube and Lagrangian mouse head meshes were coupled using LS-DYNA's penalty-based fluid-structure interaction.

Results



A 25-mm-long driver filled with 0.64 MPa air yielded a planar wave with 0.14 MPa peak overpressure, 0.5 ms positive and 0.8 ms negative durations, selected to simulate blast injuries produced by [2]. At this driver length, the Friedlander blast profile was achieved 215 mm from the driver, where the head was placed (Fig. 1C-D). Lengthening the driver increased the positive duration and distance where the correct blast profile was achieved. The eye model with all tissue structures was created and will be incorporated into the shock tube simulation to characterize intraocular tissue deformations and stress fields.

Discussion

The characterization of the effect of driver length on positive duration, target location, and tube length enables guidance to experimental testing and greater model efficiency. Future

work includes incorporating a deformable brain model and evaluating stresses experienced by specific tissues due to blast overpressure. This model contains more tissues and greater anatomical accuracy than previous FE models of the murine eye.

OA182-02

Effects of Preservation on Tensile Properties and Structure of the Meniscus

Mr. Chester Jar, Ms. Abbi Oguchi, Dr. Mohammadhamed Shahsavari PhD, Dr. Nadr Jomha PhD, Dr. Lindsey Westover PhD, Dr. Gail Thornton PhD

University of Alberta, Edmonton, Alberta, Canada

Introduction

Meniscus transplantations commonly use fresh-frozen tissue [1]. However, ice formation can disrupt meniscal microstructure [2] and the structure-function relationship is not well understood. The objective was to determine whether structural and tensile properties of menisci differ following clinical preservation methods (freezing and fresh storage). Freezing is hypothesized to negatively affect tensile properties through voids left by ice crystals which disrupt the internal collagen microstructure.

Methods

Medial and lateral menisci were obtained from porcine hindlegs the day of slaughter and allocated into four groups. Menisci were either processed immediately (Ctrl), preserved in cell culture medium (Frsh: 4 °C, 21 days), or frozen with (FrzC: -140 °C, 21 days) and without cryoprotectant (Frz: -80 °C, 21 days). Ultimate tensile strength (UTS), strain, and elastic modulus were measured from uniaxial failure tests (0.2% strain/s) in the circumferential direction (n=8). Mechanics were supplemented with scanning electron microscopy (SEM) images of the femoral surface and circumferential fibres (n=5). Linear contrasts (α=0.05) were used to compare the Ctrl with each preservation method, FrzC and Frz groups, and Frz and Frsh groups.

Results

Compared to the Ctrl, other groups had a significantly lower UTS and modulus for the lateral meniscus (p<0.002) and lower UTS for the medial meniscus (p=0.023). Compared to the FrzC group, the Frz group had a significantly lower UTS and modulus for the lateral meniscus (p<0.026) and lower modulus for the medial meniscus (p=0.010). No differences in ultimate strain were found (p>0.096). SEM revealed voids on the femoral surface of the Frz and Frsh groups, but not the Ctrl and FrzC groups. Fibre disruption and separation were also observed in the Frz and Frsh groups but were not apparent enough to be conclusive.

Discussion

Cryoprotection may benefit meniscus preservation. As transplantation is generally for younger patients, optimizing mechanical properties could improve long-term survival. Most

biomechanical studies use frozen tissue [3], leading to incorrect conclusions if treated as a reference standard. Future work should include quantitative structural analysis and viscoelastic behaviour.

Images (Optional)

Table 1: Summary of mechanical test data for medial and lateral menisci (mean ± standard deviation).

(n=8 per group)	Ctrl	FrzC	Frz	Frsh
Medial

Kneeview: An Open-Source Repository of Patient-Specific Knee Geometries and Structured Meshes

ms. Renate Janssen[1], mr. Sai Natarajan[1], mr. Francis Chemorion[1], mr. Igor Radalov[2], mr. Jordi Monfort Faure[3,4], mr. Miguel A. González Ballester[1,5], mr. Jérôme Noaílly[1]

[1]Universitat Pompeu Fabra, Barcelona, Barcelona, Spain. [2]Department of Radiology, Hospital del Mar, Barcelona, Barcelona, Spain. [3]Rheumatology service, Hospital del Mar, Barcelona, Barcelona, Spain. [4]Hospital del Mar Research Institute, Inflammation and Cartilage Research Group, Barcelona, Barcelona, Spain. [5]ICREA, Barcelona, Barcelona, Spain

Introduction

The exploitation of finite-element modeling to understand knee biomechanics is often constrained by data availability. While the osteoarthritis initiative (OAI) [1] provides invaluable imaging data, converting these images into finite-element meshes is time-consuming. Open models such as OpenKnee [2] are valuable but restricted by unstructured meshes and low subject count (n=8). To address this, we present a repository of 80 patient-specific bone geometries of the femur, tibia, patella and fibula that is being expanded with personalized structured finite-element models through mesh morphing.

Methods

The dataset included T2, fat saturated, knee MRI scans from 93 patients (38 male, 55 female) acquired at Hospital Del Mar, Barcelona. An nnUNet neural network was trained on 35 expert annotations verified by a musculoskeletal-specialized radiologist. We created a webservice, Kneeview (https://knee.view.upf.edu), to host the repository. Subjects with missing demographics were excluded and 80 subject segmentations were reported. We customize the Bayesian Coherent Point Drift (BCPD) algorithm to treat tissues distinctively: bones undergo object-specific morphing, while soft tissues are automatically interpolated.

Results

The nnUNet achieved high segmentation accuracy on a hold-out test dataset of 15 volumes with an average Dice coefficient of 0.986 ± 0.001 and IOU of 0.971 ± 0.002. The average Hausdorff Distance (HD95) was 14.464 ± 12.727. This variance was driven exclusively by distal tibial artefacts (Tibia HD95: 16.49 ± 14.22) while femur, patella and fibula gave an average HD95 of 1.46 ± 0.242. All annotated 3D models were successfully incorporated in Kneeview, in STL format. The finite-element mesh included the whole knee joint with ligaments, bones and menisci without distorted or zero-volume elements.

Discussion

A collection of 80 patient-specific models were successfully created and accessible through the new Kneeview service. The high Dice scores confirm that our automated pipeline produces geometries comparable to manual segmentation. As kneeview continues to grow, it shall address the shortage of open-source simulation-ready knee geometries. Future work will include the structured FE meshes for all subjects after these meshes have been successfully tested against finite element simulations of full gait cycles.

Gait and Tibial Cartilage Contact Pressure in Children with Cerebral Palsy vs. Typically Developing Peers: A Musculoskeletal–Finite Element Approach

Mr Dongfei Huo[1], Professor Junyan Li[2,3], Dr Xijin Hua[1]

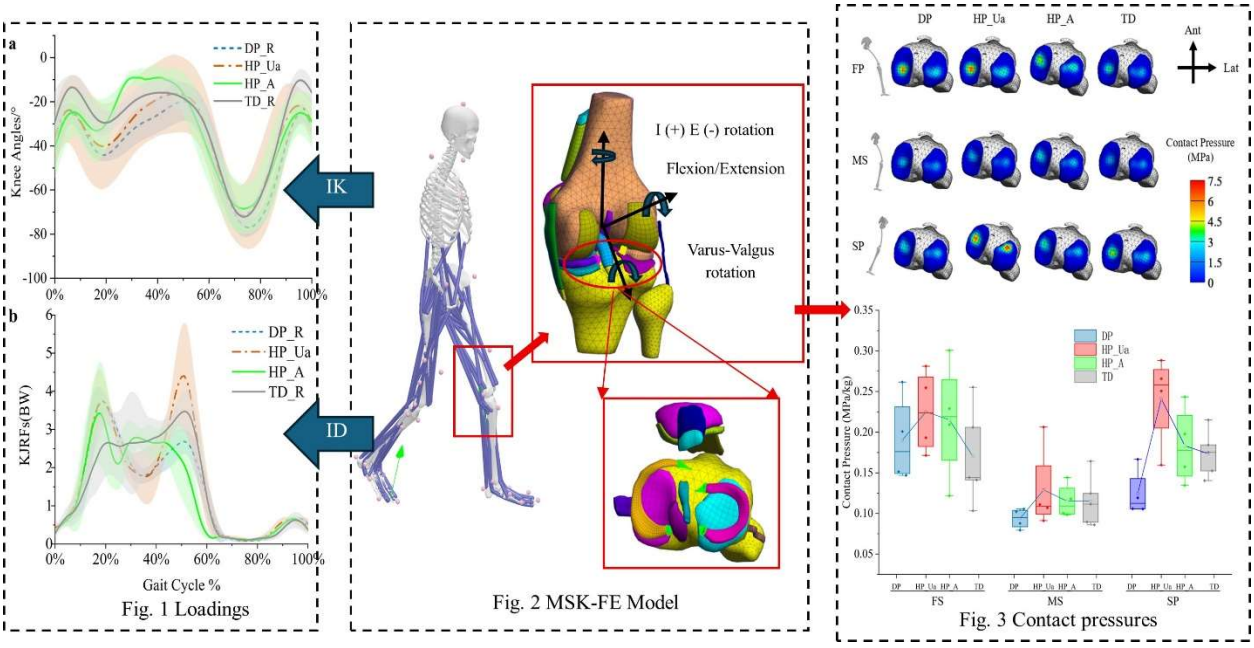
[1]University of Exeter, Exeter, Devon, United Kingdom. [2]Shanghai University of Medicine & Health Sciences, Shanghai, Shanghai, China. [3]Shanghai University of Medicine & Health Sciences Affiliated Zhoupu Hospital, Shanghai, Shanghai, China

Introduction

Cerebral palsy (CP) is associated with abnormal gait patterns that alter joint loading and predispose individuals to early-onset degenerative changes. This study developed an integrated musculoskeletal–finite element (MSK–FE) modeling framework to investigate differences in knee joint kinematics, knee joint reaction forces (KJRFs) and tibial cartilage stress distributions between children with CP and typically developing (TD) peers, allowing a multiscale description of knee joint loading that directly links abnormal gait patterns to cartilage-level mechanical responses.

Methods

Gait data from 13 children (5 TD, 4 hemiplegia (HP), 4 diplegia (DP)) were analyzed using OpenSim to obtain knee kinematics (Fig. 1a) and KJRFs (Fig. 1b). A scaled 3D FE knee model (Fig. 2) based on the OpenKnee(s) was implemented in FEBio with biphasic cartilage, menisci, and ligaments. Knee kinematics and KJFRs at first peak (FP), mid-stance (MS), and second peak (SP) were applied as loading inputs. Inter-limb symmetry was quantified using symmetry index (SI).



Results

All groups exhibited double-peak KJRFs and flexion–extension patterns. DP showed reduced mid-stance loading (1.8 BW vs. 2.5BW in TD) and lower late-stance peaks (2.5 BW vs. 3.5 BW in TD), despite near-symmetric SI. HP demonstrated the greatest asymmetry: the affected limb (HP_A) exhibited reduced early-stance loading and excessive flexion, while the unaffected limb (HP_Ua) generated the highest late-stance force (4.5 BW). Peak pressures in HP_A and DP occurred at FP (5.8–6.5 MPa), whereas TD and HP_Ua peaked at SP, with HP_Ua reaching the highest value (7.3 MPa). MS showed the lowest pressures across all groups (Fig. 3).

Discussion

The DP group showed globally reduced knee loading while maintaining good inter-limb symmetry. In contrast, the HP group exhibited marked biomechanical asymmetry, with reduced loading and excessive knee flexion in HP_A and compensatory overloading in HP_Ua. This abnormal asymmetric joint loading pattern has been demonstrated in existing studies to be closely associated with early-onset knee osteoarthritis. These findings reveal subtype-specific biomechanical adaptations in CP that may guide early screening and targeted rehabilitation to mitigate long-term knee OA risk. Limitation includes the small cohort size. Future work will incorporate subject-specific pediatric imaging and neuromuscular-informed modelling to improve clinical translation.

Introduction

Knee osteoarthritis (KOA) pathogenesis involves a complex interplay of mechanical, biochemical, and genetic factors at the cell and tissue levels, with inflammatory mediators and abnormal mechanics being critical drivers [1]. Current *in vitro* and computational models lack the biological complexity to reproduce *in vivo* observations [2, 3]. We developed a validated multiscale computational model of the knee joint to predict whether patient-specific synovial protein concentrations drive KOA.

Methods

Soluble mediators from an existing semiquantitative chondrocyte network model [4] were coupled with an articular cartilage (AC) finite-element multispecies diffusion model. Bidirectional communication was achieved using protein structure-based diffusion and degradation rates, literature-driven receptor kinetics for chondrocyte stimulation, and data-driven secretion rates. Experimentally, bovine AC explants (n=4) were stimulated (±10 ng/ml IL-1β) for 14 days, and mRNA expression was measured by qPCR. Simulations replicating experimental conditions were run (Fig. 1a). Additionally, severe KOA patient-specific simulations (n=23) were performed by fixing synovial protein concentrations for 14 days in an initially healthy AC phantom.

Results

IL-1β stimulation induced AC degradation and inflammation. The computational model's chondrocyte activity matched the mRNA expression trends, except for collagen and PIEZO (Fig. 1b). However, collagen downregulation was observed experimentally at day 7 IL-1β stimulation (not shown). Patient-specific calculations with synovial proteins diffusing into

the cartilage also shifted to KOA over the 14 simulated days, with increased network predictions of inflammatory and pro-catabolic chondrocyte activity and hypertrophy (Fig. 1c).

Discussion

The presented computational framework translates cell activity into tissue concentrations (and *vice versa*) and is validated against gene expression under IL-1β stimulation. Nevertheless, failing to increase PIEZO expression upon IL-1β stimulation suggests the necessity to incorporate mechanoreceptor biochemical regulation into the network [5]. Patient-specific results confirm the critical role of synovitis in driving KOA through diffusion [1]. Whether mechanical forces can modify this behavior is being explored, through AC mechanical loading finite-element simulations feeding the chondrocyte network.

Statistical Shape Modeling Reveals Sex-Specific Relationships Between Three-Dimensional Combinations of Tibiofemoral Bony Geometry and Knee Kinematics and ACL Force in Adult Cadaveric Knees

Presenter Lexie Bae, Submitter David Shamritsky, Submitter Isabella Gomez Hjerthen, Submitter Erin Berube, Submitter Carl Imhauser PhD, Submitter Danyal Nawabi MD, Submitter Andrew Pearle MD, Submitter Thomas Wickiewicz MD

Hospital for Special Surgery, New York, New York, United States

Introduction

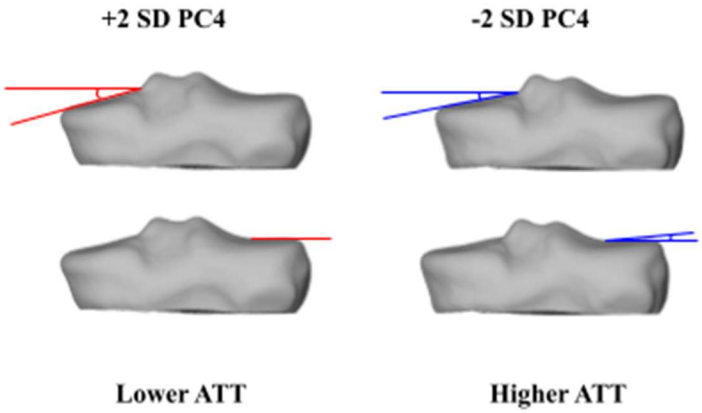
Sex-specific combinations of knee bony geometric features are risk factors for sustaining non-contact anterior cruciate ligament (ACL) rupture. However, limited studies have linked these variations in bony geometry to altered knee mechanics. Moreover, previous work has typically ignored sex as a variable and focused on geometric features measured in a single anatomic plane. Our objective was to identify sex-specific relationships between variations in three-dimensional (3D) tibiofemoral geometry and knee kinematics and ACL force (ACLF) in a cadaveric model.

Methods

Thirty-seven intact adult cadaveric knees (46±16 years, 17F/20M) were tested using a 6 degree-of-freedom robotic manipulator. Tibiofemoral kinematics (internal tibial rotation (ITR), valgus angulation, anterior tibial translation (ATT)) and ACLF were measured in response to a simulated pivot shift exam (serially applied compression (100N) and valgus moment (8Nm) at 15˚ of flexion). Each specimen's 3D tibiofemoral geometry was segmented from magnetic resonance imaging. Variations in bony geometry were quantified via statistical shape modeling. Principal component analysis identified the 10 principal components (PCs) with the largest contributions to total geometric variation. For the male and female subgroups individually, these ten PCs were related to ACLF and kinematics using stepwise multiple regression (α=0.05). To quantify the relative effect of each significant PC, the change in ACLF and kinematics corresponding to a 2-standard deviation (SD) change in each PC was reported.

Results

In females, PC1 and PC6 were associated with ACLF (p=0.001 and p=0.03, respectively). A 2-SD change in PC1 and PC6 corresponded to 32 N and 17 N increases in ACLF,



respectively. Additionally, PC2 was associated with ITR (p=0.01), and a 2-SD change corresponded to a 19.0˚ increase in ITR.

In males, PC4 was associated with both valgus angulation (p=0.02) and ATT (p=0.005). A 2-SD change in PC4 corresponded to a 1.0˚ decrease in valgus angulation and a 2.9 mm decrease in ATT.

Discussion

We identified sex-specific relationships between certain combinations of 3D bony geometric features and knee mechanics. Understanding the female-specific mechanisms that may result in increased ACL force in response to pivoting loads could lead to improved injury screening and prevention protocols.

Images (Optional)

Geometric variations captured by significant principal components were qualitatively assessed by visualizing tibiofemoral geometry spanning ±2 standard deviations for each PC. Shown is an example of bony shape variations of the tibia for PC4.
Row One: Medial-lateral tilt capturing concavity of the medial plateau
Row Two: Medial-lateral tilt capturing concavity of lateral plateau
The combination of shapes shown in the left column correspond to a lower ATT with serially applied compression and valgus loads, with the shapes in the right column correspond to higher ATT

Influence of Hip Joint Center Location and Walking Patterns on Hip Joint Contact Forces in Females with Acetabular Dysplasia

Ms. Ria Rao BS, Ms. Avery Kratzer BSE, Prof. Cara Lewis PT, PhD, FAPTA

Boston University, Boston, MA, United States

Introduction

Acetabular dysplasia, characterized by reduced acetabular coverage over the femur, is associated with abnormal hip joint loading and pain [1]. Joint loading in females with dysplasia is influenced by hip geometry, including a lateralized hip joint center location [2], and altered movement patterns during walking [3]. However, the individual contributions of the joint center location and movement are unclear. The purpose of this study was to assess the individual effects of typical and dysplastic hip joint center locations and movement patterns on hip loads.

Methods

Walking data were collected from five females with dysplasia (mean 24.8 years; 60.2kg; 1.66m) and five pain-free females (mean 26.4 years; 60.7kg; 1.67m) using motion capture and an instrumented treadmill (1.25 m/s). We created four model-movement combinations by pairing musculoskeletal models – representing typical or dysplastic hip joint centers – with group-specific walking patterns. The typical model used OpenSim's Gait2392, and the dysplastic model shifted its hip joint center 13.5mm laterally, 2.7mm anteriorly, and 5mm superiorly [2]. Models were then scaled, and walking data were applied. Percent differences in peak mean hip contact forces in each direction were calculated.

Results

Compared to the typical model and movement combination, the dysplastic model and movement combination had 14%, 26%, and 11% higher peak superior, medial, and resultant forces, respectively. Compared to the typical model, using the dysplastic model increased peak superior, medial, and resultant forces by 16-30% for dysplastic movement and by 20-28% for typical movement. Compared to typical movement, simulating dysplastic movement decreased the anterior, superior, and resultant forces by 12-23% for the typical model and by 8-15% for the dysplastic model **(Figure 1)**.

Discussion

Displacing the hip joint centers alone greatly increased contact forces. However, when both the model and movement were dysplastic, forces increased by a smaller percentage, suggesting that altered movement may partially offset the elevated loading associated with lateralized joint centers. This pattern may reflect an adaptive strategy used by females with dysplasia to reduce joint loading, and potentially alleviate pain, during walking.

OA183-04

Cam Femoroacetabular Impingement Surgery Partially Restores Hip Motion and Balance One Year Postoperatively

Mr. Mohamad El Fateh Shatila, Mr. Etienne Joulin, Dr. Trevor Birmingham, Dr. Ryan Degen, Dr. Geoffrey Ng

UWO, London, ON, Canada

Introduction

Cam-type femoroacetabular impingement (FAI) is characterized by an abnormal femoral head–neck junction, disrupting joint mechanics and leading to early hip osteoarthritis. While arthroscopic surgery aims to restore joint morphology, its long-term impact on joint stability and postural control remains unclear. This study examined hip and pelvic kinematics and hip kinetics during the hurdle-step and reach distances in the star excursion balance test (SEBT), comparing preoperative, 1-year postoperative, and control hips.

Methods

Eleven FAI patients (m:f = 5:6; age = 27 ± 9 years; BMI = 24 ± 4) were assessed before and 12 months postoperatively. Eleven age- and sex-matched healthy controls (m:f = 5:6; age = 25 ± 9 years; BMI = 24 ± 4) were recruited. 3D hip kinematics and kinetics were captured using a 12-camera motion capture system (60 Hz; Motion Analysis, USA) and two force plates (1200 Hz; AMTI, USA). The hurdle-step was performed by stepping over a hurdle bar (at knee height), performing a toe-tap, and returning to a double-leg stance. For the SEBT, single-leg reach distances were measured in eight directions and normalized to leg length. Data were processed in MATLAB to compute joint angles and moments. Statistical nonparametric mapping compared the three groups using 1D waveforms.

Results

During the hurdle-step stance phase, postoperative hips showed decreased internal rotation after hurdle clearance compared to controls (42-43%, $p = 0.02$). In the SEBT, preoperative hips showed reduced reach in the anteromedial (74% leg length) and medial (81% leg length) directions compared to controls (81%, $p = 0.01$; 88%, $p = 0.046$).

Discussion

The most important finding was that cam FAI patients demonstrated partial recovery in hip motion and balance 12 months after surgery. Persistent reductions in hip internal rotation, along with trends toward limited flexion and increased posterior pelvic tilt during the

hurdle-step, may reflect subtle pelvic compensation when hip mobility remains constrained. SEBT performance showed medial reach improvements but continued posterior limitations, indicating that dynamic balance deficits also remain. Overall, while surgical correction improves movement control, these residual motion and balance limitations highlight the need for rehabilitation targeting hip flexion, rotation, and coordinated lumbopelvic control to optimize recovery.

Increased Muscle Synergy and Activity in Post-Operative Cam FAI

Mr. Etienne Joulin[1], Mr. Mohamad Shatila MESc[1], Dr. Trevor Birmingham BA, BSc, MSc, PhD[1], Dr. Ryan Degen MD, MSc, FRCSC[1,2], Dr. Geoffrey Ng BScEng, MASc, PhD[1]

[1]Western University, London, Ontario, Canada. [2]London Health Sciences Centre, London, Ontario, Canada

Introduction

Cam-type femoroacetabular impingement (FAI) is characterized by an enlarged femoral head that damages the protective soft tissue in the hip joint, leading to early hip osteoarthritis. Pre-operative patients have shown altered kinematics and neuromuscular behaviour to avoid impingement, but it remains unclear if these muscle recruitment patterns recover or change after surgery. The aim was to determine the core and lower-limb muscle synergies between the pre- and post-operative hips of cam FAI patients during the hurdle step.

Methods

Seven symptomatic cam FAI patients (n = 7, m:f = 5:2, age = 8 ± 8 years, BMI = 24 ± 3) were tested before and 1-year after surgery. Surface electromyography (EMG) electrodes (Trigno, Delsys; USA) were positioned to the left and right lower-limb (gluteus maximus, biceps femoris, tensor fasciae latae, rectus femoris) and core muscles (erector spinae and rectus abdominus). Participants performed hurdle steps (Figure 1A) and maximum voluntary isometric contractions (peak EMG signals for normalization). Using a custom MATLAB script, EMG signals were aligned by movement phase (0% = start, 25% = initial step, 50% = toe tap, 75% = return step, 100% = end), filtered (20-500 Hz bandpass), and smoothed (6 Hz lowpass) using a dual-pass, zero lag fourth order Butterworth filter. The variance accounted for (VAF) was computed for each muscle and globally for all muscles to evaluate the synergies' ability to reconstruct the original signals. The pre- and post-operative VAFs and muscle activities were compared using the Wilcoxon signed-rank test ($P < 0.05$), where significant movement phases were identified using statistical non-parametric mapping.

Results

Global reconstruction improved post-operatively ($P = 0.02$) during the hurdle swing. Patients saw greater tensor fascia latae (TFL) activity post-operatively during both the swing ($P = 0.001$; Figure 1C) and stance phase ($P = 0.001$) of the hurdle step.

Discussion

The key finding was that cam FAI patients demonstrated greater muscle organization post-operatively, which may suggest improved neuromuscular coordination during impinging tasks. Greater TFL activity may help to control the swinging leg and improve hip-pelvic stability when reaching over the hurdle bar. A clearer understanding of muscle recruitment strategies could guide prehabilitation/rehabilitation protocols to improve surgical outcomes.

Images (Optional)

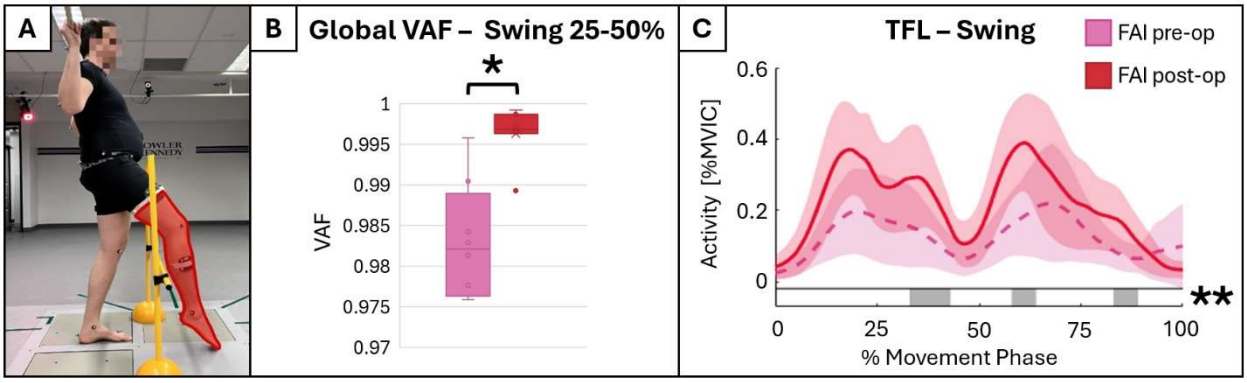

Figure 1. (A) Toe tap of the hurdle swing (50% movement phase) during the functional assessment. **(B)** Global variance accounted for (VAF) of the pre-operative and post-operative FAI patient muscle synergies during 25-50% movement phase of the hurdle swing (*$P < 0.05$). **(C)** Tensor fascia lata (TFL) activity during the hurdle swing, where significant movement phases are shaded in grey (**$P < 0.01$).

Influence of Ankle Exoskeleton on Human Joint Level Force Responsiveness and Control

Mr. Amro Alshareef, Mr. Shu Gong, Dr. Gregory Sawicki

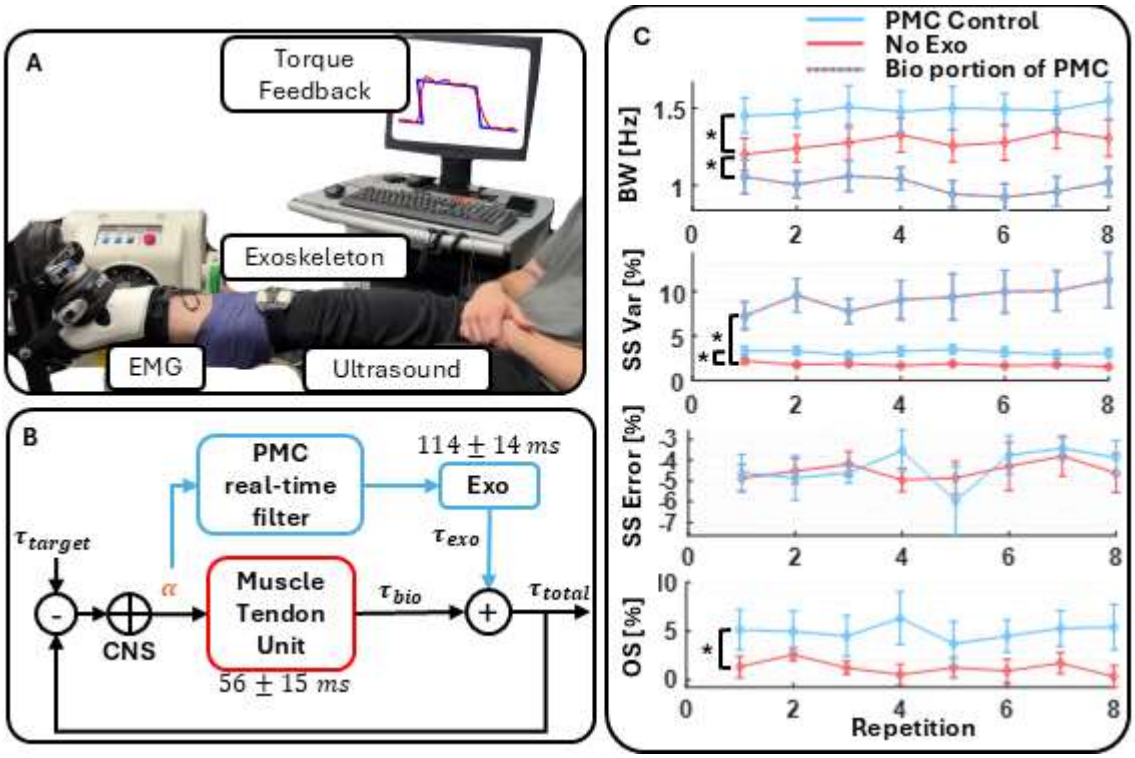
Georgia Institute of Technology, Atlanta, GA, United States

Introduction

Although exoskeletons have been developed to achieve certain energetic or stability outcomes, their interaction with our sensorimotor control system is not fully understood. Recent work has investigated human force responsiveness [1]. Here we measure human force control with exoskeleton assistance in isolated joint, torque matching tasks.

Methods

Ten young adults wearing an ankle exoskeleton completed isometric torque matching tasks in a dynamometer (Fig 1A). Participants were given an auditory metronome, a visual torque target (40% of Maximum Voluntary Contraction), and visual torque feedback. Exoskeleton condition order was randomized between no assistance and Proportional Myoelectric Control (PMC). The task was to step to the target torque for 4 seconds for ten steps per trial. Conditions were repeated eight times. The step responses were quantified using controls metrics including bandwidth (BW), overshoot (OS), and steady-state error (SSE) and variability (SSV). Higher BW indicates higher responsiveness, and a lower SSE, SSV, and OS indicates greater accuracy.



Results

The exoskeleton contributed 40 ± 17% of total torque output in the PMC condition. The exoskeleton increased total system (muscle tendon unit (MTU) + exoskeleton) BW by 0.25 ± 0.05Hz ($p<.004$) but decreased the MTU component BW by 0.23 ± 0.08Hz ($p<.007$) on average. The total system OS and SSV increased by 4.47 ± 0.8% ($p<.03$) and 1.17 ± 0.24% ($p<.005$) with the exoskeleton, respectively, whereas the MTU response SSV increased by 4.64 ± 0.59% ($p<.04$). Total system SSE was not affected by added exoskeleton assistance ($p>0.5$) (Fig 1C). The number of repetitions did not significantly affect outcomes, indicating no motor adaptation to the task or exoskeleton.

Discussion

Although the exoskeleton increased total system responsiveness, the MTU responsiveness decreased despite having a shorter onset delay than the exoskeleton (Fig 1B). This may reflect the size principle of motor unit recruitment. The exoskeleton acts fast, causing a larger overshoot, negating the need for fast motor unit recruitment after engagement of the slow motor units. The MTU's steady state variability increase seemed to largely counteract the PMC variability. Steady state error was also not affected, suggesting that an exoskeleton can increase responsiveness without compromising steady state accuracy.

OA184-03

Effects of Passive Heel Vibration on Gait and Postural Stability in Older Adults

Effects of Passive Heel Vibration on Gait and Postural Stability in Older Adults Hyesu Son Master's degree

Ewha Womans University, Seoul, -, Korea, Republic of

Introduction

Human balance control relies on sensory feedback, which is essential for postural stability. Age-related deterioration of sensory feedback impairs this control, increasing fall risk. Previous studies revealed suprasensory vibration can enhance postural stability by providing haptic feedback. However, the underlying sensorimotor mechanisms, including the influence of vibration on the relationship between muscle activity and postural sway, remain unclear, and prior work has mainly focused on acute vibration effects. This study investigates whether long-term vibration affects balance measured by Center of Pressure (CoP) sway metrics, and gait parameters. It further explores the relationship between ankle-foot muscle activity and CoP sway metrics.

Methods

Twenty healthy females (64.1 ± 4.1 years) completed pre- (PRE) and post- (POST) tests. They were assigned either vibration (n=10) or non-vibration shoes (n=10) for 10-week intervention. The vibration shoes contained permanent magnet modules generating 20–25 Hz vibration in response to heel strikes. PRE/POST assessments include gait and single-leg stance test to evaluate postural stability. Kinematic data were captured using 3D motion capture system. During single-leg stance test, CoP data were recorded using a force plate, and ankle–foot muscle activity was simultaneously measured via surface EMG. Data were analyzed using a two-way mixed ANOVA.

Results

Both groups showed significant improvements in single-leg stance test after 10-week intervention. However, the vibration group exhibited greater PRE to POST reductions in CoP path length (-53.9%, p=0.001), medio-lateral sway velocity (−49.6%, p=0.025), and antero-posterior sway velocity (-57.9%, < 0.001) compared to the non-vibration group. Ankle–foot muscle activity decreased by approximately 16–17% in both groups across the intervention period. Notably, the vibration group showed larger reduction in soleus activation (-13.9%,

p=0.03) than the non-vibration group. For gait analysis, step width decreased and cadence increased over time in both groups ($p < 0.05$).

Discussion

This study suggests that 10-week vibration intervention may have capacity to reduce CoP sway and ankle-foot muscle activity during challenging tasks. The vibration group had greater reductions in postural sway and muscle activation, suggesting heel vibration may enhance balance control by stabilizing postural sway. These findings imply that passive heel vibration could serve as a potential rehabilitation strategy for older adults.

Increasing Footwear Bending Stiffness Does Not Change Direction-Specific Functional Base of Support in Older Adults

PhD Student Paula Kramer MS[1], Associate Professor Kota Takahashi PhD[1], Professor Jason Franz PhD[2], Associate Professor Peter Fino PhD[1]

[1]University of Utah, Salt Lake City, Utah, United States. [2]University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, United States

Introduction

Standing balance is achieved by maintaining the center of mass within the base of support defined by the boundaries of the feet [1]. However, less than 30% of the anatomical footprint is typically available for balance control [2]. This available area is known as the functional base of support (fBoS) and represents how far the center of pressure (CoP) can move beneath the foot [2]. The fBoS can decrease with age [3], and smaller fBoS values are associated with a higher risk of falls [4]. Because the strength of intrinsic foot muscles can influence the fBoS [5], we hypothesized that increasing footwear bending stiffness could increase the fBoS.

Methods

Twenty-one healthy older adults (mean [range] age: 64 [61–86] years, 10F/11M) provided informed consent. Participants “leaned maximally with both feet together in one of four directions (forward, backward, right, left) without stepping”. Heels, toes, and feet could lift freely to allow full ankle range of motion. Footwear stiffness was manipulated using standardized shoes (S00), S00 with a 1.6-cm carbon-fiber insole (S16), and S00 with a 3.2-cm insole (S32). Foot boundaries and CoP data were recorded from motion capture and force plates, respectively. The directional fBoS was defined as the minimum distance between the max CoP excursion point and direction-specific foot boundary landmarks (Fig.1). Linear mixed-effects models tested whether the fBoS varied by foot stiffness for each direction.

Results

There were no differences in fBoS between S00 and S16 (all p-values > 0.068) or between S00 and S32 (all p-values > 0.398) (Fig.1).

Discussion

Contrary to our hypotheses, increasing bending stiffness did not increase the fBoS. Older adults may be unable to take advantage of the increased stiffness due to weak plantarflexor muscles [5], unwilling to risk a fall by extending further than normal.

Plantar Intrinsic Muscle Control of Postural Stability and Functional Sway Capacity: The Effects of Sway Direction and Footwear Bending Stiffness

Dr. Kavya Katugam-Dechene PhD[1,2], Ms. Megan Spencer BS[1,2], Dr. Kota Takahashi PhD[3], Dr. Jason Franz PhD[1,2]

[1]University of North Carolina at Chapel Hill, Chapel Hill, NC, United States. [2]North Carolina State University, Raleigh, NC, United States. [3]University of Utah, Salt Lake City, UT, United States

Introduction

Maintaining balance during standing and voluntary leaning requires precise neuromuscular coordination to regulate the body's center of pressure (CoP). While the role of large lower-limb muscles in postural control is well described, the contribution of plantar intrinsic muscles (PIMs), such as the abductor hallucis (AH) and flexor digitorum brevis (FDB), remains less well understood. Our primary objectives were to (1) characterize AH and FDB excitation in regulating postural stability and functional sway capacity, and (2) determine whether footwear bending stiffness modulates requisite PIM excitation. Here, functional sway capacity (FSC) refers to one's capacity to volitionally shift and control their body's center of gravity without losing balance.

Methods

Seventeen healthy young adults (18-35 years) completed a series of forward, rightward ("ipsilateral"), and leftward ("contralateral") functional sway capacity tasks under two footwear conditions – namely, a control shoe with/without custom 1.6-mm carbon fiber insoles (CFIs). Ultrasound-guided indwelling EMG electrodes recorded right-foot AH and FDB excitations at 1000 Hz. Each trial included a 10-s quiet standing phase followed by a maximal voluntary lean held for ~15 s. EMG were demeaned, filtered (bandpass 20-450 Hz), rectified, and normalized to a toe-flexor maximum voluntary isometric contraction (MVIC).

Results

There were no differences between footwear conditions in CoP metrics. Both muscles showed strong task-dependent modulation, with significant direction, phase, and direction × phase interaction effects (all $p<0.001$) that showed maximal excitation during the maximum forward lean. CFI effects were muscle- and direction-dependent. Specifically,

condition × direction interactions revealed that, compared to control shoes, wearing CFIs averaged 15% greater AH excitation during forward leaning (statistical trend, p=0.082) and 16% lesser FDB excitation during contralateral leaning (p=0.042).

Discussion

CFIs altered the neuromuscular strategies used to control the foot-ground interface. With CFIs, AH excitation increased during forward leaning, suggesting greater reliance on medial PIMs to modulate arch and forefoot stiffness and/or greater excitability from better sensory perception. Conversely, FDB excitation decreased during contralateral leaning, consistent with passive forefoot stiffness from CFIs partially offloading PIM demands. Direction-specific changes suggest that CFIs may redistribute how PIMs contribute to postural stability, revealing motor-equivalent solutions that preserve performance while reshaping local control.

Images (Optional)

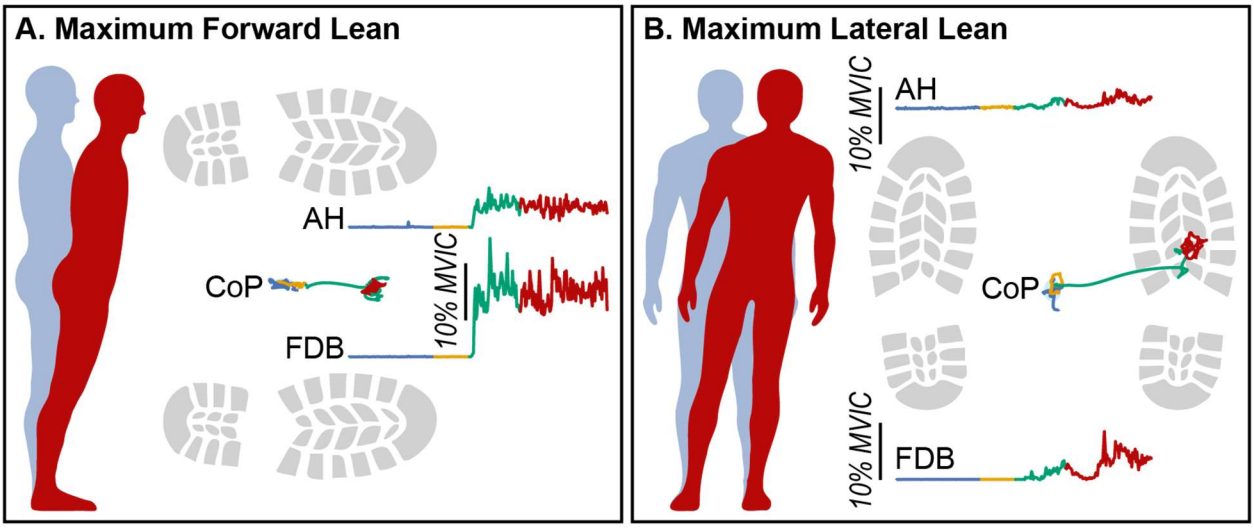

Figure 1: Illustration of functional sway capacity tasks showing **(A)** maximum forward and **(B)** maximum lateral lean. Corresponding examples of center-of-pressure (CoP) trajectories relative to feet position, and abductor hallucis (AH) and flexor digitorum brevis (FDB) excitation responses, are shown from the no CFI condition. Colors correspond to 10 seconds of still-standing (blue), countdown to lean (yellow), motion to achieve maximal lean (green), and maximal lean hold (red).

Brain Vascular Age and Generative Modeling of Cerebrovascular Aging

Dr. Kaveh Laksari PhD[1], Dr. Aditi Deshpande PhD[1], Mr. Amin Ebrahimzadeh[1], Dr. Pouya Tahsili-Fahadan MD, MBA, FAHA[2,3], Dr. Greg Ver-Steeg PhD[1], Dr. Amit Roy-Chowdhury PhD[1]

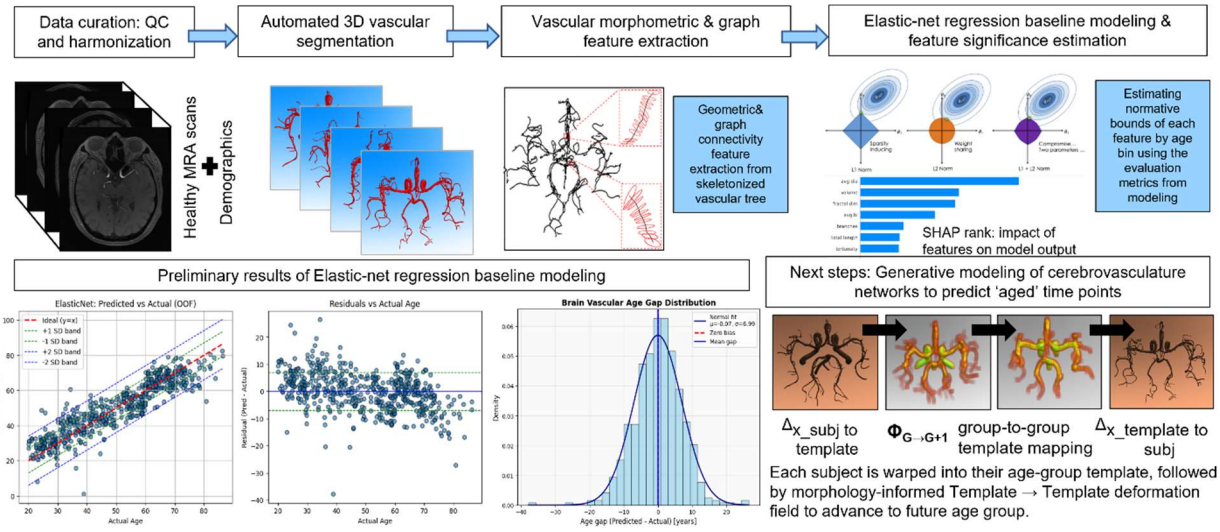
Dr. Kaveh Laksari

Introduction

Cerebrovascular morphology evolves across the healthy adult lifespan, yet deviations from normative aging patterns are among the earliest indicators of neurovascular disease and cognitive decline. Existing brain-age models focus on tissue atrophy, overlooking the vasculature, despite evidence that vascular alterations often precede neuronal & tissue loss. We introduce a framework for quantifying cerebrovascular aging using (1) a Brain Vascular Age Index (BVAI) using vascular morphology and topology, and (2) a generative AI model to forecast individualized vascular networks across age. This provides a mechanistically interpretable approach to vascular aging and a foundation for vascular biomarkers of cognitive impairment.

Methods

Time-of-flight MRA scans from 915 healthy adults (ages 20–90) were segmented using our validated CNN-based cerebrovascular segmentation algorithm. The resulting 3D vascular trees were skeletonized to extract morphological and graph-network features. An Elastic Net regression model was trained to predict chronological age and derive BVAI as the difference between predicted biological and chronological age (Fig. 1). Subsequently, to model longitudinal vascular aging, we developed a diffusion-based generative model that maps subject-specific vascular networks into a latent template space (Fig. 1) conditioned on age groups. This enables counterfactual inference—i.e., generating how an individual's vasculature would look at older ages—without longitudinal data. Anatomical constraints learned from baseline modeling are incorporated for biological plausibility.



Results

The regression model achieved prediction performance of (MAE ≈ 6–8 years; R^2 ≈ 0.70–0.78) and identified tortuosity, diameter, branch count, and fractal dimension as the most predictive aging markers. BVAI successfully distinguished early vascular deviations in out-of-distribution subjects, showing sensitivity to vascular patterns associated with disease. The generative diffusion model produces topologically coherent age-progressed 3D vascular networks (given specific age values), capturing age-related increases in tortuosity and branch loss. Phantom experiments with controlled morphology will be implemented to confirm alignment of generated trajectories with empirical aging trends.

Discussion

This work introduces the first regression-generative framework for cerebrovascular aging. BVAI provides a quantitative, interpretable metric of aging, while the generative model produces subject-specific aging trajectories revealing vascular evolution over time. Together, these tools establish a foundation for vascular biomarkers of cognitive decline, neurodegeneration, and cerebrovascular disease.

Deep Learning Super-Resolution for Preclinical Bone Imaging: Reconstructing Trabecular and Cortical Microarchitecture from MicroCT Imaging

Mr. Amine Lagzouli[1,2], Prof. Alice Othmani[3], Dr. Kim Harrison[4], Prof. David Cooper[4], Prof. Peter Pivonka[1], Prof. Vittorio Sansalone[2]

[1]School of Mechanical, Medical, and Process Eng., Queensland University of Technology, Brisbane, Queensland, Australia. [2]Univ Paris Est Creteil, Univ Gustave Eiffel, CNRS, UMR 8208, MSME, Creteil, Ile de France, France. [3]Université Paris-Est Créteil (UPEC), LISSI, Vitry-sur-Seine, Ile de France, France. [4]Department of Anatomy, Physiology, and Pharmacology, University of Saskatchewan, Saskatoon, Saskatchewan, Canada

Introduction

High-resolution micro-computed tomography (microCT) and synchrotron radiation-based microCT (Sr-microCT) are widely used in preclinical bone research to characterize bone microarchitecture and assess remodeling and therapeutic responses. Despite their excellent spatial resolution, there are several limitations in their use, especially in *in-vivo* settings, including radiation exposure, imaging artifacts, scan-time limitations, and high storage requirements. These challenges are particularly relevant in preclinical animal studies, where accurate characterization of fine bone microstructure is essential.

Super-resolution (SR) aims to recover anatomical details that are unresolved in lower-resolution acquisitions. Deep-learning SR approaches have gained traction in biomedical imaging for both clinical and preclinical applications. In this work, we evaluate several state-of-the-art SR architectures and propose an improved variant of SwinIR [1] that incorporates spectral channel attention within the encoder to amplify frequency components critical for preserving minute bone microarchitectural features.

Methods

To evaluate SR performance for recovering bone microstructure, we trained several benchmark deep-learning SR models, along with our proposed spectral-attention model, on two high-resolution *ex-vivo* microCT datasets. The mouse dataset comprised 10 proximal tibiae acquired at 5 µm voxel size targeting trabecular bone. The rabbit dataset comprised 5 distal tibiae acquired at 7 µm voxel size targeting cortical porosity. Low-resolution (LR) inputs were simulated by downsampling the high-resolution scans and attenuating high-frequency components in the Fourier domain. Three SR scales (×5, ×6, ×7; 25-35 µm) were generated for the mouse dataset and four (×2, ×4, ×6, ×8; 14-56 µm) for the rabbit dataset.

Results

Deep-learning models demonstrated strong SR reconstruction performance, with our proposed model outperforming all state-of-the-art baselines. It successfully recovered fine trabecular structures in mice (Fig. 1a) and cortical pores in rabbits (Fig. 1b), closely matching ground truth (GT). Regional analyses showed consistent performance across distinct anatomical zones.

Discussion

The proposed model showed robust SR performance across anatomically distinct *ex-vivo* datasets, effectively reconstructing fine microarchitectural features even at coarse input resolutions. Future work will apply the model to real low-resolution *in-vivo* microCT and match it to corresponding high-resolution *ex-vivo* scans, enabling reduced radiation exposure and improved recovery of microstructural features typically lost to imaging artifacts.

Introduction

Anomalous aortic origin of the coronary arteries (AAOCA) is a rare congenital disease in which one of the coronary arteries may originate from the aorta but in an abnormal position. Often the diagnosis of AAOCA is incidental during examinations for other medical reasons, although in a significant proportion of the cases, the first manifestation of the disease, especially in young athletes, may be a sudden cardiac death event or a myocardial infarction [1]. So far, the recognition and the classification of the coronary anomaly is deeply operator-dependent and there is no a clinical standard practice. Hence, the aim of the current work is to develop an automatic AI-based pipeline able to standardize and optimize the diagnosis and screening process of the AAOCA pathologies.

Methods

A total of 274 patients underwent contrast-enhanced coronary CT angiography at two clinical centers. Expert operators manually segmented the resulting 3D images, which were then used to train a 2.5D neural network [2] for multi-class segmentation of the ascending aorta, the left ventricle, the pulmonary artery and the coronary arteries. To ensure robust and unbiased performance evaluation, a 5-fold cross-validation procedure was implemented. Leveraging the automated segmentations, a geometry based algorithm was developed to classify coronary anomalies. The pipeline consists in: i) analysis of the different components connected to the aorta; ii) recognition of left or right coronary artery and its originary sinus; iii) identification of the anomalous coronary course; iv) classification of the anomalous type.

Results

Segmentation performance is summarized in Table 1 and reported in terms of Dice Score, expressed as the median and interquartile range (IQR) of the results obtained across the five test sets of the cross-validation. While the performances of the geometrical-based classification algorithm are reported in Table 2

Discussion

The AI-based developed pipeline can reconstruct all the anatomy for a proper classification of the pathology. Moreover, the fully automatic geometrical algorithms proved to be able to classify properly the different kind of pathology, making the proposed tools very useful in clinical practice.

Images (Optional)

Table 1

Class	Dice Score Median (IQR)
Aorta	0.95 (0.1)
Lef Ventricle	0.96 (0.04)
Pulmonary Artery	0.61 (0.24)
Coronary Arteries	0.74 (0.12)

Table 2

	Accuracy	Precision	Recall	F1-score
Control vs. Pathology	0.99	0.98	1	0.99
Right vs. Left Coronary Artery	0.99	0.97	1	0.98
Classification	0.97	0.97	0.93	0.94

Hierarchical Deep Reinforcement Learning Coordinates I*n Silico* Agent-Based Cellular Functions of Bone Remodeling from Time-Lapsed I*n Vivo* Imaging

Ms. Sorour Khadivi, Mr. Jack J. Kendall, Dr. Gisela A. Kuhn, Dr. Friederike A. Schulte, Prof. Dr. Ralph Müller

Institute for Biomechanics, ETH Zurich, Zurich, Zurich, Switzerland

Introduction

A self-adaptive framework that enables *in silico* models to learn temporal behavior patterns and simultaneously adapt to subject-specific bone remodeling dynamics as assessed from time-lapsed *in vivo* imaging would greatly enhance computational modeling. Our previous micro-multiphysics agent-based (micro-MPA) bone remodeling model [1] successfully encoded biological rules for individual cell behaviors. However, it lacked a mechanism to coordinate the frequency and sequence of concurrent biological processes to simulate subject-specific remodeling. We employ a Hierarchical Deep Reinforcement Learning (HDRL) framework to precondition and optimize the coordination of cellular processes to enhance *in silico* remodeling rates.

Methods

The HDRL framework takes decisions at two levels of hierarchy; a top-level q-value function (meta-controller) identifies the remodeling phase, and learns a policy that maximizes expected extrinsic reward, while a lower-level network (controller) activates the optimal cellular functions to achieve the chosen phase goal [2]. This process iteratively trains the model to reach the target state. Extrinsic rewards are defined based on target bone formation rate (BFR), bone resorption rate (BRR), bone volume fraction (BV/TV), and spatial alignment of *in vivo* remodeling patterns, measured from time-lapsed *in vivo* micro-computed tomography (micro-CT) of the sixth caudal vertebrae of four ovariectomized (OVX) C57BL/6 mice [3]. *In vivo* measurements started at week 15 to simulate five weeks of bone loss (week 20).

Results

The HDRL-enhanced micro-MPA model reduced iterations by 66% to reach target bone structures (Figure 1a) through a more efficient preconditioning and dynamic switching between optimal cellular functions. As shown in Figure 1b, the HDRL-enhanced model improved BFR (by 65%) and BRR (by 21%) compared to the non-HDRL-enhanced *in silico* model. Additionally, inter-subject variation increased, indicating successful adaptation to subject-specific remodeling.

Discussion

This self-adaptive HDRL framework enabled the micro-MPA model to adapt to subject-specific remodeling dynamics while adhering to underlying biological rules. This adaptability paves the way for personalized treatment and drug development, allowing the *in silico* model to learn patient-specific remodeling responses and optimize therapeutic strategies, thereby improving *in vivo* imaging capabilities.

Images (Optional)

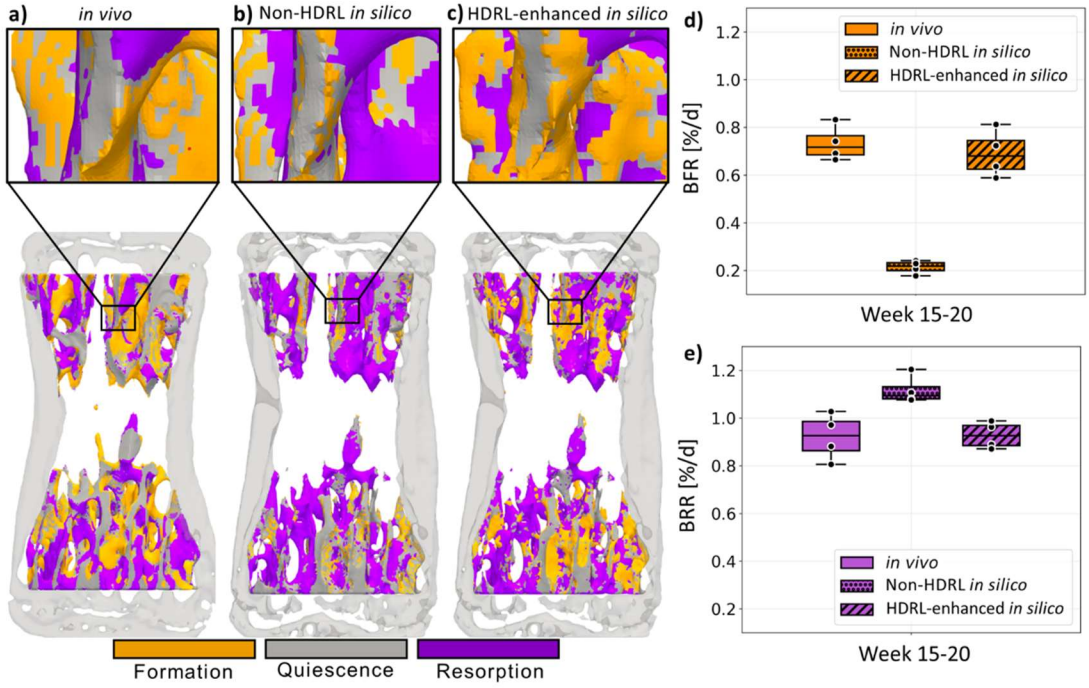

Figure 1: Visualizations of formation, quiescence, and resorption regions at week 15–20 of **(a)** the *in vivo* micro-CT, **(b)** the non-HDRL-enhanced *in silico* micro-MPA model, and **(c)** the HDRL-enhanced *in silico* micro-MPA model. The HDRL-enhanced *in silico* model shows improved alignment with *in vivo* **(d)** BFR and **(e)** BRR.

The Influence of Cashier Workstation Arrangement on Muscular Demands in the Upper Extremity

Dr Clark Dickerson, Ms. Oliva Szczepanek, Mr. Aidan Armitage, Ms. Alexandra Blandford, Mr. Alireza Karimi, Dr. Alan Cudlip

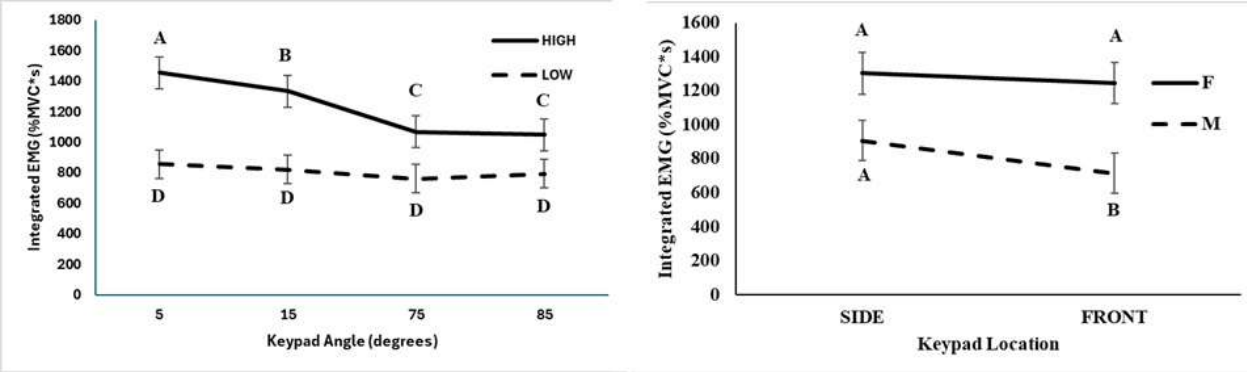
University of Waterloo, Waterloo, ON, Canada

Introduction

Occupational disease is common in environments that feature repetitive work. Grocery cashiers are susceptible as they often experience repetitive strain injuries due to the awkward postures and poor workstation design encountered in their work.[2] These overuse injuries are often affect the upper extremities, where up to 51% are shoulder disorders.[3] While previous research indicated high workstation height, bagging plastic or reusable bags and high workstation intensity contribute to shoulder disorders,[1] little research has been conducted on upper extremity loading related to input device use in cashiers. The purpose of this study was to 1) identify differences in postures, muscle activation strategies and perceived effort and discomfort across emulative workstation setups and 2) quantify kinematic and activation changes between planar and oblique keyboard orientations.

Methods

40 healthy, right handed university-aged individuals (20M, 20F) completed scanning and keypad entry tasks in two workstation orientations (keypad in front of the participant, keypad to the right of the participant), two keypad heights (low, high) and four keypad angles (5/15/75/85° from horizontal). Activity of 16 upper extremity muscles was collected through surface electromyography (sEMG) electrodes, sampled at 1500 Hz. Perceived exertion was also recorded for each task condition. An analysis of variance (ANOVA) evaluated the influence of task conditions on muscle activation and perceived discomfort and exertion scores.



Results

Keypad height and location interacted to influence upper trapezius activity (Figure), and females generally had higher middle deltoid requirements, particularly for higher keypads (Figure). Higher discomfort was generally reported (2-3x) for the shoulder than other body regions, and for right keypad orientations (1.5-2x).

Discussion

The placement of keypads within the cashier workstation had profound influences on muscular demands, and these demands were influenced by interactions with sex for several muscles. Generally, high keypad placements combined with more horizontal orientations increased muscular demands, and females experienced overall more muscular demands for the same task. Adjustability should be considered in workstation design, particularly for those occupational environments with many female workers.

Effects of Hand Dominance, Sex, and Fatigue on Shoulder Muscle Synergies During a Repetitive Overhead Task: A Preliminary Study

Dr. Yiyang Chen[1,2], Dr. Erika Renda[1], Dr. Julie Côté[1,3]

[1]McGill University, Montreal, Quebec, Canada. [2]The University of Memphis, Memphis, Tennessee, United States. [3]University of Ottawa, Ottawa, Ontario, Canada

Introduction

Previous studies have shown arm- and sex-specific effects of fatigue on shoulder muscle electromyography (EMG). However, no previous studies have quantified how muscles coordinate into synergies as a function of arm and sex. This study aimed to investigate how hand dominance, fatigue and sex influence shoulder muscle synergies during a repetitive overhead fatiguing task.

Methods

Thirty right-handed healthy young adults (15 females) performed a repetitive overhead shoulder flexion task until fatigue, as determined by the Borg CR-10 scale, using the dominant arm in one session and the non-dominant arm in the other. Surface EMG signals were recorded using the Delsys system (2000 Hz) from the upper and lower trapezius, the anterior, middle and posterior deltoid, pectoralis major, latissimus dorsi, and biceps brachii muscles, and intramuscular EMG signals were collected from the supraspinatus, infraspinatus, and subscapularis.

Non-negative matrix factorization method was used to extract muscle synergies. K-means clustering was applied to functionally classify synergies based on the center of activity and full width at half maximum of the activation coefficients and synergy structures. Cosine similarity analysis was performed to compare synergy structures.

Results

In the dominant arm, females showed an unchanged number of synergies with fatigue, while males showed increased synergies with fatigue. In the non-dominant arm, females showed increased muscle synergies, while males showed a decrease. The functional clustering rate of each synergy was below 80% across all groups (Table 1).

Discussion

The overall low clustering rate suggests that the extracted synergies did not converge into consistent patterns and therefore could not be reliably clustered into the same functional roles. Future work should incorporate larger samples, consider more functionally constrained tasks (e.g. load-bearing overhead reach), and explore other clustering approaches. Results also suggest the presence of sex differences in how laterality impacts the formation of arm synergies and how they respond to fatigue. Although these results are consistent with known sex differences in mechanisms of shoulder fatigue and injury, these interpretations should be made with caution, as the functional roles of each synergy must be established first.

Images (Optional)

Table 1. Synergy clustering rate and extracted synergy number across hand dominance and fatigue conditions in both sexes.

Group	Synergy clustering rate	Synergy number
Non-dominant arm_Female_Fatigued condition	Synergy 1 = 40% Synergy 2 = 53% Synergy 3 = 53% Synergy 4 = 27%	4
Non-dominant arm_Female_Non-fatigue condition	Synergy 1 = 20% Synergy 2 = 40% Synergy 3 = 53%	3
Dominant arm_Female_Fatigued condition	Synergy 1 = 50% Synergy 2 = 43% Synergy 3 = 50%	3
Dominant arm_Female_Non-fatigue condition	Synergy 1= 43% Synergy 2 = 43% Synergy 3 = 79%	3
Non-dominant arm_Male_Fatigued condition	Synergy 1 = 36% Synergy 2 = 50% Synergy 3 = 29%	3
Non-dominant arm_Male_Non-fatigue condition	Synergy 1 = 57% Synergy 2 = 57% Synergy 3 = 57% Synergy 4 = 29%	4

Interaction Forces at the Pelvis–Belt Interface of a Passive Shoulder Exoskeleton and Their Effect on Lumbar Joint Loading

Dr Chris Hayot[1], Mr Olivier Morel[1], Mr Etienne Ricard[1,2], Dr Kévin Desbrosses[1], Dr Charles Pontonnier[2]

[1]French National Research and Safety Institute for the Prevention of Occupational Accidents and Diseases, Vandoeuvre-lès-Nancy, Grand Est, France. [2]ComBO research team, Université de Rennes, Inria, CNRS, IRISA-UMR 6074, Rennes, Bretagne, France

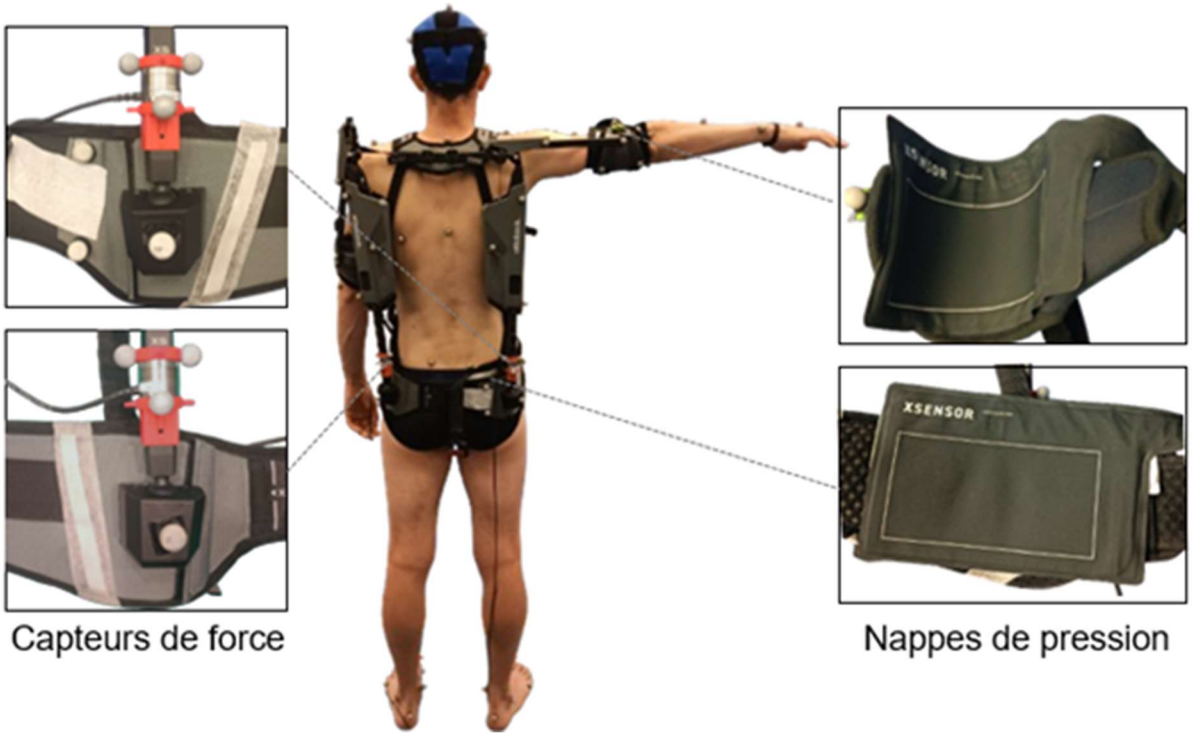
Introduction

The increasing use of industrial exoskeletons aims to reduce workers' exposure to biomechanical risk factors associated with musculoskeletal disorders. Passive upper-limb exoskeletons effectively decrease shoulder loading during overhead work [1], yet recent studies report unintended mechanical consequences linked to their passive structures and force-transmission pathways [2]. Because assistance is generated distally but transmitted proximally through the pelvic belt, additional loads may arise at the lumbar spine. While shoulder assistance mechanisms are well described [3], proximal load redistribution remains poorly understood [4]. This study therefore measured interaction forces at the pelvis–belt interface of a passive shoulder exoskeleton and evaluated their contribution to lumbar joint loading.

Methods

Eight healthy adults performed ten cycles of shoulder flexion without and with the exoskeleton, which included four assistance levels presented in randomized order. Whole-body kinematics were captured using a 16-camera motion-capture system with 59 body markers and 32 exoskeleton markers. Belt interaction forces were recorded via two six-axis load cells, and pressure sensors identified contact locations. Lumbar joint moments were estimated using OpenSim 4.5 [5] from kinematics and external forces, including modeled humeral forces. Statistical Parametric Mapping assessed condition and assistance-level effects on force measures and lumbar moments.

Results



Belt interaction forces increased with exoskeleton arm opening and assistance level, while pressure center remained stable. Belt forces significantly altered lumbar loading, reducing flexion moments and progressively increasing extension, lateral bending, and axial rotation

moments across most of the movement cycle, indicating substantial assistance-dependent redistribution of lumbar joint mechanics.

Discussion

This study quantified pelvis–exoskeleton interaction forces during dynamic arm elevation and showed that belt forces increased with arm opening and assistance level, reflecting the device's torque-generation mechanism. These measurements provide the first full three-dimensional description of pelvic loading for this type of passive exoskeleton. Exoskeleton use also altered lumbar joint moments, with higher assistance levels progressively increasing extension, lateral bending, and axial rotation moments, indicating compensatory trunk loading. These findings align with reports of increased proximal joint moments due to reaction forces at support interfaces. Overall, the results highlight the need for models that integrate realistic interface forces to better predict mechanical side effects.

The Long & Short of It: Vertical Range & Load Impact Effort Durations of Lifting & Lowering Tasks

Miss Gillian Slade MHSc Candidate[1], Mr Michael Watterworth PhD Candidate[1], Miss Hayley Janes BHSc[1], Dr Jim Potvin PhD[2], Dr Nicholas La Delfa PhD[1]

[1]Ontario Tech University, Oshawa, Ontario, Canada. [2]Work(s) Ergo Inc, Tecumseh, Ontario, Canada

Introduction

Shoulder injuries are one of the most costly workplace musculoskeletal injuries, yet few ergonomics assessment tools evaluate shoulder risk in manual materials handling. One approach uses estimates of arm strength with corrective equations to control for the fatiguing effects of task repetition. To utilize this approach, both task frequency (e.g., lifts/min) and the effective duration of each effort (seconds/lift) must be known. Task frequency is straightforward to determine, but effective duration is difficult to measure in applied settings, and limited empirical data are available for lifting and lowering. As such, this study investigated how vertical range and load influence effective duration during two-handed lifting and lowering tasks.

Methods

Twenty-one healthy adults (12F, 9M; aged 18–30) with no recent upper/lower extremity injury completed 72 bilateral lifting and lowering trials (3 loads × 6 vertical ranges × 2 directions × 2 repetitions). A custom-built box with an embedded force transducer recorded force–time histories. Trials were block-randomized by vertical range, with rest periods to mitigate fatigue. Effective duration was calculated by dividing the impulse of the force–time curve by the smoothed peak force. A four-way ANOVA examined effects of vertical range, hand load, trial number, and action type (lift vs. lower). Tukey post hoc tests identified significant pairwise differences ($\alpha = 0.05$).

Results

Heavier loads produced significantly longer effective durations across all conditions (Figure 1). Lowering required slightly longer durations than lifting (~3% on average). This effect increased at higher vertical ranges. For example, in the knuckle-to-overhead condition, lowering the 23-lb load required 22% longer effective duration than lowering the 8-lb load, whereas the corresponding lifting difference was 10%.

Discussion

Vertical range influences effective duration, and therefore the duration of muscular effort. Interestingly, lifting in the shoulder-to-overhead range (51cm) took slightly longer than the 102 cm floor-to-shoulder range, particularly with heavier box weights. This is possibly due to less favourable joint postures associated with elevated arm positions. Load magnitude further amplified differences across ranges, indicating prolonged upper-limb mechanical loading at higher elevations. These findings provide needed empirical force-time data and effort-duration values to improve analysis of upper-limb manual materials-handling tasks.

Implanted Microscaffolds Can Control the Mechanobiology of Fibrotic Progression

Prof. Claudio Conci[1], Dr. Alberto Bocconi[1], Mr. Leonardo Cherubin[1], Dr. Chiara Martinelli[1], Ms. Giada Mainieri[1], Ms. Giulia Lodola[1], Prof. Emanuela Jacchetti[1], Mr. Matteo Vicini[1], Dr. Alessandra Nardini[2], Dr. Rebeca Martinez-Vazquez[2], Prof. Manuela Raimondi[1]

[1]Department of Chemistry, Materials and Chemical Engineering "Giulio Natta", Politecnico di Milano, Milan, Lombardia, Italy. [2]Istituto di Fotonica e Nanotecnologie (IFN)-CNR, Milan, Lombardia, Italy

Introduction

While genetic mutations initiate breast cancer, tumor progression is mostly influenced by changes in tissue mechanical microenvironment, related to fibrosis. Its progression promotes tumor stiffening. The embryonated avian egg chorioallantoic membrane (CAM), a unique alternative model, allows for real-time imaging of fibrosis in an in-vivo organism. In this work, we used a CAM model to recreate three different progression states of a foreign-body reaction, at a single timepoint and implantation site. We used nonlinear microscopy to quantify in-vivo matrix stiffness and vascularization within the fibrotic microenvironments, consisting of implanted microscaffolds, repopulated by the host cells and blood vessels (Fig1a).

Methods

We produced three sets of microscaffolds on the same glass coverslips (Ø=12mm), shaped as grids with a pore size of 10x10μm^2,30x30μm^2,50x50μm^2, 80μm height, by using two-photon polymerization of SZ2080. We implanted this array in live chick embryos, and we conducted the CAM assay 7 days post-implantation, as previously described by our group [1]. Ex-ovo inspection of the imaging window was performed using two-photon microscopy and second harmonic generation (SHG) imaging.

Results

Microscopy analyses at the implantation sites in chick embryos (Fig.1b,c) revealed tissue infiltration inside and around the microscaffolds. Neo micro vascularization inside the scaffolds highlighted capillaries 10 times shorter, 1.4 times thinner from the inner to the outer part of the scaffold and 200 and 17 times shorter and thinner, respectively, compared to unimplanted samples, (Fig.1d). In the 50x50μm^2 microcapillaries had a vascular density 2.9-fold greater compared to the ones in the 30x30μm^2, and 200-fold greater than in the

10x10μm^2. SHG revealed the presence of a collagen-I layer that was preferentially orientated and had a density significantly lower than in peri-implant areas, and greatly varying with scaffold type.

Discussion

Microscaffolds successfully reproduced different levels of fibrotic progression, mimicking tumor-associated stroma by regulating collagen synthesis and revascularization. The differences in vascular density and collagen content, across scaffold types, replicated microenvironments with three increasing levels of fibrosis, likely driving breast cancer progression. This study validates the embryonated avian egg as a versatile platform for modeling fibrosis, allowing real-time, ethical, and cost-effective imaging compared to in-vitro and mammalian models.

Images (Optional)

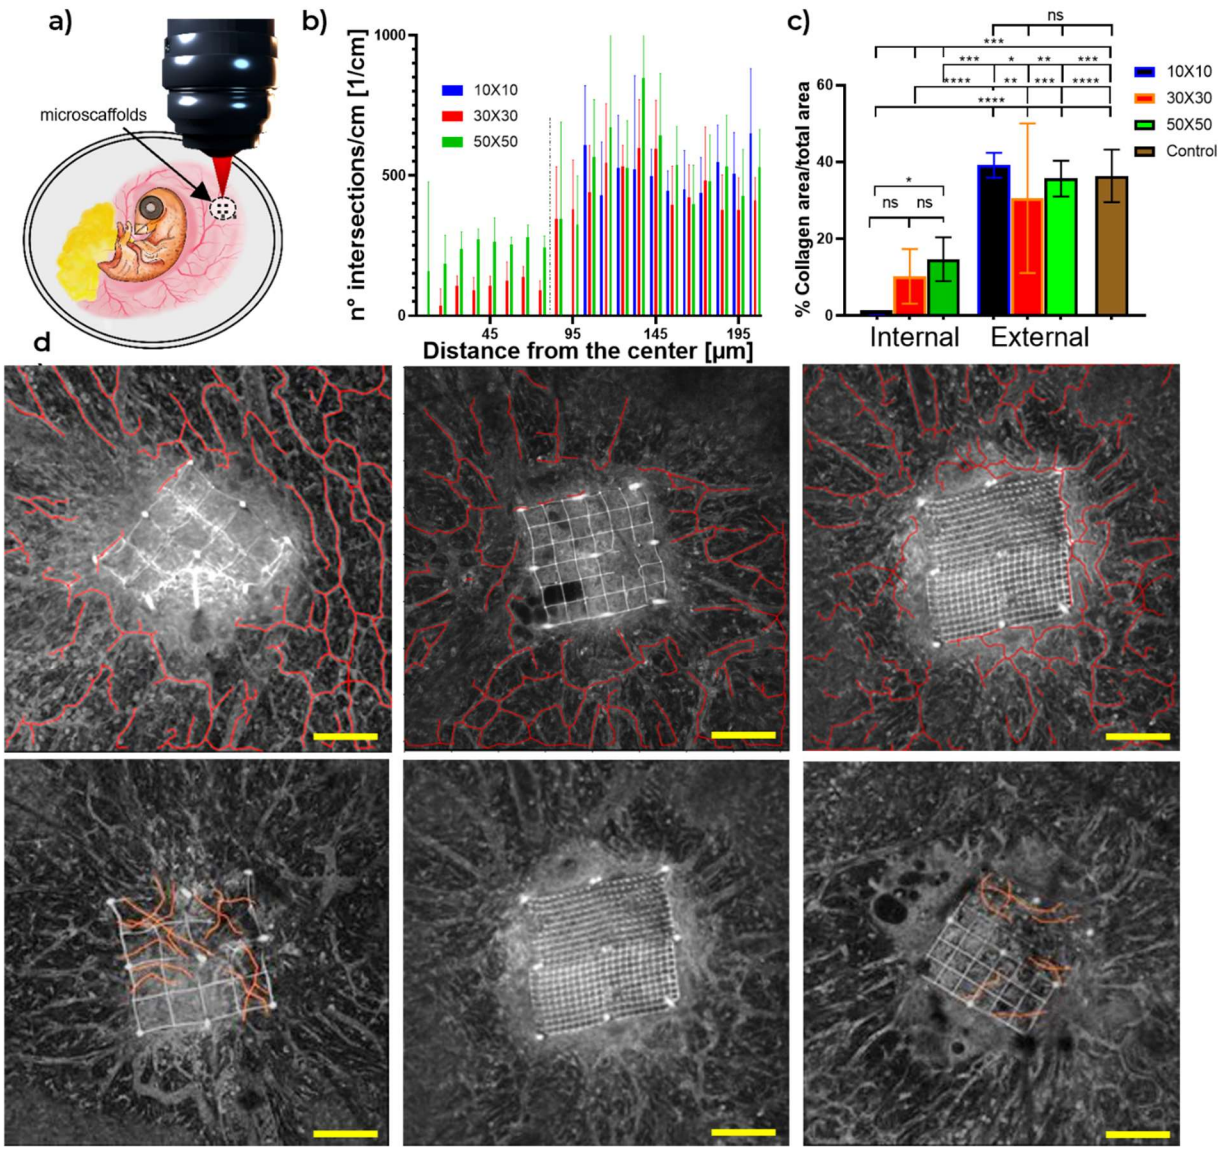

Fig.1. (a) Representation of the assay. (b) Blood vessels density in the microscaffolds and surrounding tissue (number of intersections per test line). (c) Inspected volume occupied by collagen fibers (SHG). (d) Microscaffolds implanted in the CAM taken under TPEF (λ_{Ex}= 910 nm, λ_{Em}:535/50 nm) at EID14 (scalebar = 100 µm).

Microneedles Patch With Tunable Stiffness Regulates wound Scar-Free Repair

PhD Candidate Danli Chen, Professor Xufeng Niu

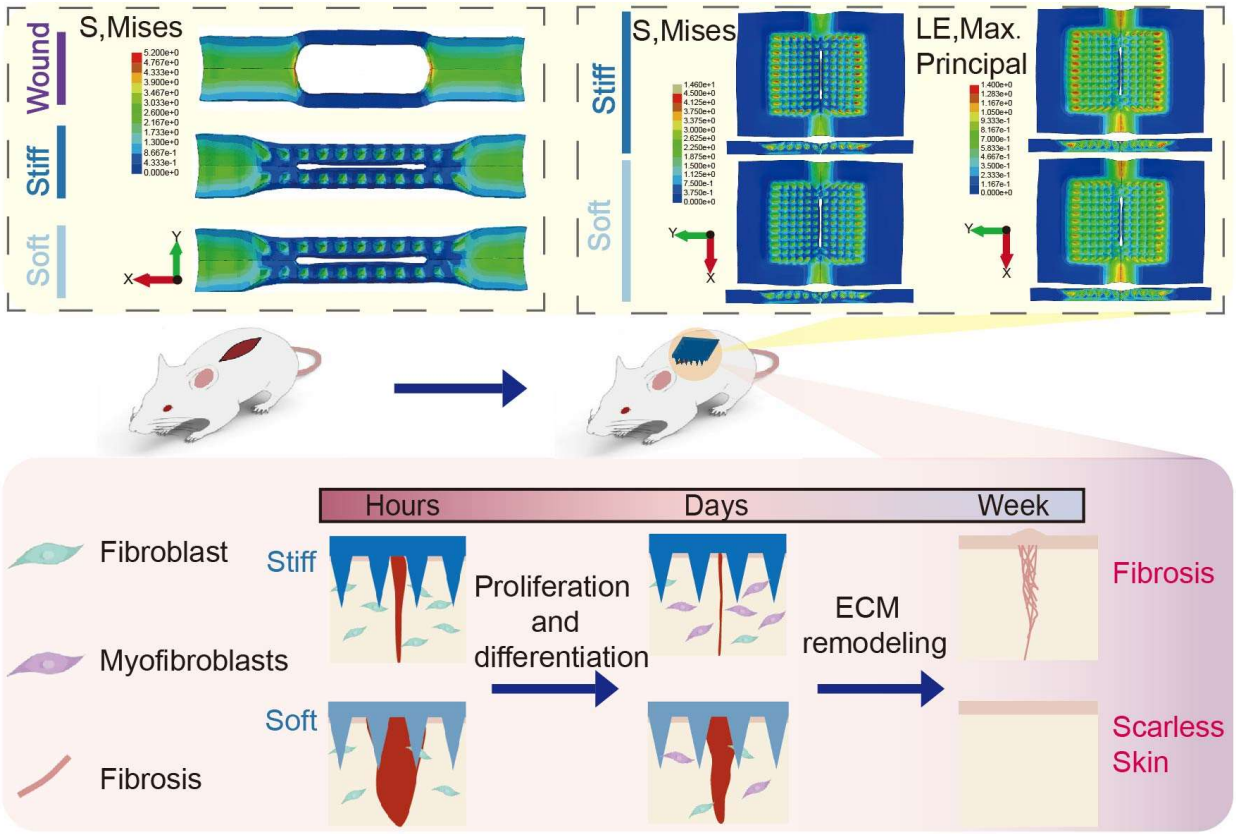
Beihang University, Beijing, Beijing, China

Introduction

The application of microneedles (MNs) as a mechanotherapy strategy to modulate mechanical microenvironment of wounds has garnered increasing attention. However, the influence of mechanical properties of MNs on wound healing and fibrosis remains underexplored.

Methods

In this study, we developed a MNs patch composed of genipin cross-linked carboxymethyl chitosan (CMCS) and examined how variations in patch stiffness influence wound healing and fibrosis. To assess mechanical environment improvement, we constructed a finite element model of MNs patch-closed wounds (n=4). Additionally, *in vivo* wound-healing experiments (n=4) and *in vitro* co-culture studies (n=3) were performed to elucidate the mechanisms by which MN-mediated modulation of the mechanical microenvironment influences wound repair.



Results

MNs patches were fabricated through mold casting. The mechanical properties varied with the degree of crosslinking. In the dry state, stiff MNs exhibited a Young's modulus of 499.45 ± 61.73 MPa, compared with 255.36 ± 77.55 MPa for soft MNs. Results from the finite element modelling simulations revealed that stiff MNs patch better reduced wound area but also elevated stress in peri-wound area. Via *in vivo* experiments and co-culture experiments with fibroblasts, we confirmed that stiff MNs patch accelerated wound closure ($3.55 \times 10^{-2} \pm 8.81 \times 10^{-3}$) than soft MNs patch ($5.38 \times 10^{-2} \pm 3.68 \times 10^{-3}$, $p=0.029$), but promoted fibroblast proliferation ($8.70 \times 10^{-1} \pm 9.32 \times 10^{-2}$ for stiff MNs and $6.60 \times 10^{-2} \pm 2.28 \times 10^{-3}$ for soft MNs, $p<0.0001$) and myofibroblast differentiation ($0.58 \pm 6.85 \times 10^{-3}$ for stiff MNs and $0.44 \pm 1.14 \times 10^{-2}$ for soft MNs, $p<0.0001$), contributing to fibrosis. In contrast, soft MNs patch facilitated scar-free repair, and the height of wound applied with soft MNs patch achieved comparable thickness to normal skin (h_{MNsoft}=1493.24 ± 74.70 μm, h_{normal}=1581.58 ± 57.88 μm, $p=0.528$).

Discussion

In conclusion, MNs patches promote wound healing, stiffer MNs patches are more effective during initial stages of wound healing, whereas softer patches are preferable for minimizing fibrosis in later stages. These findings underscore that MNs' mechanical properties must be carefully tailored to balance early-stage repair efficacy with long-term goal of scar-free healing.

Nanovibrational Control of Chondrogenic Differentiation

Miss Ioanna Rigou PhD Researcher, Dr Rosalia Cuahtecontzi Delint Research Associate, Dr Monica Tsimbouri Research Technologist, Prof Manuel Salmeron-Sanchez Professor of Biomedical Engineering, Prof Mathew Dalby Profesor of Cell Engineering

University of Glasgow, Glasgow, Scotland, United Kingdom

Introduction

Osteoarthritis (OA) is a prevalent degenerative joint disease, and current treatments cannot restore the structure or mechanical function of damaged articular cartilage. Its limited repair capacity means that both surgical and TGFβ-based tissue-engineering approaches often produce fibrocartilage and induce hypertrophy. These limitations highlight the need for personalized, growth factor-free strategies capable of generating durable hyaline tissue. This study investigates nanoscale vibrational mechanostimulation (Nanokicking) as a clinically scalable approach to promote collagen II while suppressing collagen X in OA-derived BMMSCs.

Methods

The study followed an engineering-driven comparative design evaluating how nanoscale vibrational stimulation (30 nm, 1 kHz) modulates the mechanobiological behaviour of STRO-1^+ osteoarthritic BMMSCs. Donors ranged from 21-year-old males to 90-year-old females. Micromass responses were quantified by qPCR across ten donors, with mechanobiological characterisation integrating nanoindentation measurements with collagen II, collagen X and aggrecan expression profiles. Immunofluorescence imaging further revealed the spatial distribution of collagen within the constructs, completing the mechanobiological assessment. Bulk RNA sequencing on six donors (three male, three female) profiled the transcriptional pathways engaged under nanovibrational stimulation. Data were analysed using statistical approaches suitable for multi-donor mechanobiology studies.

Results

Across multiple OA donors, nanovibration increased SOX9, ACAN, and COL2A1 expression while suppressing COL10A1 at days 7, 14, and 21, confirmed at both the gene and protein level. Histology showed markedly enhanced proteoglycan deposition under NK stimulation. The mechanobiological behavior of the micromasses reflected these

molecular changes: NK cultures displayed a more compliant, hyaline-like viscoelastic profile than non-stimulated controls and remained significantly less stiff than TGFβ-treated micromasses ($p < 0.05$), consistent with a non-fibrocartilaginous phenotype. RNA sequencing revealed dynamic ECM-organisation changes and implicated BMP and Wnt signaling as potential regulators of the COL2A1-dominant, non-hypertrophic program. Together, these findings demonstrate that nanoscale vibration drives BMMSCs towards a mechanically and molecularly stable hyaline-like phenotype, supporting its use as a growth-factor-free chondrogenic strategy.

Discussion

These findings support nanoscale vibrational stimulation as a promising biophysical strategy for generating stable, non-hypertrophic cartilage, aligning with the broader clinical need for growth factor–free and mechanically informed approaches to cartilage repair. In our next steps, inhibitors will be used to identify the possible mechanism that activates the chondrogenic phenotype.

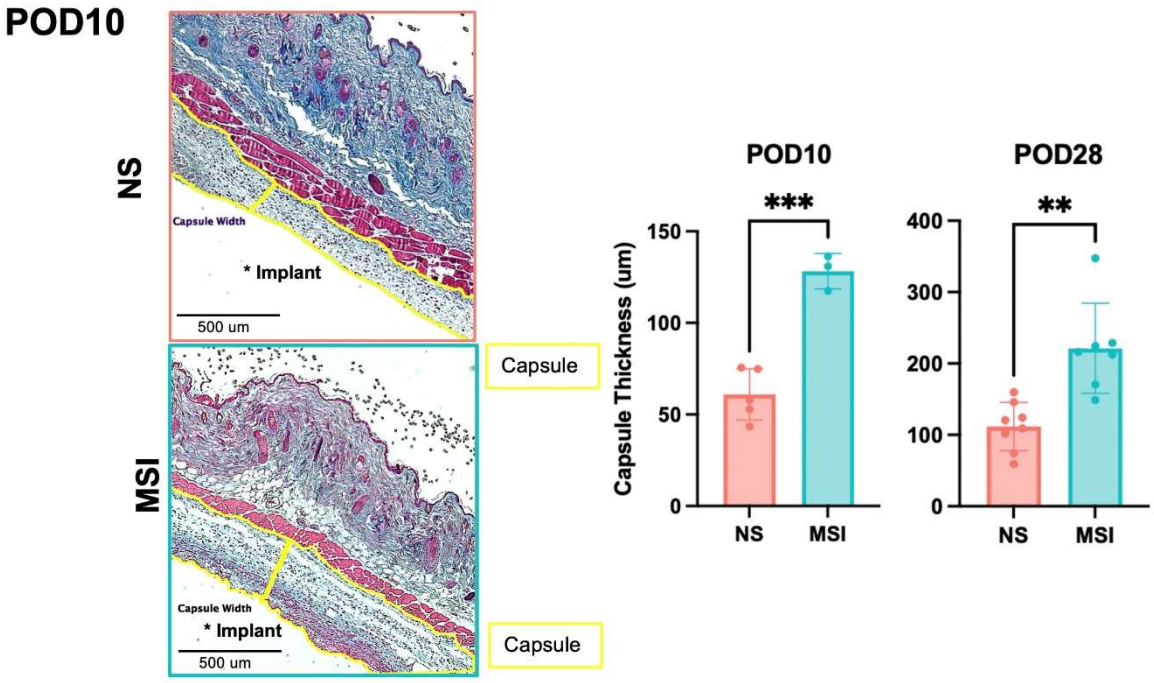
Introduction

Implantable biomedical devices are a hundred-billion-dollar industry [1]. These devices often fail after implantation due to the foreign body response (FBR), in which the body's immune reaction creates a fibrotic encapsulation of the device. Although we have demonstrated that external tissue mechanical forces promote severe FBR in mice and humans, the underlying cellular mechanisms remain incompletely understood [2].

Methods

We engineered a novel, wirelessly powered mechanically stimulating implant (MSI) to increase extrinsic tissue mechanical forces and promote human-like FBR in mice. 30 wild type (WT) and 6 Rac2 knockout (KO) mice received devices with no-stimulation (NS) or MSI, and fibrotic capsules were collected at postoperative day (POD) 10, 28. We performed single cell RNA sequencing (scRNA-seq) on mild and severe FBR (n=3) human breast implant capsule tissue. We compared these samples to previously published murine data. We virtually screen small molecule drugs that could specifically target RAC2. MSI WT mice were injected subcutaneously with 10 mg/kg dose of RAC2-specific inhibitor (RAC2i) daily for 10 days.



Results

MSI WT mice at POD10 caused a 110.5% increase in capsule thickness from 60.90 um to 128.2 um (p = 0.0007) between NS and MSI. At POD28, MSI WT mice showed capsule thickness increasing by 97.9% compared to NS, from 111.8 um to 221.3 um (p = 0.0027). MSI Rac2KO mice decreased the capsule thickness by 45.0% compared to WT mice (p = 0.0016) at POD28. ScRNA-seq revealed that both severe human FBR and MSI murine capsules upregulated RAC2+ mechanoresponsive myeloid cells, with an increase in inflammatory and fibrotic pathways. MSI + RAC2i caused a 55.9% decrease in capsule thickness at POD10 (p = 0.001) and 43.4% decrease at POD28 (p = 0.014) compared to MSI treated with only saline.

Discussion

Our results demonstrate that wireless mechanical stimulation activates mechanosensitive immune pathways and exacerbates FBR. We identified a potential RAC2 specific inhibitor that is effective in reducing severe FBR. By uncovering the important genes and pathways we open new avenues for treating and preventing this reaction to biomedical implantable devices.

Two-Year Sheep *In Vivo* Study Of Porous Calcium Phosphate Implant Anchored By Ultrasonically Liquefied Polymer, For Sports Medicine Applications: Short-Term Micro-CT Bone Ingrowth Analysis

M.Sc. Alice Della Casa[1,2], med.vet. Benedikt Schluse[3], Dr. Marina Rubert[2], Prof.em. Dr.med.vet. Brigitte von Rechenberg[3], Dr. Jörg Mayer[2], Dr.med.vet. DVM, PhD Karina Klein[3]

[1]Swiss Federal Laboratories for Materials Science and Technology, St. Gallen, St. Gallen, Switzerland. [2]Surgical Fusion Technologies, Schlieren, Zurich, Switzerland. [3]Musculoskeletal Research Unit, University of Zurich, Zurich, Zurich, Switzerland

Introduction

Anterior Cruciate Ligament (ACL) tears are one of the major injuries in Sports Medicine, with common complications in reconstruction surgeries linked to poor osseointegration. A new graft fixation concept, consisting of a porous 3D-printed Calcium Phosphate (CaP) implant press-fitting the graft, is securely anchored to the cancellous bone with an ultrasonically liquefied polymer pin (SupraFusion®). An *in vivo* study to test the osseointegration in a pelvic model [1] in sheep is underway, and micro-CT data at early timepoints is evaluated in terms of bone ingrowth inside the structure.

Methods

Fourteen sheep were operated. Different material combinations were implanted in both iliac bones: a porous CaP implant (PC, Ø7x10mm: LithaBone™, Lithoz, Austria) made of beta-Tricalcium Phosphate (TCP) or Hydroxyapatite (HA), was anchored by SupraFusion using a polylactide pin (PLDLLA, Ø2.4x24mm: LR 706S Resomer®, Evonik, Germany). One sheep per survival group (at 8 (8w) and 26 (26w) weeks) was selected, and the HA and TCP implants (n=1) from a single pelvis side were imaged by micro-CT. Cross-sections at 9 different heights (Fig.1A, spaced by 1mm) were extracted, smoothed (median filter, σ=10) and segmented using python scripts. The average amount of ingrown bone in each PC, as fraction of the masked cross-section, was calculated (mean±SD%, n=9).

Results

Analysis of the cross-sections showed 16.64±2.55% bone ingrowth in TCP at 8w, and 20.03±8.23% at 26w. In the HA samples, the bone ingrowth was 7.98±2.24% at 8w and 22.5±3.58% at 26w.

Discussion

In both HA and TCP, there was an increase in the average bone fraction at 26w, compared to 8w. At 8w, there was more average bone in the TCP, and slightly more bone at 26w in HA, in which the bone fraction almost tripled. These data are supplementing bone morphometric analysis from histological sections by providing a qualitative 3-dimensional representation of bone ingrowth that can otherwise not be achieved. Further analysis at timepoints 52 and 104 weeks will be carried out to verify whether porous HA and TCP show promising osseointegration, making them candidates for graft fixation in ACL Reconstruction.

ACL Reconstruction is Associated with Significant Differences in Contralateral Tibial Morphology Compared to Controls

Mr. Matthew Milcsik BSE[1], Dr. Kareem Omran MD[1], Dr. Matthew Tao MD[1], Dr. Elizabeth Wellsandt PT, DPT, PhD[1], Dr. Kevin Dibbern PhD[1,2]

[1]University of Nebraska Medical Center, Omaha, NE, United States. [2]Children's Nebraska, Omaha, NE, United States

Introduction

Posterior tibial slope (PTS) is a commonly accepted risk factor for primary anterior cruciate ligament (ACL) injury and ACL reconstruction (ACLR) graft failure. Traditional single-parameter PTS measurements may inadequately capture complex 3D morphological variations influencing biomechanics and outcomes. Statistical shape modeling (SSM) quantifies anatomical variation and may aid understanding of morphological variance within PTS toward improving ACLR and PTS correction. The objective of this study was to apply SSM to evaluate contralateral limb morphology in ACLR patients compared to uninjured control morphology.

Methods

A total of 30 participants with knee MRI were analyzed: 10 unilateral ACLR (5 adolescent, 5 adult) and 20 controls (10 adult, 10 older adult). Contralateral limbs of individuals after ACLR were segmented to approximate premorbid tibial geometry. Iterative back projection was used to obtain super-resolution images from coronal and sagittal plane proton density scans (0.3mm isotropic). ShapeWorks was used to create SSMs of all tibiae and automated 3D measures of both medial and lateral PTS were computed in Matlab. Morphological variation was evaluated with principal component analysis (PCA) of correspondence particles and Horn's parallel analysis to identify significant shape modes. Normality checks and Student’s t- or Wilcoxon tests evaluated differences between ACLR and healthy knees.

Results

Parallel analysis retained 2 significant PCA modes explaining 67% of variance between tibiae. Mode 1 demonstrated subtle lateral PTS while mode 2 demonstrated more medial PTS and deepening of condyles (Figure 1). Mode 1 demonstrated no differences between ACLR and control component scores, while mode 2 identified significant differences between ACLR and control groups. No differences were found in medial or lateral PTS between groups but mode 1 was significantly correlated with lateral PTS.

Discussion

Significant 3D morphological variation beyond traditional PTS measurements was identified in ACLR patients versus controls. Differences included condylar depth, tibial spine position, and subtle PTS variations (<6°). Articulation size and depth may be associated with age-related changes in older controls, while PTS values were lower than previous reports. Future studies with larger sample sizes may aid stratification of graft failure risk and guide surgical corrections using SSM and automated 3D PTS measures.

Images (Optional)

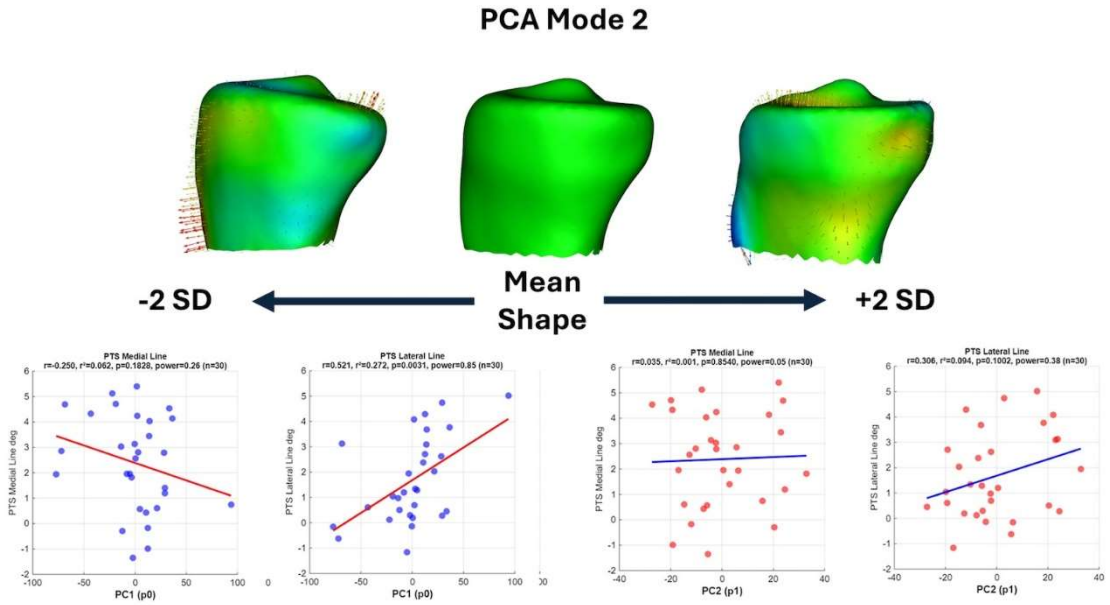

Figure 1. (Top) PCA mode 2 demonstrated posterior tibial slope (PTS) but was not significantly correlated with 3D PTS scores (bottom right, red dots with blue lines). PCA mode 1 was significantly associated with lateral but not medial PTS (bottom left, blue dots with red lines).

Meniscal Kinematics Following Posterior Medial Meniscus Root Repair with Adjustable All-Suture Anchor Aperture Fixation: A Cadaveric Biomechanical Evaluation

Dr. Clayton Nuelle MD[1], Dr. Garrett Jackson MD[1], Mr Will Bezold BS[1], Mr. Benjamin Smith MS[2], Dr James Cook DVM, PhD, OTSC[1]

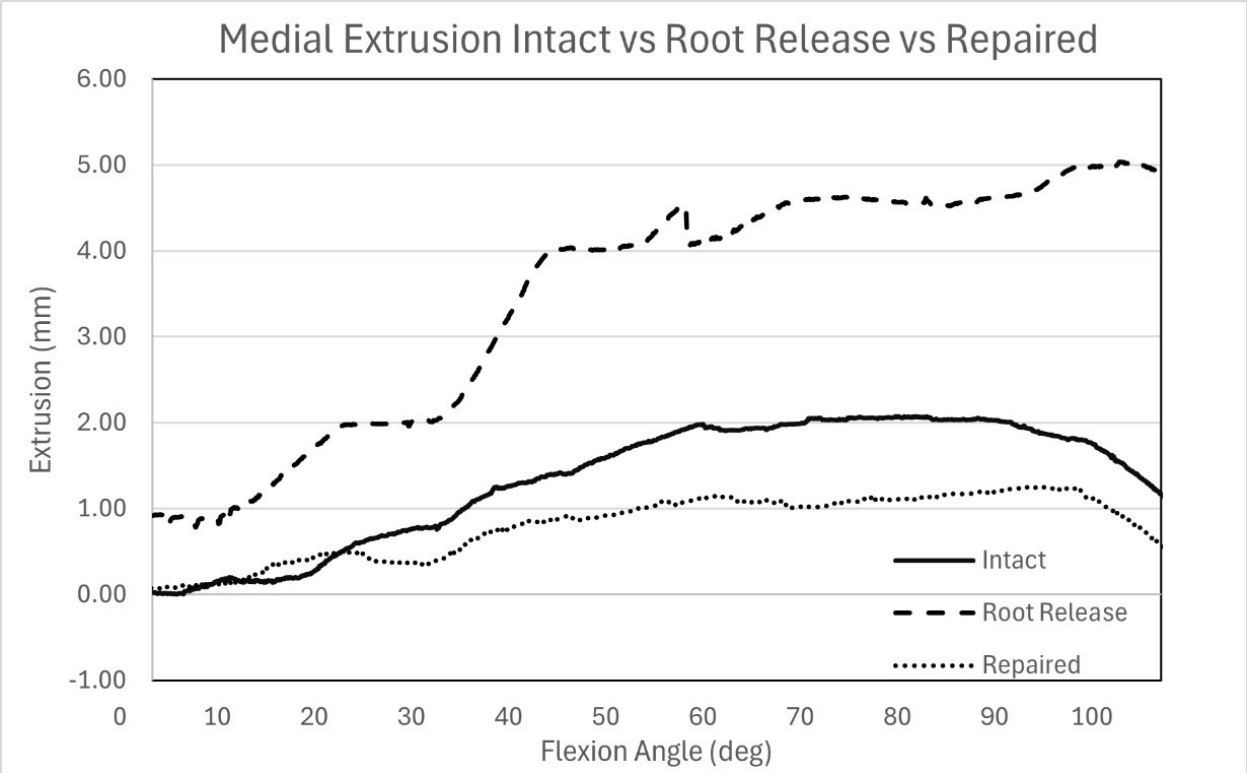
[1]University of Missouri, Columbia, MO, United States. [2]Arthrex, Inc., Naples, FL, United States

Introduction

Recent biomechanical evidence has demonstrated that, in the setting of posterior medial meniscus root (PMMR) tears, adjustable all-suture anchor (ASA) aperture fixation better restores native meniscal function compared to the gold-standard transtibial pull-through repair. However, these studies are limited to isolated meniscotibial loading models, and meniscal kinematics through loaded knee range of motion have not been investigated. It was hypothesized that ASA PMMR repair would restore meniscus translation similar to the native meniscus and maintain those parameters through a loaded cyclic knee flexion arc.

Methods

8 fresh-frozen human cadaveric knees (4 male, 2 female; mean age = 44.9) were tested. Meniscal translation was evaluated in each knee under 1) Intact, 2) PMMR release, and 3) PMMR repair conditions. Repairs were performed by one board-certified orthopedic surgeon and fixed with a knotless adjustable ASA device in a Mason-Allen configuration. In each condition, knees were axially loaded with 30 N of force through range of motion to test meniscus excursion, extrusion, and hoop strain at 0°, 30°, 60°, 90°, and 100° of flexion after 10 cycles. A 6-degree-of-freedom robotic testing platform was utilized. Statistical analysis utilized repeated-measures ANOVA or one-way ANOVA with Tukey post-hoc tests ($p<0.05$).



Results

Meniscal extrusion was significantly greater with PMMR release compared to the intact and repair conditions at 0° ($P<0.001$), 30° ($P=0.007$), 60° ($P<0.001$), 90° ($P<0.001$), and 100° ($P<0.001$). Extrusion in the repair condition was similar to, or less than, the intact condition across every flexion angle. Meniscus hoop strain in the repaired and intact conditions was significantly greater than in the PMMR release condition ($P<0.001$). Meniscal excursion was significantly greater with PMMR release compared to intact and repair conditions at 30° ($P=0.001$). However, excursion was significantly lower in the intact state at 60° ($P=0.021$) and 100° ($P=0.018$) compared to PMMR release and repair states.

Discussion

The results confirm the hypothesis that PMMR repair with adjustable ASA aperture fixation restores intact meniscal translation following a PMMR tear. This study provides clinically relevant full-construct evidence that builds upon existing in vitro models supporting novel aperture PMMR fixation. The findings could potentially afford accelerated post-surgical rehabilitation in pair with clinical evidence.

Integrating Computational Modeling and Quantitative MRI to Relate Knee Instability and Longitudinal Changes in ACL Graft Composition: A Framework to Understand Mechanisms of Early Graft Failure

Ms. Isabella Gomez Hjerthen BS, Ms. Erin Berube BS, Mr. Jack Consolini MS, Ms. Elizabeth Koretsky MS, Mr. David Shamritsky MS, Ms. Deborah Jones PT, OCS, SCS, Dr. Theresa Chiaia PT, DPT, Dr. Andrew Pearle MD, Dr. Thomas Wickiewicz MD, Dr. Scott Rodeo MD, Dr. Danyal Nawabi MD, FRCS, Dr. Hollis Potter MD, Dr. Matthew Koff PhD, Dr. Carl Imhauser PhD

Hospital for Special Surgery, New York, NY, United States

Introduction

Graft failure is a devastating complication that occurs in up to 18% of young athletes undergoing primary anterior cruciate ligament reconstruction (ACLR). Instability of the ACL-deficient knee, graded via subjective clinical pivot shift exam, is related to graft failure two years after ACLR. However, it is unclear whether pre-operative instability influences the graft's post-operative remodeling process, which may affect tissue quality and likelihood of failure. Our goal was to objectively assess pre-operative knee instability via computational modeling and relate it to post-operative changes in graft structure and composition from quantitative MRI.

Methods

Fifteen subjects (9 female; age: 23±7 years) undergoing primary ACLR were enrolled in this longitudinal study. To date, data have been collected for ten subjects at 6-weeks and six subjects at 6-months post-operatively. Ultra-short echo (UTE) images of the ACLR were acquired on a clinical 3T system: TEs/TR: 0.03-25ms (ΔTE=2.5ms) / 256.6ms; voxel size $0.31x0.31x1.5mm^3$. A mean T2* of graft voxels was calculated. Subject-specific bone, cartilage, and meniscus geometries, as well as ligament insertions, were integrated into an established computational knee modeling pipeline. Tissue properties were standardized. The tibia was flexed to 15°, and a pivot shift exam was simulated by sequentially applying compression (100N), valgus (8Nm), and anterior (30N) loads. Anterior tibial translation (ATT) and internal tibial rotation (ITR) were estimated at the peak applied loads. T2* values at 6-weeks and 6-months post-operative were compared using unpaired t-test (α=0.05). Changes in T2* from 6-weeks to 6-months post-operative were related to ATT and ITR using simple linear regression (R^2; α=0.05).

Results

Mean T2* increased by 4.3±1.8ms from 6-weeks to 6-months ($p<0.05$) (Fig. 1A). Interim analysis revealed a negative trend in the relationship between change in T2* and ATT ($p=0.064$), but not ITR (Fig. 1B, 1C).

Discussion

Our finding of increased T2* between 6 weeks and 6 months after ACLR is corroborated by previous imaging studies. Continued follow-up will clarify the potential relationship between change in T2* and pre-operative pivot shift instability, particularly ATT. Relating objective and quantitative measures of instability with noninvasive measures of graft structure and composition may help clarify why pre-operative instability affects risk of ACLR failure.

Images (Optional)

Risk of Lateral Extraarticular Tenodesis Graft Slippage Is Highly Sensitive to Femoral Anchor Location and the Flexion Angle at Which the Graft Is Anchored

Mr. Herman Feller MS, Dr. Molly Day MD, Dr. Joshua Roth PhD

University of Wisconsin-Madison, Madison, WI, United States

Mr. Herman Feller

Dr. Molly Day

Introduction

Adding a lateral extraarticular tenodesis (LET) graft to mitigate instability and anterior cruciate ligament (ACL) graft failure after ACL reconstruction (ACLR) is becoming more common. However, there is not wide spread agreement of key surgical parameters, including (1) the location the LET graft is anchored to the femur and (2) the flexion angle at which the graft is anchored. Prior literature has largely focused on how graft engagement varies when the joint is loaded, but it is possible that the combination of these two surgical parameters may lead to intraoperative graft slipping during a passive range of motion assessment. Thus, our objective was to determine which combinations of these two modifiable surgical parameters increase the risk of intraoperative LET graft slippage.

Methods

Using our established probabilistic modeling framework, we generated a virtual cohort of 3000 ACLR+LET patients with differing knee mechanics. We modelled an LET graft using the mechanical properties of the iliotibial band and randomly varied both the femoral attachment with respect to the LCL, and the knee flexion angle at which the LET graft was anchored. We then performed forward dynamic simulations of passive flexion from 0° to 90° to determine LET graft tension throughout flexion. Using the probability distributions previously reported for the failure load of common LET graft anchors, we computed the probability of graft slippage for each combination of femoral anchor location and flexion angle of LET graft anchoring.

Results

We found LET grafts anchored posteriorly to the LCL attachment with the knee in 30° to 90° flexion were at the highest risk of slippage. All LET grafts anchored at flexion angles between 0° and 30° had minimal risk of slippage (Figure).

Discussion

Our key finding that the risk of LET graft slippage was highly sensitive to both femoral anchor location and knee flexion indicates surgeons must consider these important decisions when planning and executing an LET to mitigate the risk the graft slippage that undermines the intended contribution of the LET. Slippage alters the engagement of the LET graft, which limits its ability to contribute to knee stabilization and offloading of the ACLR graft.

Images (Optional)

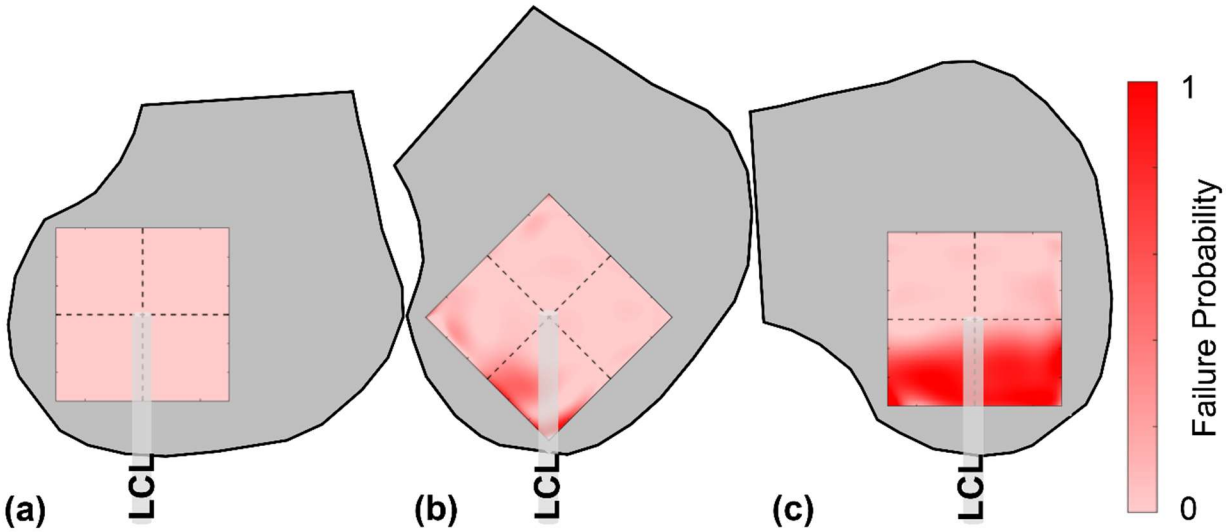

Figure 1: Heatmaps show the probability of LET graft slippage intraoperatively during passive flexion between 0° and 90° flexion for attachment locations spanning a 30 mm x 30 mm area centered on the attachment point of the LCL at fixation angles of (a) 0°-30° of flexion, (b) 30°-60° of flexion, and (c) 60°-90° of flexion.

Bonenet: Rapid and Clinically Feasible Femoral Neck Load Prediction Using Neural Network

Dr Zainab Altai[1,2], Dr Jason Moran[3], Dr Xiaojun Zhai[4], Dr Andrew T M Phillips[5], Dr Bernard X.W. Liew[3]

[1]School of Sport Rehabilitation and Exercises Sciences, , University of Essex, COLCHESTER, ESSEX, United Kingdom. [2]Institute of Public Health and Wellbeing, , University of Essex, COLCHESTER, ESSEX, United Kingdom. [3]School of Sport Rehabilitation and Exercises Sciences, University of Essex, COLCHESTER, Essex, United Kingdom. [4]School of Computer Science and Electronic Engineering, University of Essex, COLCHESTER, Essex, United Kingdom. [5]Department of Civil and Environmental Engineering, Imperial College London, London, London, United Kingdom

Introduction

Methods

Thirty-seven healthy, active participants (age 40.3 ± 13.1 y; height 1.7 ± 0.08 m; mass 68.4 ± 11.7 kg) were recruited with ethical approval. Motion-capture used 14 vicon cameras and 38 lower-limb markers, while seven IMUs on the trunk, shanks, thighs, and feet recorded accelerations and angular velocities. Participants performed walking, running, countermovement jump, squat jump, unilateral hopping, and bilateral hopping at three intensity levels.

MSK-FE models were generated in OpenSim and ANSYS to predict peak tensile and compressive FN strains. BoneNet, an eXplainable Convolutional Neural Network [3] in Python (Numpy v1.20.3, Pandas v1.3.4, Scipy v1.7.1), was trained on IMU data to predict these strains, using a 75/25% train/test split over 500 epochs with learning rates 0.1–0.2. MSK-FE strain data were outcomes; IMU signals were predictors. Peak strains were ranked and compared to walking to assess osteogenic potential, and BoneNet accuracy was evaluated via Pearson's correlation (r) and RMSE.

Results

Running at all intensities and low-intensity unilateral hopping produced significantly higher FN strains than walking (up to 47%, $p < 0.001$), whereas all other exercises generated lower peak strains (up to 175%) (Figure 1). BoneNet predicted strains with high accuracy, showing

strongest correlations during walking (r = 0.96) and lowest for squat jumps (r = 0.80), with a RMSE range of 145-551 με across exercises.

Discussion

Running at any speed and low-intensity unilateral hopping effectively stimulate FN osteogenesis, whereas bilateral jumps may not. Additionally, BONENET provide a practical, cost-effective method to monitor bone strain and support interventions to enhance bone health.

Images (Optional)

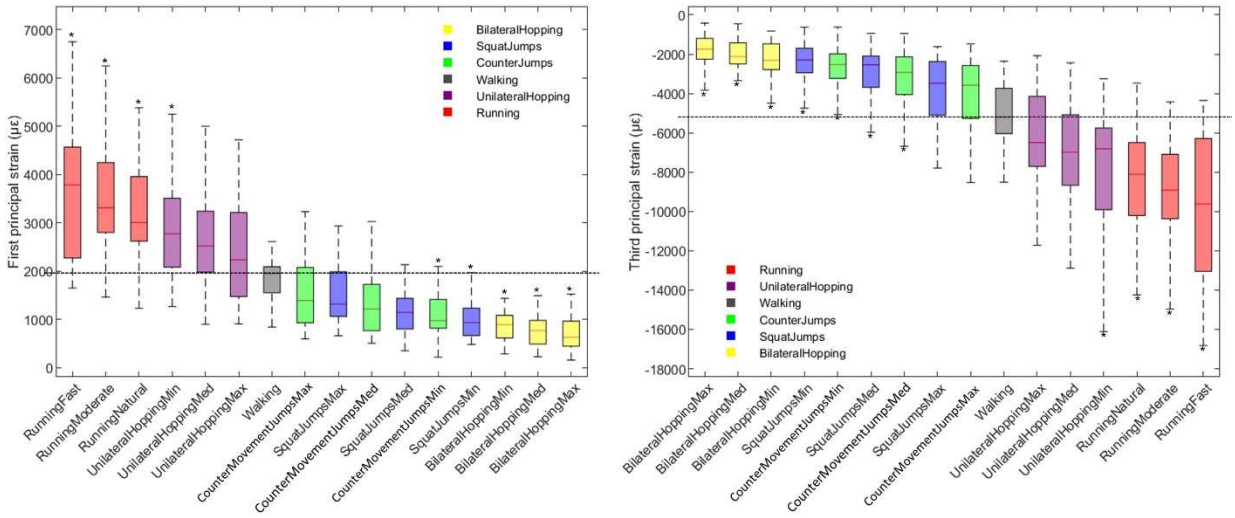

Figure 1. Box plot of large significant difference of peak first principal strain (left) and peak third principal strain (right) of the femoral neck under different levels of various dynamic exercises compared to walking at a self-selected speed indicated by the horizontal line. Asterisks denote the exercises with significant difference (*p < 0.05) compared to walking.

Postpartum Biomechanical Adaptations of the Linea Alba in a Rat Model: Implications for Diastasis Recti Abdominis in Women

Ms Mya Lax BSc, Ms Mary Morgan BSc, Ms Sabrina Sinopoli MSc, Dr Diane Gregory PhD

Wilfrid Laurier University, Waterloo, Ontario, Canada

Ms Mya Lax

Ms Sabrina Sinopoli

Introduction

The linea alba (LA) is a fibrous connective tissue that joins the rectus abdominis muscles and plays a critical role in abdominal wall integrity. Physiological changes, particularly during pregnancy, have been shown to disrupt this structure. As fetal growth increases the intra-abdominal pressure, the inter-rectus distance widens due to LA stretching. If this widening is substantial, it can result in the diagnosis of diastasis recti abdominis (DRA). This study aimed to identify these changes by evaluating LA tensile strength in abdominal tissue of rats at two time points postpartum.

Methods

Twenty Sprague-Dawley rats were tested: five 3-day postpartum, five 8-week postpartum, and 10 age-matched nulliparous. Three 7.5x7.5mm LA samples were dissected from the abdominal wall of each animal: one from the level of the umbilicus, one just cranial, and one just caudal to the umbilicus. These samples underwent tensile mechanical testing at a rate of 0.5%/sec until failure. An additional six animals (three nulliparous and three 3-days postpartum) were used for histological analysis of the LA.

Results

Yield point stress (p=0.0003) and maximum stress (p=0.001) of the LA were found to be higher in the 3-day postpartum compared to both nulliparous and 8-week postpartum animals. Stiffness was also found to be higher in the 3-day postpartum animals, though not significant (p=0.062). In corroboration of this finding, histology indicated greater connective

tissue between the rectus abdominis muscles of the 3-day postpartum animals compared to nulliparous (Figure 1).

Discussion

The elevated yield and maximum stress values in the 3-day postpartum samples indicate that the LA may adapt to withstand increases in abdominal wall tension late in gestation. The corresponding histological evidence of increased connective tissue further supports the idea that structural reinforcement occurs during this period. However, as the mechanical properties returned closer to nulliparous levels by 8-weeks postpartum, this suggests the remodelling is temporary and may serve a protective role by helping maintain abdominal wall integrity during and immediately after pregnancy. It is possible that individuals who experience DRA do not undergo the same degree or timing of this remodeling response, making the LA more susceptible to separation when mechanical demands are high.

Images (Optional)

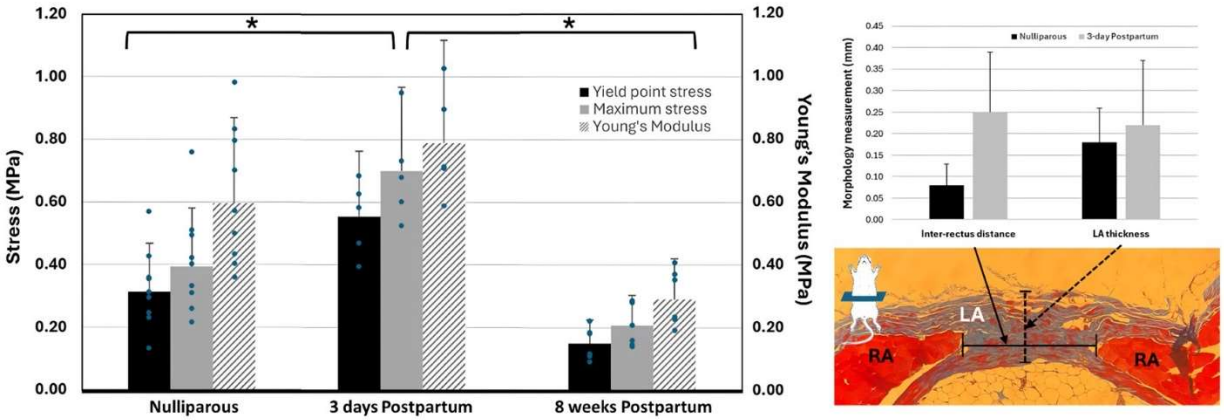

Figure 1. Left: Mean (±SD) yield point stress, maximum stress, and Young's modulus determined from tensile testing of the linea alba from control (nulliparous), 3-days postpartum, and 8-weeks postpartum animals. For all each variables, 3-days postpartum was higher than both nulliparous and 8-weeks postpartum. Right top: Mean (±SD) inter-rectus distance and linea alba thickness in the nulliparous (grey bars) and 3-day postpartum (black bars) sections. Right bottom: The inter-rectus distance and linea alba thickness measurements are shown in the representative histological image, with the rectus abdominis (RA) and linea alba (LA) labelled.

The Impact of Pregnancy on Hip, Knee, and Ankle Strength

Ms Kaitlyn Kleeman BS, Mrs. Maryam Golmohammadi MS, Dr. Amanda Paluch PhD, Dr. Sarah Roelker PhD

University of Massachusetts Amherst, Amherst, MA, United States

Introduction

Physiological and musculoskeletal changes occur during pregnancy, including increased body mass (1), fatigue (2), and joint laxity (3,4), which may contribute to falls. Muscle forces regulate balance during walking (5), however pregnancy-related changes in strength have only been evaluated in abdominal (6) and hip adductor (7) muscles, for which absolute strength decreased during pregnancy. This study aims to determine the effect of pregnancy on hip abductor and knee and ankle extensor strength. We hypothesized that strength at each joint would 1) decrease from the 2nd (P-T2) to 3rd (P-T3) trimester, and 2) be lower in pregnant (PREG) than age-matched nulligravida (NG) individuals, particularly in P-T3.

Methods

Isometric hip abductor, knee extensor, and plantarflexor strength was collected on a Biodex dynamometer in PREG (n = 17, 34 ± 4.3 yrs) at P-T2 and P-T3 and once in NG (n = 8, 34 ± 4.6 yrs). Participants performed three 5s contractions (15s rest between trials). Absolute strength was quantified as the maximum torque produced across all trials and relative strength was calculated by dividing absolute strength by body mass. For absolute and relative strength at each joint, paired t-tests assessed for differences between P-T2 and P-T3, while separate two-sample t-tests assessed for differences between NG and P-T2 and NG and P-T3 with Bonferroni Corrections.

Results

Relative knee extensor strength decreased from P-T2 to P-T3 (Fig. 1A). Compared to NG, PREG had significantly lower relative hip abductor strength at both timepoints (Fig. 1B). Despite no significant differences, large effect sizes (Fig. 1B) suggest PREG have potentially meaningfully lower normalized knee extensor strength than NG at both timepoints. Absolute strength did not differ between groups or timepoints at any joint.

Discussion

Decreased relative knee strength from P-T2 to P-T3 and lower relative hip strength in PREG compared to NG may influence balance regulation during pregnancy.

Images (Optional)

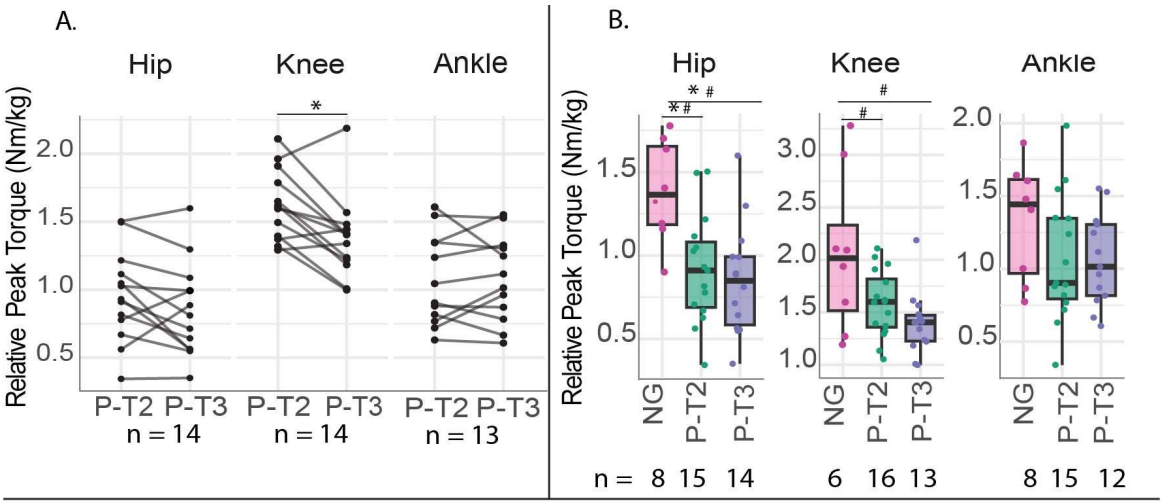

Figure 1: Body mass relative hip abductor, knee extensor, and ankle plantarflexor peak torques in nulligravida and pregnant individuals. (A) Within participant changes in relative peak torque form P-T2 to P-T3. A significant decrease in knee strength was observed from P-T2 to P-T3 ($p = 0.042$, Cohen's $d = 0.649$). (B) Boxplots of relative peak torque for NG, P-T2, and P-T3. Filled circles represent individuals. Compared to NG, hip strength was significantly lower in P-T2 ($p = 0.021$, Cohen's $d = 1.469$ and P-T3 ($p = 0.009$., Cohen's $d = 1.659$). Compared to NG, large effect sizes suggest lower knee strength in P-T2(Cohen's $d = 0.956$) and P-T3 (Cohen's $d = 0.739$). * denotes a statistically significant difference. # denotes a large effect size.

High-Functioning Older Adults Use Greater Muscle Contributions to Whole-Body Angular Momentum than Younger Adults to Regulate Balance

Mr. Nikolaj Freschlin M.S., Dr. Sarah Roelker Ph.D., Dr. Katherine Boyer Ph.D.

University of Massachusetts, Amherst, Amherst, MA, United States

Introduction

Balance is maintained by regulating the whole-body angular momentum (*H*) about the center-of-mass [1]. Older adults (OLDER) often have larger peak-to-peak ranges of *H* than younger adults (YOUNG), which indicates poorer balance control [2] and increased fall risk. Muscles regulate *H* by contributing to the net external moment (NetExtM) about the center-of-mass [3]. Identifying age-related changes in muscle contributions to the NetExtM may provide insight into balance mechanisms in OLDER. The purpose of this study was to compare individual muscle contributions to *H* regulation between YOUNG and OLDER.

Methods

Motion capture data of 5 YOUNG (37.4±3.2 years) and 5 OLDER (71.8±1.6 years) walking at their preferred speed (YOUNG: 1.4±0.2 m/s; OLDER: 1.5±0.1 m/s) were used to generate simulations in OpenSim [4]. OpenSim MoCoInverse [5] estimated muscle forces while tracking electromyography from 10 muscles. Muscle forces were used to calculate muscle contributions to NetExtM [3] in frontal and sagittal planes. The *H* range and integral of each muscle's contribution to NetExtM over stance were normalized to height, weight, and speed and compared between age-groups using independent samples t-tests ($\alpha<0.05$).

Results

H range did not differ in the sagittal plane; yet, OLDER had larger contributions to forward *H* from the medial hamstrings and gastrocnemius, and larger contributions to backward *H* from the rectus femoris, vasti, and tibialis anterior than YOUNG (Fig. A-B; $p<0.05$). OLDER had lower frontal *H* range than YOUNG ($p=0.043$) and larger contributions to *H* towards the contralateral leg from the gluteus maximus, vasti, and gluteus medius (Fig. C-D; $p<0.05$).

Discussion

Compared to YOUNG, OLDER used greater muscular effort to regulate similar sagittal plane and greater frontal plane H range. This greater muscular effort may be a cautious strategy to avoid falls by more tightly controlling balance regulation and may contribute to greater energy cost of walking in OLDER.

Images (Optional)

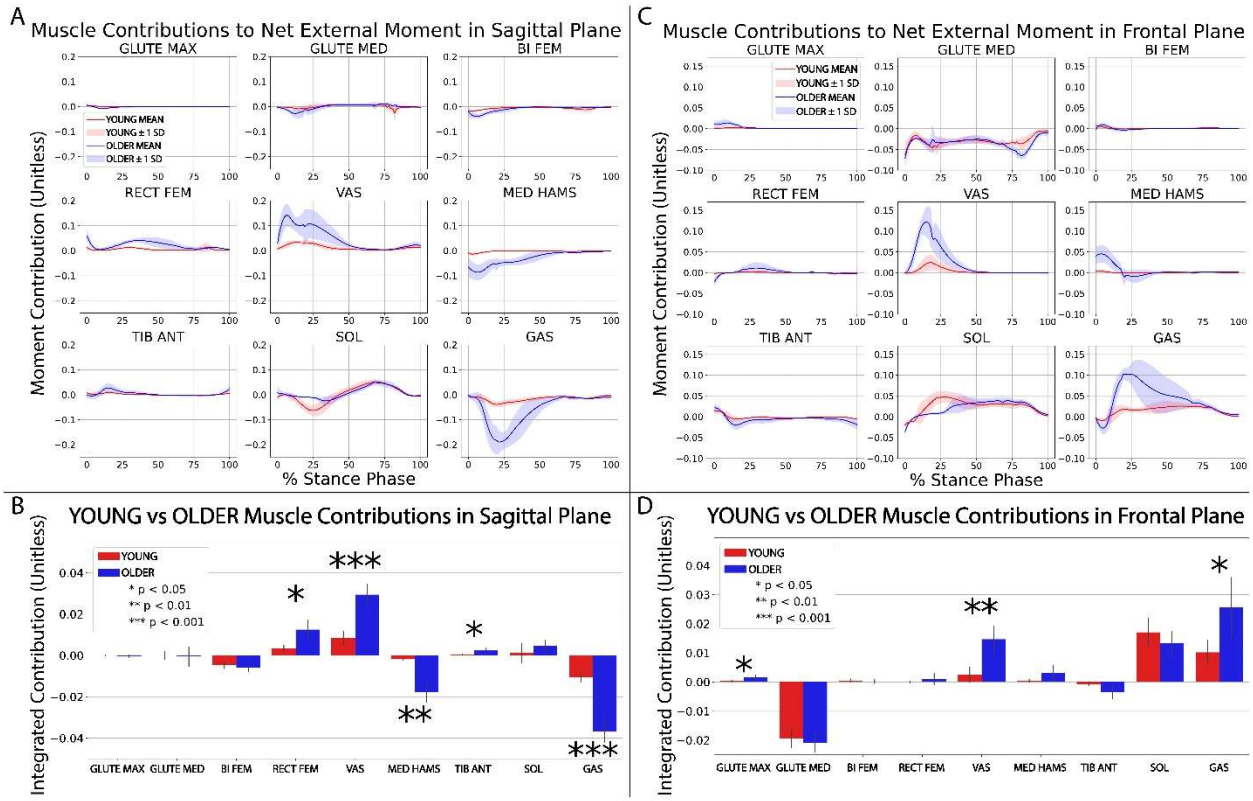

Fig. 1: Muscle contributions to balance regulation in younger and older adults. A) Muscle contributions to the sagittal NetExtM. B) Integrated muscle contributions to the sagittal NetExtM. C) Muscle contributions to the frontal NetExtM. D) Integrated muscle contributions to the frontal NetExtM. In the sagittal plane, positive (negative) values indicate the muscle is producing backward (forward) H. In the frontal plane, positive (negative) values indicate the muscle is producing H toward the contralateral (ipsilateral) limb. Muscle contributions from gluteus maximus and gluteus medius lines of action were summed in GLUTE MAX and GLUTE MED, respectively. Muscle contributions from semimembranosus and semitendinosus were summed in MED HAMS, from medial and lateral gastrocnemius were summed in GAS, and from vastus medialis, lateralis, and intermedius were summed in VAS. BI FEM (biceps femoris long head), RECT FEM (rectus femoris), TIB ANT (tibialis anterior), and SOL (soleus) each represent contributions from one muscle.

Age-related Differences in Locomotor Response to Fall-Related Anxiety in Virtual Reality Settings Across Time

Dr. Kelly Poretti[1], Dr. Toby Ellmers[2], Dr. Quentin Sanders[3], Dr. Nathalia Peixoto[3], Dr. Christopher Rhea[4], Dr. Tiphanie Raffegeau[1]

[1]George Mason University, Manassas, VA, United States. [2]Imperial College London, London, London, United Kingdom. [3]George Mason University, Fairfax, VA, United States. [4]Old Dominion University, Norfolk, VA, United States

Introduction

Up to 60% of older adults report a fear of falling, and while certain levels of concern serve adaptive purposes, excessive fall-related anxiety can disrupt movement planning when balance is threatened. Due to age-related differences in stepping pattern adaptation, differences might also exist adapting to virtually-induced fall-related anxiety environment (e.g. simulated high elevations). The purpose of this study was to determine age-related differences in response to virtually-induced fall-related anxiety across time.

Methods

Participants (N = 30, 14 older adults) experienced one minute of self-paced walking at virtual low elevations (ground) followed by five minutes at virtual high elevations (~15m) on a walkway adjusted to allow ~6 steps per pass based on individuals' step length. Visualization of the absolute distance between the headset and ankle trackers (HTC Vive Pro Eye) was used to calculate gait parameters (gait speed, step length and width, and double support). The first (T1) and last (T2) six steady state steps were extracted to determine changes across time. Linear mixed-effect regression compared parameters due to Age (2 levels: Older, Young Adults), Height (2 levels: Low, High), and Time (2 levels: T1, T2).

Results

Both groups adapted similarly, walking with longer steps over time at low [$F = 10.25$, $p = .001$] and high [$F = 83.78$, $p < .001$] elevations. However, neither group altered step width, gait speed, or percent time in double support over time in low or high settings ($p > .179$).

Discussion

Both young and older adults habituate gait similarly with exposure to virtual anxiety-inducing settings, taking longer steps over time. In this paradigm, step lengths are not mechanically limited and are orthogonal to the direction of postural threat, thus both

groups adapted by decreasing cadence to maintain speed and take longer steps. However, neither group adapted the percent time in double support, indicating they adapt locomotion under threat by lengthening steps while sustaining the time spent in stable phases of the gait cycle.

Images (Optional)

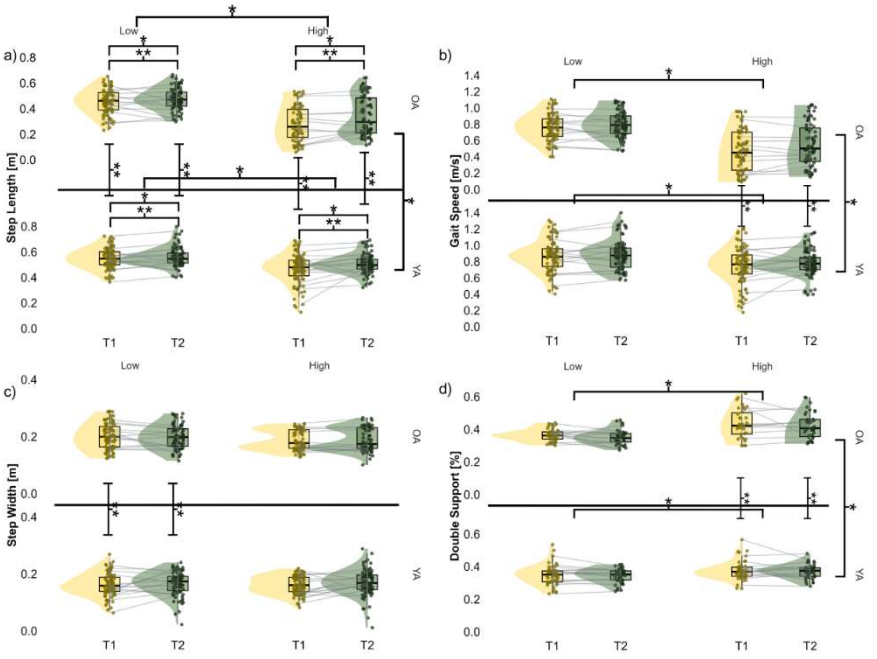

Figure 1(a-d): Age-related differences in adaptations of (a) step length, (b) gait speed, (c) step width, and (d) double support to fall-related anxiety across repeated exposures. Compensatory changes to gait parameters from the beginning of a five-minute exposure (T1) and the end of an exposure (T2) as well as between the first five-minute exposure (E1) and the second exposure (E2) to anxiety-inducing virtual settings. Older adult (OA) data is represented in the figures above the horizontal line, while young adult (YA) data is represented in the figures below. Scattered dots represent subject means, while variability is represented by the violin plots. T1 is represented by the yellow-colored violin plots, while T2 is represented by the green-colored plots. Significant main effects of group, exposure, and/or time are indicated with a single asterisk and brackets, while significant interaction effects of exposure and time are indicated with a double asterisk.

Does Prefrontal Cortex Activation Predict Decision-Making Performance on a Reactive Jump Landing Task?

Dr. Fatemeh Aflatounian[1,2], Ms Alexandra Lynch[1], Dr. Keith Hutchison[1], Dr. James Becker[1], Dr. Corey Pew[1], Dr. Scott Monfort[1]

[1]Montana State University, Bozeman, Montana, United States. [2]Virginia Commonwealth University, Richmond, Virginia, United States

Introduction

Anterior cruciate ligament (ACL) injuries happen often without contact in sport and are frequently linked to interruptions in cognitive–motor control during unanticipated movements. Although biomechanical risk factors have been widely studied, growing evidence suggests neural processes underlying visuomotor coordination and attention control as risk factors. Functional near-infrared spectroscopy (fNIRS) enables non-invasive measurement of cortical activation during dynamic tasks. This study examined whether prefrontal cortex activation (PFC) during an attention control task relates to decision-making performance through unanticipated jump-landings associated with ACL injury risk.

Methods

Thirty-one healthy recreational athletes (15F/16M; 23.1±2.6years) completed a computerized attention-control battery[1] while wearing an fNIRS cap targeting Brodmann areas (BA) 46 and 9. Neural activation (t-statistics) was derived using an autoregressive iterative reweighted least squares general linear model with short-separation channel regressors. Participants performed unanticipated conditions that included a simple task (Simple) of landing on the limb towards an image on one side of the screen, and a complex task (Complex) of landing on the limb towards a picture of the basketball or away from a simulated opponent. Failed trials involved incorrect cue responses and landing on the wrong limb(s). Failed trial percentage (Failed%) was calculated for each cognitive condition. Pearson correlations tested associations between fNIRS activation and Failed%.

Results

PFC in BA46 and BA9 showed no significant correlations with Failed% in either challenging condition ($p > 0.05$, Figure 1). Small-to-moderate effect sizes ($|r| \approx 0.3$) suggested a nonsignificant trend toward fewer failed landings with greater prefrontal activation.

Discussion

PFC measured during isolated cognitive testing was not associated with decision-making accuracy during dynamic jump-landings, suggesting that landing errors were not explained by baseline cognitive activation. Instead, failures likely reflected task-specific cognitive–motor demands during reactive movement. This aligns with behavioral work showing that attention-control tests typically demonstrate only small–moderate associations with task accuracy (r≈0.20–0.40), underscoring the challenge of capturing cognitive variability through isolated tasks alone. Future work should incorporate real-time neural measures and refined task designs to better characterize rapid cognitive load fluctuations preceding movement errors.

OA189-06

Arm Swing As A Mediator Of Age-related Slip-Fall Risk

Mr Shilin Wang, Feng Yang

Department of Kinesiology and Health, Georgia State University, Atlanta, Georgia, United States

Introduction

Slip-induced falls lead to injuries in older adults. Upper-extremity reactions, especially the arm swing strategy, may help restore balance after a slip by redirecting whole-body momentum. Aging appears to reduce protective arm responses [1], yet it is unclear to what extent the arm-swing strategy explains age differences in slip-induced fall risk. This study quantified age-related differences in protective arm use and slip-fall and tested whether arm swing mediates the association between age and slip-fall.

Methods

Secured by a harness connected to a loadcell, 61 young and 64 older adults (Table 1) experienced a standing-slip on an ActiveStep treadmill. Slips were induced by a 0.36-m forward belt translation over 0.6 s. A slip was deemed a fall if the peak loadcell force exceeded 30% bodyweight [2]. Motion data was used to classify each trial as arm swing (shoulder flexion≥45° post-slip) or no arm swing (shoulder angle<45°). Associations between age, arm use, and falls were quantified with χ^2 tests and generalized linear models. Single-mediator models estimated direct and indirect effects of age on fall risk through arm use. SPSS 29.0 with α of 0.05 was used.

Results

60.9% of older and 34.4% of young adults fell (odds ratio (OR)=2.97, p=0.003). Significantly fewer older adults swung their arms than younger adults (71.9% vs 91.8%, OR=0.23, p=0.007). Slips with arm swing exhibited a lower probability of falling than slips with no arm use after adjusting age (41.2% vs 78.3%; OR=0.19, p=0.003). Mediation analysis indicated that reduced arm use in older adults led to an indirect increase in fall risk of 6.0%, accounting for about 22.8% of the overall association between age and falls.

Discussion

Our results indicated that the ability to use arm swing as a protective strategy responding to a standing-slip is a fall risk factor. Aging could compromise such an ability. Findings

highlight protective arm swing as a potential training target to improve older adults' balance recovery after perturbations. Future work should test other perturbation types and high-fall-risk populations.

Images (Optional)

Table 1 Demographic information in mean ± standard deviation and distribution of participants grouped by age, the use of arm swing, and slip outcome.

Group	Arm use	Faller status		Age (years)	Sex (F/M)	Body height (cm)	Body mass (kg)
		Faller	Non-faller				
Older	Yes	26	20	64.9 ± 5.7	34 / 12	166.8 ± 10.5	65.8 ± 13.6
	No	13	5	70.3 ± 8.8	16 / 2	162.1 ± 7.7	66.3 ± 12.9
Young	Yes	16	40	23.6 ± 4.4	45 / 11	165.3 ± 8.1	64.4 ± 11.5
	No	5	0	23.0 ± 0.0	2 / 3	173.4 ± 9.1	65.3 ± 15.1

Female Hip Joint Contact Differences in Table Tennis Are Associated With Anatomical Shape and Not Mechanical Loading

Ms Xiaoyi Yang[1], Associate Professor Qichang Mei[2], Dr Vickie Shim[1], Professor Justin Fernandez[1]

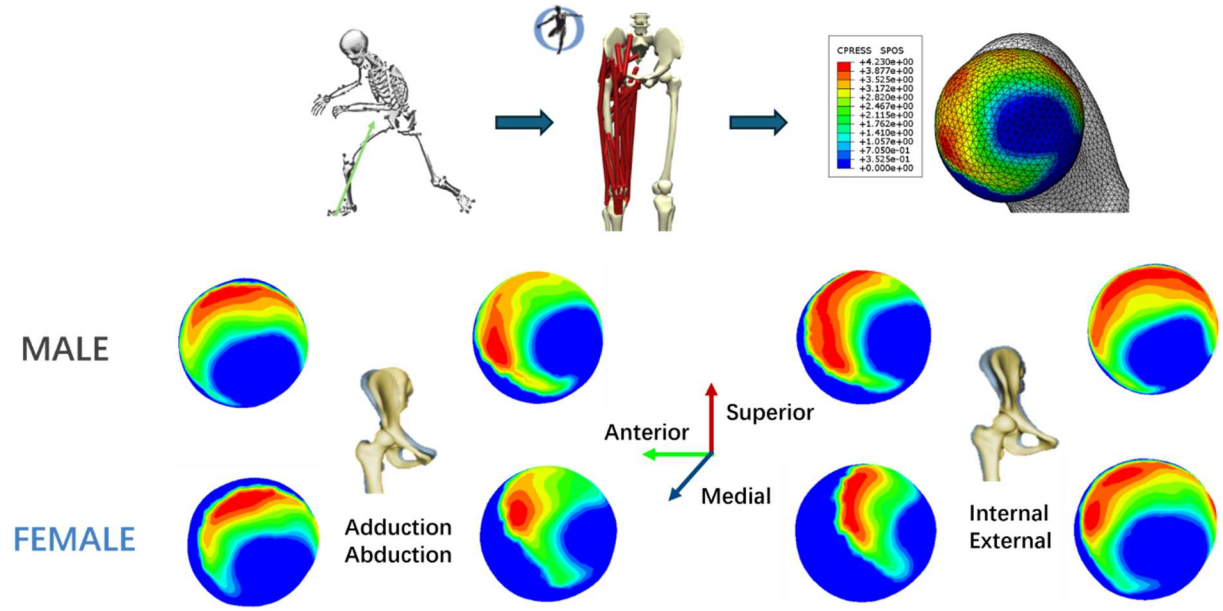
[1]University of Auckland, Auckland, CBD, New Zealand. [2]Ningbo University, Ningbo, Zhejiang, China

Introduction

Female table tennis athletes experience higher rates of hip joint injury, however, it is not fully understood if this is associated with mechanical differences or anatomical variations between the biological sexes [1]. The objective of this study was to investigate hip joint loading between female and male elite level table tennis players integrating motion analysis, finite element modelling, and statistical shape analysis to elucidate the contribution of mechanics and shape variation to hip joint loading.

Methods

Following ethical approval and player consent, 18 females and18 males (aged 20-29) performed the widely used chasse-step table tennis movement. Kinematics, kinetics, and EMG were collected and processed in OpenSIM. In parallel, a statistical shape model was created from 60 aged-matched geometries from the Victorian Institute for Forensic Medicine using GIAS3. A finite element model was constructed in Abaqus to match the OpenSIM model for a mean male and mean female. The maximum transverse loading side-step movement was simulated using each players hip orientation. Firstly, we evaluated kinetic differences (muscle and joint contact forces) on hip loading, and secondly, we evaluated shape differences using statistical shape analysis.



Results

Our models supported a finding that maximum hip contact pressure was similar in both males and females, despite males having larger hip joint forces and having significantly higher muscle forces across the hip. In contrast, adduction-abduction hip shape variation highlighted that hip contact zones were superior-medial in females and superior-anterior in males. Further, internal-external hip shape variation revealed hip contact zones were medial-superior in females, but anterior-superior in males. Hence, despite peak pressure being similar in range, the contact zones were significantly different.

Discussion

Our study findings suggest that hip loading differences between sexes may be associated with joint contact zone differences linked to biological sex anatomical shape and not due to mechanical loading. This highlights that shape models considering biological sex differences are important when considering dynamic sports, like table tennis, and investigating sports performance and injury prevention.

Interlimb Strength and Loading Characteristics During Dynamic Tasks in Female Special Operation Forces Personnel

Ms. Tatiana Djafar[1], Dr. Nicholas Heebner[1], Mr. Tyler Cardinale[1], Dr. Benjamin Cuddy[1], Mr. Brad Lambert[2], Dr. Jeremy Ross[1], Dr. Joshua Winters[1]

[1]University of Kentucky, Lexington, KY, United States. [2]United States Marine Forces Special Operations Command, Camp Lejeune, NC, United States

Introduction

Female military personnel have high rates of reported injury, often associated with the rigorous nature of their tactical training. Lower limb strength and loading symmetry are commonly used for return to activity criteria following an injury. The purpose of this study was to examine the relationship between strength symmetry and functional loading during dynamic tasks in female Special Operations Forces (SOF) support personnel.

Methods

Sixteen female SOF support personnel (age: 26.25±4.54yrs; height: 164.70±5.28cm; mass: 64.78±6.08kg) who were cleared for unrestricted duty underwent a functional performance assessment (vertical jump (VJ: peak concentric and landing force), isometric mid-thigh pull (IMTP: net peak force)) on bilateral force plates and completed a running mechanics evaluation using a markerless motion capture system (peak vertical ground reaction force, impulse, average loading rate). Isometric quadriceps and hamstring strength were also measured. Paired-samples t-tests ($\alpha = 0.05$) with Hedges' g effect sizes determined limb differences. Pearson correlations were used to assess relationships between strength and dynamic tasks.

Results

Mean absolute asymmetries are presented in Table 1. VJ peak concentric force was the only statistically significant interlimb difference (6.24%, p=0.021, g=0.610). Quadriceps strength, but not peak concentric force, correlated with VJ height (dominant: r=0.508, p=0.045; non-dominant: r=0.498, p=0.050). Dominant limb quadriceps strength also moderately correlated with IMTP net peak force (dominant: r=0.574, p=0.020; non-dominant: r=0.329, p=0.213).

Discussion

Female SOF support personnel only demonstrated a statistically significant interlimb asymmetry during VJ take-off. Though there were no statistical differences in strength, the average asymmetry in the quadriceps was 12.05%, and 7/16 participants exceeded 10% asymmetry, a threshold commonly used for return-to-sport-criteria. Peak VJ landing force also exceeded this threshold with 12.39% asymmetry. However, only VJ height was correlated to quadriceps strength. From a clinical standpoint, strength may be a stronger indicator of functional performance but not necessarily of shock attenuation strategies during dynamic tasks. Though female SOF support personnel demonstrated strength and landing asymmetries greater than clinical thresholds, a lack of relationship between these metrics as well as minimal interlimb differences among other characteristics of these dynamic tasks suggest consideration for a different approach to limb symmetry evaluation.

Sex-differences in Preparatory Step Biomechanics During a 90° Cutting Task

Ms. Katherine Batista MSc, Dr. Robin Trama PhD, Ms. Meghan Rogers, Ms. Emily Dittmer BSc, Dr. Zi Xiang Gao PhD, Dr. Darren Stefanyshyn PhD, Dr. John Wannop PhD

The University of Calgary, Calgary, Alberta, Canada

Introduction

Lower-limb biomechanics during cutting maneuvers have been extensively studied to gain insight into injury mechanisms and performance determinants in sport. Although research often focuses on the final change-of-direction step, emerging evidence suggests that the preceding steps prior to the change of direction may influence performance and potential injury risk variables [Jones et al., 2016; Dos'Santos et al., 2019, 2021]. Although studies have examined these preceding steps in male and female athletes separately [Dos'Santos et al., 2019; Mulligan, 2022;], no studies have directly compared sex differences. Therefore, the purpose of this study was to compare lower extremity biomechanics of the antepenultimate, penultimate, and ultimate steps between male and female athletes during a 90° cutting task.

Methods

Fifteen soccer players (5 female, 10 male) performed five maximal effort 90° cutting trials in standardized soccer cleats on artificial turf. Three-dimensional ground reaction force data were collected via three in-series force platforms for the antepenultimate, penultimate, and ultimate steps during the cutting task. Kinematic data were also collected, but only ground reaction force (GRF) data is presented in the current study. Sex differences in time-normalized vertical (vGRF) and horizontal (hGRF) ground reaction force waveforms (normalized to body weight, BW) were compared using Statistical Parametric Mapping (SPM; $a = 0.10$).

Results

Significant sex-differences were present in hGRF and vGRF across all steps. Females exhibited lower hGRF than males in the penultimate (8-32% and 73-95% stance) and ultimate (58-96% stance) steps. Conversely, females exhibited higher vGRF during the antepenultimate (23-58% stance) and penultimate (8-27% stance and 32-82% stance) steps.

Discussion

Females displayed greater vertical and lower horizontal body weight normalized GRF during the preparatory (antepenultimate and penultimate) steps, compared to male athletes. These results highlight sex-specific cutting strategies, potentially reflecting different braking or load-distribution patterns prior to the final change-of-direction step. Future work will examine accompanying kinematic (joint angles) and kinetic (joint moments) variables to provide a better understanding of these sex differences.

Images (Optional)

Neuromuscular Activation Patterns During Dual Task Cutting in NCAA Soccer Players with and without Ankle Sprains

Ms. Abigail McCarthy B.S., Dr. Susan D'Andrea Ph.D.

University of Rhode Island, Kingston, RI, United States

Ms. Abigail McCarthy

Introduction

Lateral ankle sprains (LAS), one of the most common injuries in soccer, accounts for approximately 15% of non-contact injuries in collegiate soccer. [1,2] LAS has a high rate of recurrence, with the potential to develop into chronic ankle instability.[3] Traditional rehabilitation focuses on sensorimotor control, dynamic posture and functional exercises, but often lacks cognitive components common in gameplay. Research on dual-task interference in athletes with LAS during sport specific tasks remains limited. This study will investigate neuromuscular responses during cutting movements under cognitive load in NCAA Division I soccer athletes, focusing on differences between healthy individuals and those with a history of lateral ankle sprains.

Methods

Sixteen male and female soccer players aged 18–24 were recruited, eight participants reporting at least one unilateral LAS in the past 12 months and eight sex-matched healthy controls. Following a standardized warm-up, 34 reflective markers and six electromyography (EMG) sensors were placed bilaterally on the lower extremity. A modified flanker task was used and participants were instructed to perform a 45° cutting maneuver in the direction indicated by the middle arrow leading with the ipsilateral foot (Figure1A). Sixteen randomized trials (eight congruent, eight incongruent) were collected with 5–12 seconds of rest between trials.

Results

Six female soccer players are included in the analysis. To understand reaction time, the point at which the flanker arrows appear was determined by video. EMG data were filtered, rectified and enveloped. Latency was determined as the time from flanker initiation to the

onset of muscle activity on the contralateral limb. Peak EMG amplitudes from foot strike to toe off were determined for the cutting leg (Figure 2:B/C).

Discussion

Data show trends that indicate decreased peroneus longus (PL) activity in the stance phase and decreased PL latency for participants with recent ankle sprains. The alteration in PL activation may be indicative of functional instability at the ankle. Further exploration of the data will correlate kinematics to muscle activation and make comparisons between males and females.

Non-Invasive Estimation of Pulmonary Vascular Pressure Using In-Vivo Imaging, In-Silico Modeling, and Physics-Informed Neural Networks

Mr. Rana Raza Mehdi[1], Dr. Sunder Neelakantan[1], Mr. Emilio Mendiola[1], Dr. Kyle Myers[1], Dr. Peng Zhang[2], Dr. Gaurav Choudhary[2], Dr. Reza Avaz[1]

[1]Texas A&M University, College station, Texas, United States. [2]Brown University, Providence, Rhode Island, United States

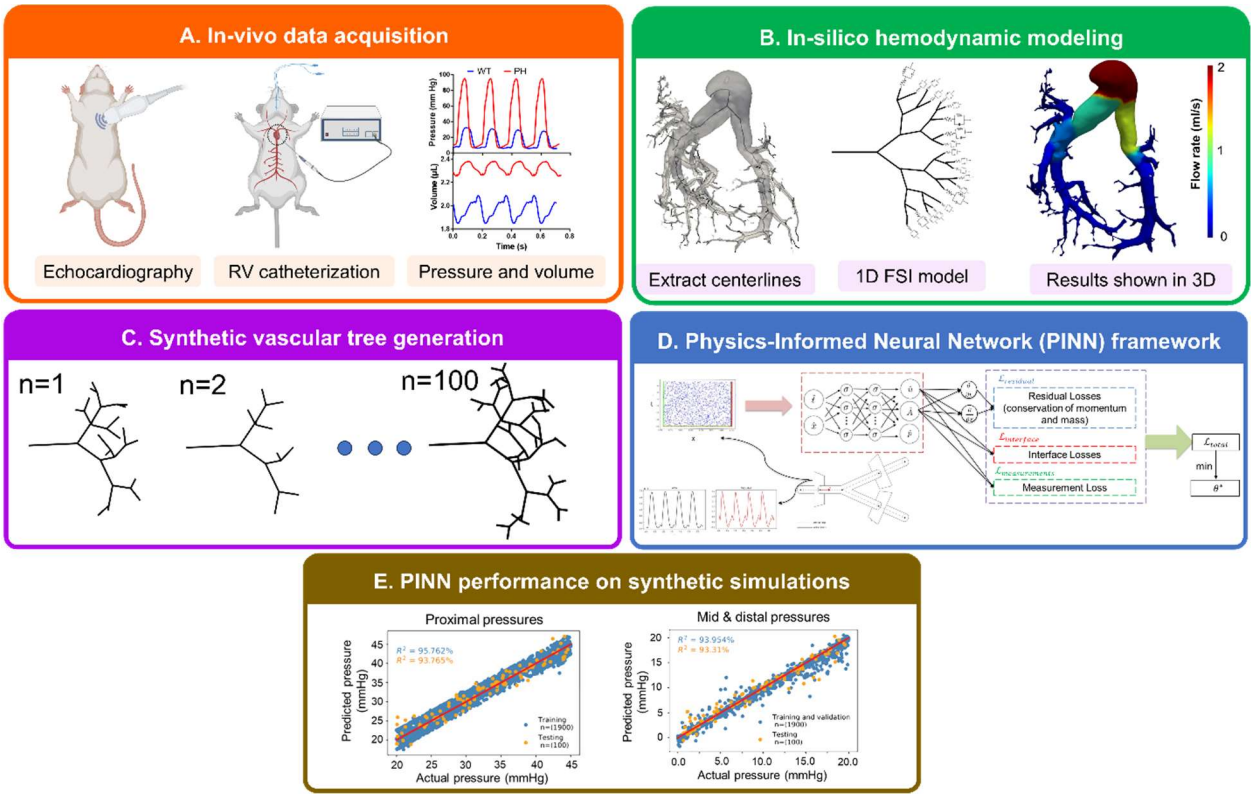
Introduction

Accurate estimation of pressure in terminal pulmonary vessels is essential for diagnosing and managing pulmonary hypertension (PH), yet current methods such as right heart catheterization are invasive and cannot resolve pressures in small distal vessels. Non-invasive modalities (ultrasound, MRI) offer indirect flow-derived measures but lack the spatial resolution needed to characterize pressures across the pulmonary vascular tree. To address this gap, we developed a physics-informed neural network (PINN) framework that integrates in-vivo CT-based vascular imaging with in-silico 1D fluid–structure interaction (FSI) modeling to predict vessel-level pressure distributions non-invasively.

Methods

Pulmonary vascular geometries were reconstructed from high-resolution CT imaging in control (n=7) and Sugen–hypoxia (n=7) rat models of PH. These geometries were used to generate high-fidelity pressure–flow simulations via a 1D FSI model under physiologic inflow and boundary conditions (Fig. 1A,B). To increase geometric diversity beyond the available animals, a set of low-fidelity synthetic vascular trees (n=2000) was generated by perturbing vessel lengths, radii, and branching angles (Fig. 1C). The combined dataset was used to train a PINN model that incorporates vessel geometry, flow inputs, and boundary specifications while embedding governing conservation laws directly into the loss function (Fig. 1D). This hybrid training strategy enabled the PINN to learn pressure fields consistent with vascular mechanics across a broad anatomical range. Model performance was evaluated by holding out real rat geometries as independent test cases.

Results



The PINN accurately reproduced pressure distributions across synthetic trees, showing strong agreement with simulated pressures (Fig. 1E). When applied to held-out real rat vasculature, the model demonstrated robust generalization, with predicted pressures closely matching high-fidelity FSI ground truth. The method remained stable in highly

asymmetric and deeply branched regions, successfully capturing distal pressure drops that conventional imaging-based approaches cannot resolve.

Discussion

This study presents a unified, non-invasive framework that couples in-vivo CT imaging, in-silico biomechanics, and physics-informed learning for accurate pulmonary vascular pressure estimation. By combining low-fidelity synthetic data with high-fidelity rat simulations and enforcing physics constraints, the approach achieves high accuracy and strong generalizability. This framework shows promise for future translation using patient-specific CT geometries to rapidly assess pulmonary vascular load without catheterization.

Introduction

Diameter and growth rate remain the dominant surrogates for assessing abdominal aortic aneurysm (AAA) rupture risk, yet rupture reflects localized imbalances between wall stress and wall strength. We hypothesize that graph neural networks (GNNs) operating on surface meshes derived from computed tomography angiography (CTA) images can leverage spatially distributed geometric and biomechanical features to improve rupture risk classification.

Methods

We used a multi-institution cohort of 147 AAA CTA exams (76 ruptured/symptomatic within 6 months of last exam and 71 unruptured/asymptomatic). After U-Net assisted segmentation and mesh reconstruction, each aneurysm was represented as a connectivity graph whose nodes (mesh elements) carry seven primary features: wall thickness (*WallTHK*), thrombus thickness (*ILTTHK*), Gaussian and mean curvatures (*K*, *M)*, wall stress, wall strength, rupture potential index (*RPI*=stress/strength), and radial distance to the centerline (r_L) as spatial descriptors. We benchmarked GNN variants (GCN/GraphSAGE) with stratified 5-fold cross-validation, early stopping, and feature-set ablations to identify parsimonious, high-performing combinations. Performance was evaluated with accuracy, area under the curve (AUC), precision/recall, and calibration; class imbalances were handled with stratification and loss re-weighting.

Results

Experiments on the independent 147-patient cohort trained 127 GNNs across feature subsets. The best fold achieved **96.55%** accuracy and AUC = 0.9762 using *WallTHK*, *K*, and *M* as shown in Table 1. When averaging across folds, the top configuration reached **83.0%** accuracy, indicating robust generalization beyond single-fold performance.

The features recurring in the top 10 models included *WallTHK*, *K*, *M*, and *RPI*, suggesting a complementary value from biomechanical and geometric descriptors.

Discussion

Representing AAAs as surface graphs enables GNNs to exploit local heterogeneity that is lost in global or diameter-based metrics. Early findings support the importance of combining geometric (curvature, thickness) and biomechanical (stress, strength, RPI) features. Future work should be focused on (i) completing a compact feature set, (ii) assessing alternative edge/positional encodings and weighted graphs, and (iii) exploring multimodal extensions (local graph features + global graph features, such as sex and maximum diameter). If validated, this approach could provide a scalable, anatomy-aware classifier to support patient-specific rupture risk stratification in routine CTA workflows.

Non-invasive Quantification of Left Ventricular Myocardial Stiffness In Vivo using DENSE MRI and a Physics-Informed Constitutive Model

Mr. Tawfik Hussein, M.S.[1,2], Dr. W. Robert Taylor, M.D., Ph.D.[2,3], Dr. John Oshinski, Ph.D.[2]

Introduction

Heart failure with preserved ejection fraction (HFpEF) is a complex syndrome with poor long-term prognosis. A key feature is increased myocardial stiffness, yet current clinical tools to assess stiffness are invasive or indirect. The Criscione–Hussein model (CHM) has the potential to capture local, microstructural myocardial stiffness *non-invasively* using pixel-wise displacements from high-resolution displacement encoding with simulated echoes (DENSE) [1]. The goal of this study was to combine DENSE and CHM to quantify local mean *fiber strain α_2, stress σ_{ff}, and stiffness Λ*, and mean *laminar thickening strain α_3, stress σ_{rr}, and stiffness Φ* in human myocardium. We hypothesized that combining DENSE and CHM could capture local myocardial stiffness, and that fiber stiffness would exceed laminar thickening stiffness.

Methods

Ten healthy adults (6 males, 4 females, ages 22–59 years) underwent ECG-gated cine DENSE imaging in short-axis and long-axis views of the LV. Displacements from both views were combined to compute α_2 and α_3 in each segment of the AHA bullseye. Using published diastolic pressure values for healthy myocardium, CHM was used to fit pressure–strain relationships for each subject, producing subject-specific stiffness parameters. From these parameters, σ_{ff} and σ_{rr} were computed. Mean and standard deviation of all metrics were calculated across subjects, with the segmental means visualized as AHA bullseyes.

Results

Shown in **Figure 1**, α_2 and α_3 indicated greater laminar thickening than fiber shortening, with the lateral wall deforming more than the septal wall. The spatial distributions of σ_{ff} and σ_{rr} were largely homogeneous; σ_{ff} values were negative while σ_{rr} values were positive, consistent with fiber shortening and radial thickening, respectively. For stiffness, Λ exceeded Φ, with both showing higher magnitudes in septal regions compared to lateral regions.

Discussion

The strain patterns align with prior findings that laminar thickening exceeds fiber shortening due to sheetlet shear. This implies *greater stiffness along fibers than in the radial direction*, as well as negative σ_{ff} and positive σ_{rr}. Quantifying stiffness along material directions reveals microstructural physiology and may offer mechanistic insight into LV remodeling. These stiffness measures may ultimately serve as predictive markers of adverse remodeling in HFpEF.

Aortic Wall Biomechanics in Marfan Versus Non-Marfan Patients: Linking FE Simulations and Geometric Deep Learning

MsC Davide Astori[1,2], MsC Ione Ianniruberto[1], MsC Sofia Di Filippo[3], MsC Davide Milesi[1], Prof Alberto Redaelli[1], PhD Simone Saitta[4], Prof Emiliano Votta[1]

[1]Department of Electronics, Information and Bioengineering, Politecnico di Milano, Milano, Milano, Italy. [2]European Society of Biomechanics (ESB), Milano, Milano, Italy. [3]3D and Computer Simulation Laboratory, IRCCS Policlinico San Donato, San Donato Milanese, Milano, Italy. [4]Department of Biomechanical Engineering, TU Delft, Delft, South Holland, Netherlands

Introduction

Ascending aortic aneurysm is a leading cause of mortality in Marfan patients [1]. Optimal surgical correction timing is crucial for preventing acute dissection; however, current geometry-based clinical guidelines fail to accurately stratify risk in 60% of cases [2]. Stress-based risk assessments derived from finite element (FE) simulations have shown promise in predicting aortic dissection, but are time-expensive [3]. Here, we compare aortic wall biomechanics in Marfan *vs.* non-Marfan (Control) subjects, and investigate geometric deep learning (GDL) as a faster alternative to FE.

Methods

400 CT scans of ascending aortas were processed automatically to implement aortic wall FE models as in [2].

320 anatomies were used to generate the training dataset for a PointNet++-based GDL model aimed to infer axial and circumferential wall stresses (t_z, t_θ) from geometry, intraluminal pressure, and condition label. For each geometry, FE simulations were run using Marfan-specific and physiologic material properties to compute t_z and t_θ for pressures between 50 and 180 mmHg.

For the remaining 80 subjects with known clinical history (40 Marfan, 40 Controls), GDL model predictions were tested *vs.* FE simulations with condition-specific properties, for pressures ranging from 50 to 180 mmHg.

Results

FE simulations in the training set indicated that, on the same geometry, Marfan material properties were associated with increased t_z and t_θ *vs.* physiological properties (11.9% and 23.5% at 120 mmHg). In the test set, Marfan patients showed higher t_z and t_θ than controls at 120 mmHg (t_z=15.4±4.5 *vs.* 13.2±7.0 kPa, p<0.01; t_{circ}=55.7±13.0 *vs.* 43.9±9.8 kPa, p<0.0001), but not in hypertensive conditions. The GDL model reproduced FE-derived stresses with a 5.30±2.51% normalized mean absolute error on the test set, requiring ~3 seconds/case *vs.* ~40 minutes/case for FE analyses.

Discussion

Marfan-specific material properties substantially affect aortic wall stresses, revealing significant differences between Marfan patients and Controls at physiological pressures. The proposed pathology-aware GDL model well reproduces FE stresses with drastically reduced computation time, supporting fast, patient-specific biomechanical risk assessment.

Images (Optional)

Long-Term Implantable Sensor System for High-Resolution In Vivo Spinal Kinematics in Large Animal Models

Dr. med. vet. Sandra Reitmaier, Mr Marcel Simon Reich, Prof. Dr. Hendrik Schmidt

Charite - Universitätsmedizin Berlin, Berlin, Berlin, Germany

Introduction

Accurate long-term monitoring of spinal kinematics is essential for understanding postoperative biomechanics and evaluating interventions in preclinical models. While large animal models, such as sheep, mimic human spinal anatomy and loading [1-3], existing methods lack sufficient precision, durability, and biocompatibility for extended in-vivo measurements. To address this gap, we developed an implantable sensor capable for capturing multi-planar-motion over prolonged periods, enabling detailed assessment of vertebral biomechanics in a clinically relevant setting.

Methods

We engineered a biocompatible sensor module integrating accelerometers, gyroscopes, and magnetometers to record flexion/extension (FE) and axial rotation (AR) of individual vertebrae. The device is encapsulated in silicone with epoxy-reinforced electronics, ensuring mechanical stability. A low-power circuit and high-capacity Li-Po battery enable continuous operation for up to 24 days, controlled via magnetic switch. System performance was evaluated in laboratory calibration experiments and implanted in one sheep to assess signal fidelity, robustness under physiological loading, and long-term stability.

Results

Laboratory testing confirmed that the system achieved angular accuracy well within the targeted resolution. For FE, mean squared error (MSE) was 0.013°, root mean squared error (RMSE) 0.115°, with a mean deviation (MD) of 0.044° and a standard deviation (SD) of 0.108°. For AR, MSE was 0.011°, RMSE 0.104°, with a MD of 0.064° and a SD of 0.083°. Magnetic field characterization showed near-linear sensor behavior, enabling reliable reconstruction of angular motion using a two-point calibration. In vivo, the implanted system operated consistently throughout the monitoring period, maintaining stable signal quality (Fig.1). No degradation of sensor performance was observed, confirming the mechanical robustness and feasibility of long-term implantation.

Discussion

This study presents a robust, biocompatible, and accurate implantable system for long-term spinal kinematic monitoring in large animals. By enabling multi-planar, continuous in-vivo measurements, the system allows objective evaluation of spinal interventions and provides a foundation for translational research linking preclinical biomechanics to clinical outcomes. This technology offers a novel approach to assess post-surgical adaptations, tissue mechanics, and neuromuscular responses in a controlled, physiologically relevant environment.

Images (Optional)

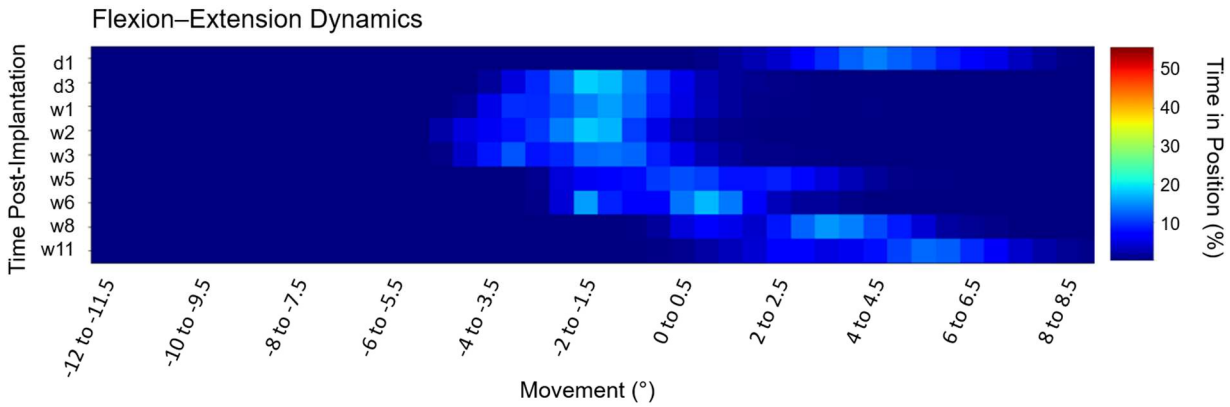

Fig. 1 Temporal profile of flexion-extension (FE) angles recorded by two implanted sensors (L2, L4). After sensor implantation, movement amplitudes are confined to a narrow, low-magnitude range (d3 to w2), likely reflecting postoperative discomfort. Thereafter, a progressive increase in the occurrence of larger-amplitude movements is observed.

Negative values indicate extension, positive values indicate flexion.
Abbreviations: d = day; w = week; d1 = day of sensor implantation.

Sensitivity of a Soft Tissue Kalman Filter to Material Parameters

Ms. Genevieve Bonnor BASc, Dr. Calvin Kuo PhD, P.Eng

University of British Columbia, Vancouver, British Columbia, Canada

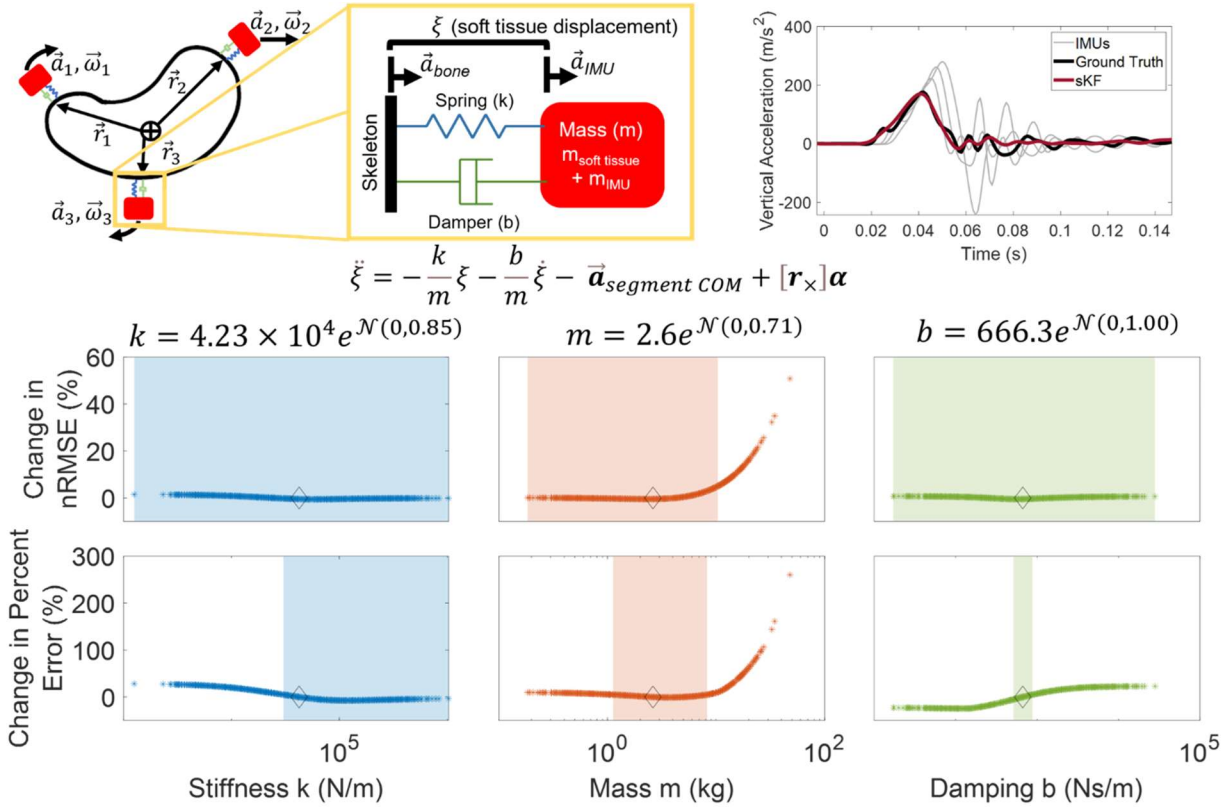
Introduction

Inertial measurement units (IMUs) are a popular tool to measure human motion outside the lab. However, in applications such as impact characterization, dynamic soft tissue artifacts (dSTAs) introduce IMU measurement errors through overestimation of peak skeletal kinematics (upwards of 100%) and post-impact oscillations [1]. We developed a soft-tissue Kalman filter (sKF) that utilizes a spring-mass-damper (SMD) system to model the effect of dSTAs and improve kinematic estimates. SMD parameters can be optimized to minimize error from a skeletal ground truth, but if no ground truth is available (as in *in vivo* testing), parameter identification becomes difficult. Since the sKF relies on these parameters to accurately model soft tissue movement, we wanted to explore the sensitivity of the sKF to variabilities in the parameters.

Methods

The sKF's SMD model uses stiffness (k), mass (m), and damping coefficient (b) parameters to estimate behaviour of dSTAs. We first optimized a generalizable set of parameters that minimized ground truth skeletal errors across 270 impacts in silicone rubber phantoms with different material properties, sensor placements, and impact severities. We then performed a Monte Carlo (10,000 iterations) on one representative impact, varying SMD parameters within a log-normal distribution (log of SMD parameters obtained when minimizing error for individual impacts). We computed the vertical acceleration normalized root mean square error (nRMSE) and peak percent error compared to the ground truth for each iteration.

Results



The vertical acceleration nRMSE and peak percent error were most sensitive to mass parameter changes. However, the damping parameter has a smaller range with acceptable (≤5% change) peak percent error. The sKF is most robust to stiffness parameter changes.

Discussion

We found that the sKF is robust to variations in stiffness, and that the mass parameter can be estimated within an order of magnitude. However, the damping parameter must be finely tuned to the sensor location and tissue type, and would benefit from further *in*

vivo testing to identify a setpoint. This methodology shows promise to improve impact estimation, and with future parameter adjustment, may be applied *in vivo*.

IMU Misalignment Correction and Calibration Methods for Patient-Placed IMUs in Telemedicine Segmental Symmetry Gait Analysis

Mr. Joseph Redmond, Mr. Kuper Banghart, Prof. Corey Pew

Montana State University, Bozeman, MT, United States

Introduction

Inertial Measurement Units (IMUs) provide a low-cost option for accessible gait analysis. For clinicians, IMUs can provide an objective measure of gait asymmetry using sagittal plane gyroscopes [1]. For patients in remote regions, IMUs could be self-placed for a virtual visit to forgo travel to the clinic. IMU alignment to anatomical segments is critical for accurate measures. While an experimental protocol partially constrained IMU self-placed misalignment, longitudinal axis rotation persisted, producing artificial asymmetry in readings. We hypothesize an algorithmic calibration can mitigate effects of misalignment on asymmetry score repeatability.

Methods

Four IMUs were self-placed by participants using a removable pin aligning the vertical axis of thigh and shank sensors. Participants were recorded treadmill walking. Optical motion capture (MoCap) quantified sensor misalignment. Placement was done twice to evaluate repeatability. IMUs misalignment was corrected using 3 methods: 1) An ideal correction computed using MoCap, 2) A 3-axis magnitude, 3) Optimized correction, orienting maximum gyroscope variance between the thigh and shank to one axis, assuming hinge-like knee behavior [2]. Asymmetry scores were computed by average Euclidian difference of sequential sagittal gyroscope cycles on the left and right sensor [1]. Method inter-trial variance was compared using Pitman-Morgan tests.

Results

MoCap generated Shank asymmetry scores on 9 Healthy Controls (6F; 53±19yrs.) produced a Minimal Detectable Change (MDC) of 2.55 points exceeded by 4% of repeated trials. Uncorrected IMU had higher variance than MoCap (Variance Ratio=3.7; p=0.001); 30% MDC exceedance. Ideally Corrected IMU was statistically the same as Mocap (Ratio=1.4; p=0.263); 15% MDC exceedance. A 3-axis magnitude showed increased variance (Ratio=2.13; p=0.038); 18% MDC exceedance. Optimized corrections had marginally equivalent variance (Ratio=1.9; p=0.056); 11% MDC exceedance.

Discussion

Realigning IMUs using a MoCap-dependent correction improves score variability under repeated conditions to match MoCap. Optimization did not depend on MoCap; while corrections were not exact, score variance improved over no correction. Additional analysis will evaluate thigh data, quantify misplacement impacts on intra-trial scoring error relative to MoCap, and discuss acceptable margins of misalignment for score reliability.

Obtaining Dynamic Soft Tissue Model and Mechanical Properties In-Vivo Using Wearable Inertial Measurement Unit Sensors

Mr Vishak Nandan Aathresh BEng, Dr Calvin Kuo PhD, PEng

University of British Columbia, Vancouver, British Columbia, Canada

Introduction

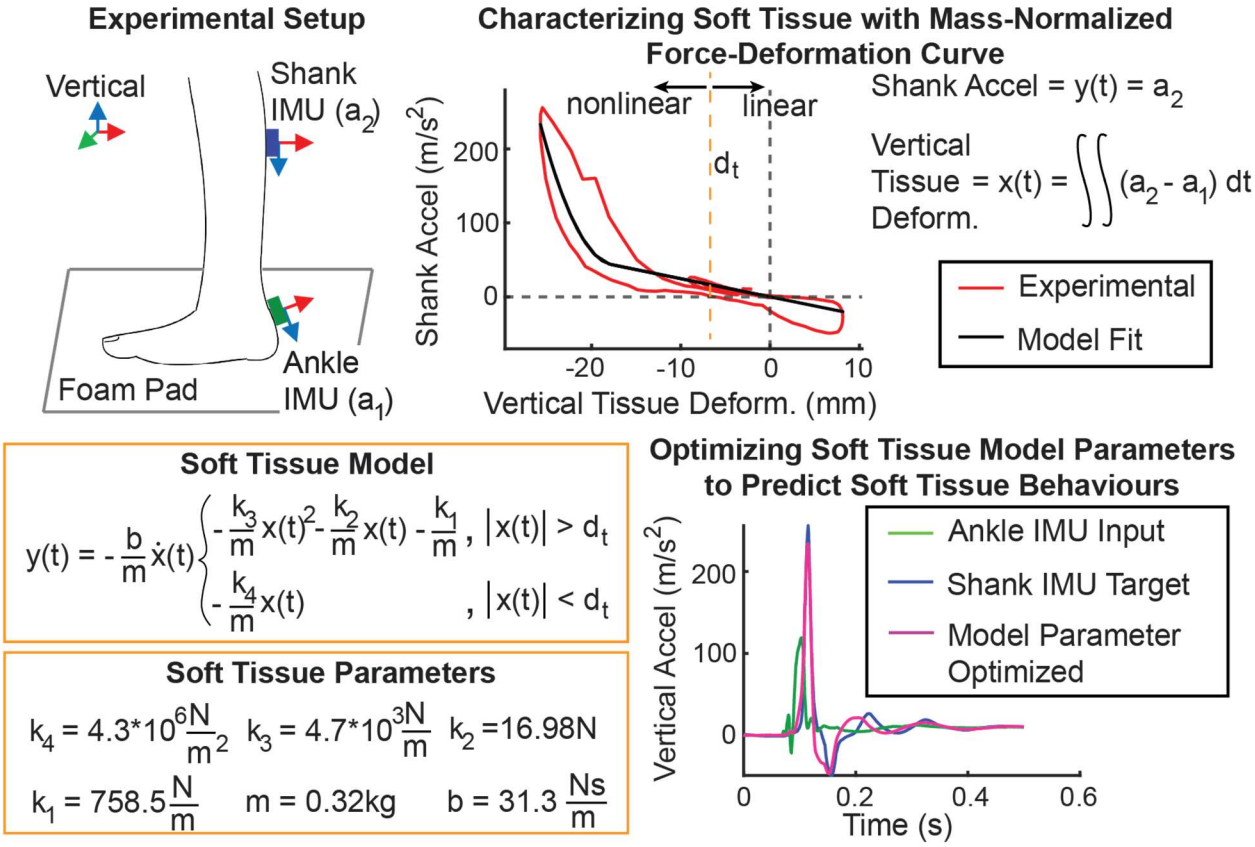
Characterizing soft tissue material properties has applications across computer vision, medicine, and biomechanical research. Material properties such as soft tissue stiffness can be used to indicate health or help develop realistic simulations of injury. Currently, soft tissue material properties are obtained in-vivo using low-deformation rate quasi-static indentation testing or low-deformation rheometric analysis. However, it is difficult to obtain high-deformation and high-deformation rate material properties using these methods. Impacts to the body can excite soft tissue, producing dynamic high deformations and deformation rates. This study presents a method to measure soft tissue during impacts with inertial measurement units (IMUs) to obtain dynamic material properties in-vivo.

Methods

We previously collected mild leg impact data from a participant at 1000Hz using an IMU at the posterior shank with dynamic soft tissue deformations and an IMU behind the ankle representing a reference. The shank was dropped from a height of 21.6cm onto a foam pad to generate vertical impacts along the shank. The IMU mass was adjusted between 5-37grams, which was necessary to solve for all material properties.

Shank IMU vertical inertial acceleration was plotted against soft tissue deformation from double-integration of vertical acceleration difference between the IMUs. This produced a mass-normalized force-deformation curve, to which five polynomial spring models were fit. We selected the polynomial spring model with the highest r-squared and performed a forward optimization to obtain material properties that best simulate soft tissue response across mass conditions.

Results



The quadratic-linear piecewise model best represented the mass-normalized force-deformation curves, detailing a low-deformation region that behaves like a linear spring-mass system with increased stiffening at high deformations. The fit mass was 0.32kg and

the linear stiffness was 758.5N/m, which falls within previous work modeling natural soft tissue oscillations [1].

Discussion

This study presents a method to obtain dynamic soft tissue model and material properties in-vivo by measuring soft tissue response during impacts with IMUs. This methodology expands tissue characterization to high-deformation and high-deformation rate scenarios, which are relevant particularly in injury modeling and assessment. Future work will expand this to other movement directions to obtain 3D dynamic material characterization.

A Tightly Coupled IMU-to-Model Method for Estimating Shoulder Kinematics and Kinetics

Mr. Hassan Osman, Dr. Manon Kok, Dr. Ajay Seth

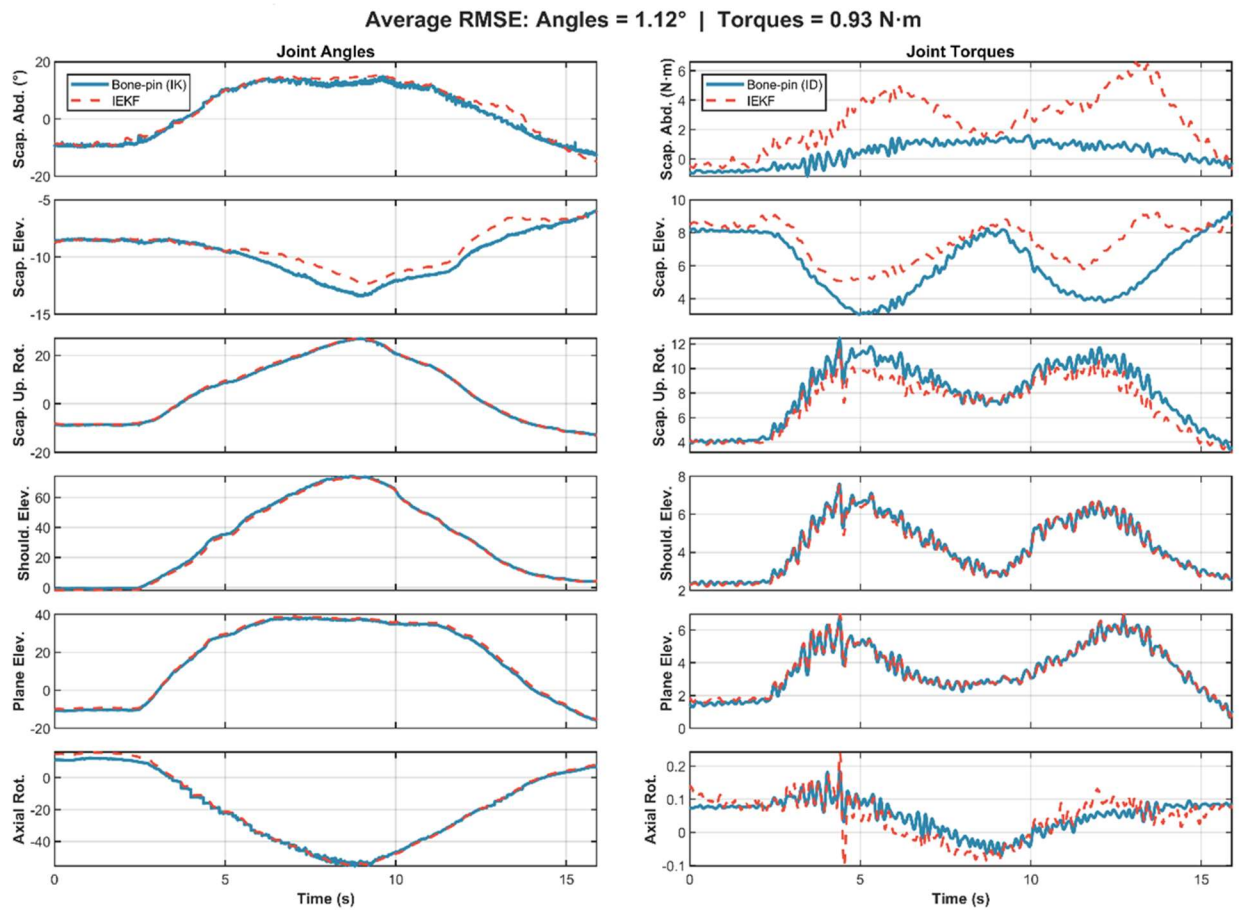
Delft University of Technology, Delft, Zuid-Holland, Netherlands

Introduction

The demand for portable motion capture systems is growing with the rising number of mobility disorder patients due to their ability to provide quantitative motion analysis for medical practitioners that helps them in diagnosis and treatment [1]. Sports applications further contribute to this demand, as motion capture systems provide quantified measurements that can optimize athlete performance and help prevent injuries [2]. Upper extremity movement from IMU-estimated orientations is challenging due to ferromagnetic disturbances [3] and orientations are estimated independent of the musculoskeletal dynamics. In this work, we extend a tightly-coupled IMU-based motion capture algorithm [4], to estimate shoulder movements directly from IMU-measured angular-velocities and linear-accelerations.

Methods

We formulate an iterated extended Kalman filter (IEKF) with a subject-scaled shoulder dynamical model [4,5] implemented in OpenSim [6] with its outputs coupled to IMU-measurements to estimate scapula and glenohumeral joint angles and torques. To test our approach, virtual IMU-measurements of angular velocity and linear acceleration were generated from ground truth shoulder kinematics derived from bone-pins [5]. Four virtual IMUs were attached on the acromion, thorax, humerus and radius. Scapular motion was represented by a 4-coordinate scapulothoracic joint and subject to an acromioclavicular constraint. Initial joint angles and sensor locations were assumed to be known, and initial joint torques were obtained from inverse dynamics when static in the starting pose.



Results

We tested our algorithm on shoulder flexion and abduction movements involving different scapular movements. The figure shows joint angle and torque estimated from our tightly-coupled IEKF approach and compared against bone-pin Inverse Kinematics (IK) and Inverse Dynamics (ID) derived estimates for a shoulder flexion task.

Discussion

Our approach demonstrates the ability to estimate the kinematics and kinetics of the shoulder that includes the scapula from IMU-measurements without the magnetometer and estimates of sensor orientation. Future work will evaluate the algorithm over a broader range of upper-extremity movements, from real IMU data.

Reconstructing Intermediate Spinal Segment Positions Using Two Inertial Measurement Units: A Proof-of-Concept Study

MSc. Roelien Smit-Russcher, MSc. Raymond Zandbergen

Movella Technologies B.V., Enschede, Overijssel, Netherlands

Introduction

The accurate measurement of spinal motion is critical for biomechanics research, motion analysis, and ergonomic assessment, as spinal range of motion (ROM) directly influences whole-body kinematics including arm reach and postural stability. Most studies rely on three or more inertial measurement units (IMUs) to capture gross spinal movements, yet cannot resolve intermediate vertebral motions without dense instrumentation [1]. The present model extends beyond prior approaches by reconstructing intermediate spinal segment positions using only two IMUs. This enables the model to capture the natural spinal rhythms in healthy subjects, characterized by the transition from an S-shape in standing to a C-shape during flexion.

Methods

The continuous orientation model is driven by two IMUs placed at the pelvis and sternum (projected onto T8), with positions derived from orientations. The model extends spherical linear interpolation (SLERP) to incorporate spinal rhythm through two parametrized basis functions, defined independently for the sagittal and frontal planes.

The proof-of-concept was evaluated on one healthy male subject performing five repetitions of standardized spinal movements. IMUs were placed at pelvis and sternum segments. A Qualisys optical motion capture system with 12 markers along the spinal column served as reference. Model parameters were optimized using one rotational motion, then applied to all movements to evaluate generalization. Movement-specific optimization assessed maximum achievable accuracy. Metrics included RMSE averaged over all segments and Pearson's correlation.

Results

See Table 1.

Discussion

The two-IMU model achieved RMSE below 4 cm with generalized parameters and showed strong correlations ($r = 0.80–0.98$, $p < 0.001$). Movement-specific optimization reduced errors to 1.07–2.32 cm ($r \geq 0.97$). Performance was optimal for rotation with pelvis motion (1.07 cm) and lower for fixed pelvis movements (3.97 cm), improving substantially with tuning (1.17 cm). While multi-IMU systems achieve slightly higher accuracy [1], this minimal two-sensor approach offers practical advantages for whole-body analysis. High correlations demonstrate that biomechanically-informed modelling can compensate for reduced sensor density.

The rhythmic spine model successfully reconstructs intermediate spinal segment orientations with sub-4 cm accuracy. Future work will extend the validation to a larger, more diverse cohort to establish generalizability across populations and movement patterns.

Variations in Cervical Muscle Morphology: Implications for Parametric Human Models and Ergonomic Safety Design

Student Jaron Larson[1,2,3], Assistant Research Scientist Sujata Khandare[3,2], Professor Jingwen Hu[3,2]

[1]Northwestern Michigan College, Traverse City, MI, United States. [2]University of Michigan, Ann Arbor, MI, United States. [3]University of Michigan Transportation Research Institute (UMTRI), Ann Arbor, MI, United States

Student Jaron Larson

Assistant Research Scientist Sujata Khandare

Introduction

Neck muscle forces are critical for head stabilization and injury (e.g., whiplash), yet cervical morphology remains poorly represented across the population, including the midsize male model used in most crash injury assessment models. Limited empirical data on cervical muscle structure restricts our ability to represent demographic variability in injury biomechanics. Cervical muscle cross-sectional area (CSA), a key determinant of force-generating capacity, varies widely, but existing datasets are small and demographically narrow. This study quantifies how sex, stature, BMI, and age influence muscle CSA based on a large CT cohort to support development of parametric human models and population-representative ergonomic design.

Methods

Neck CT scans from 636 adults (294 Male, 342 Female; 18–79 years) were processed using TotalSegmentator [1], an AI-based segmentation tool. Levator Scapulae, Prevertebral, and Sternocleidomastoid muscles were analyzed. A custom workflow generated 3D muscle geometries and longitudinal centerlines, and applied perpendicular slicing to compute CSA for selected muscles. A targeted quality control (QC) subsample showed 89% segmentation accuracy. During CSA computation, autofiltering algorithms removed subjects with potential errors (e.g., disconnected meshes, truncated centerlines). After CSA extraction, outliers were reviewed; invalid anatomies were excluded. Demographic

effects were modeled using Analysis of Covariance (ANCOVA) with sex, stature, and age; a supplementary model substituted BMI.

Results

Mean CSA was 1049 ± 224 mm^2 (M) and 755 ± 157 mm^2 (F). In the primary ANCOVA (controlling for stature and age), sex was a significant predictor ($F=206.0$, $p<0.001$); males maintained 264 mm^2 higher CSA than females. Stature ($F=11.5$, $p<0.001$) and age ($F=52.3$, $p<0.001$) were statistically significant (Model $R^2=0.48$). A supplementary model substituting BMI for stature confirmed these effects ($F=183.5$, $p<0.001$; $R^2=0.43$), indicating sex differences in neck CSA persist regardless of body size and shape.

Discussion

Automated CT-based analysis confirms sex is a significant determinant of cervical muscle CSA independent of stature, age, or BMI. Crucially, males exhibit consistently larger CSA, suggesting current scaling methods may overestimate female capacity without considering sex effects. This scalable, QC-verified pipeline enables large-cohort morphometry, providing population-representative inputs for parametric human models to support more equitable injury-risk assessment and crash-dummy design.

Images (Optional)

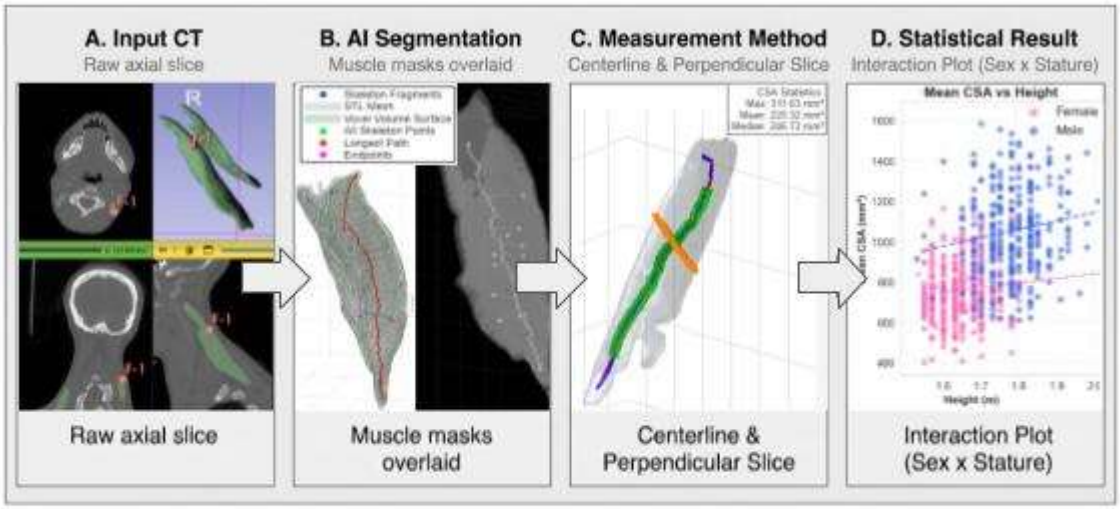

Figure 1: Automated pipeline for cervical muscle CSA quantification. (A) Raw CT input is processed to generate (B) AI-based muscle segmentations. (C) A custom workflow computes 3D centerlines and cross-sectional areas. (D) Statistical analysis reveals significant sex differences independent of body size.

Associations Between Muscular Strength and Shock Exposure at the Head and the Lumbar Spine During Downhill Mountain Biking

Ms Barbara Halmai, Professor Timothy P Holsgrove, Dr Genevieve K R Williams

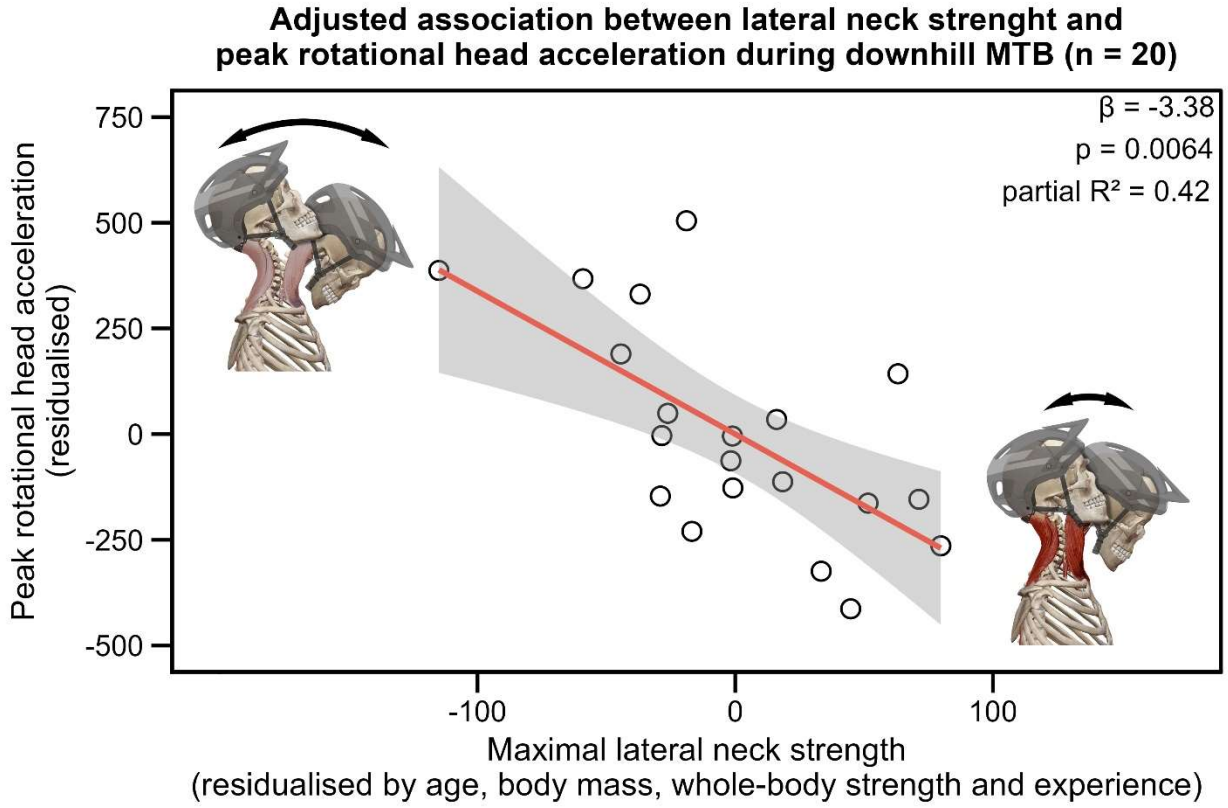
University of Exeter, Exeter, Devon, United Kingdom

Introduction

Downhill mountain biking (MTB) athletes are exposed to high-magnitude shocks during descents, even in the absence of crashes. While advances in bike suspension and wheel configurations can reduce shock exposure, substantial impacts are still transmitted to the head and lumbar spine, raising concerns about musculoskeletal and neurological health. Skeletal muscles play a key role in energy absorption during impacts, suggesting that stronger athletes may be better equipped to attenuate trail-induced shocks. The study aimed to investigate whether greater whole-body and neck strength are associated with reduced head and lumbar acceleration exposure during downhill MTB.

Methods

Twenty experienced downhill riders (36.0±13.6 years; 1.80±0.1m; 81.7±10.9kg; 15.4±12.8 years of experience) participated in the study. Maximal whole-body strength was evaluated using the isometric mid-thigh pull, and maximal isometric neck strength was assessed using a custom-built apparatus. Riders completed four downhill runs wearing inertial measurement units attached to the head and the lumbar spine. Peak linear acceleration was identified for the head and the lumbar spine, and peak rotational acceleration was calculated for the head. Acceleration events exceeding daily activity thresholds were also counted (linear head >3g, rotational head >400rad.s^{-2}, lumbar >8g). Multiple linear regression models were used to examine whether maximal strength predicted acceleration exposure, while controlling for age, body mass and experience.



Results

Greater lateral neck strength was associated with lower rotational head accelerations during downhill riding ($t=-3.79$, $p<0.01$), with every 1N increase in strength predicting a 3.38rad.s^{-2} reduction. Whole-body strength did not significantly influence head or lumbar acceleration exposure. However, higher body mass was associated with greater lumbar acceleration peaks ($t=2.41$, $p<0.05$) and a higher number of peaks exceeding normal thresholds ($t=2.38$, $p<0.05$).

Discussion

Findings indicate that lateral neck strength contributes to rotational stabilisation of the head under transmitted shocks, potentially via an enhanced capacity for synchronous force production by cervical flexor and extensor muscles. Targeted neck strengthening and bodyweight management may represent strategies to reduce cumulative head and lumbar loading in downhill MTB athletes. This work provides the first field-based evidence that neck strength influences head accelerations under shock exposure, with important implications for injury prevention and long-term brain health.

OA193-03

A Novel Neck Surrogate that Recreates Buckling Mechanics in Head Compressive Loading

Mr. AJ Hinman, Ms. Sophie Beauchesne, Mr. Aaron Brice, Dr. Christopher Dennison

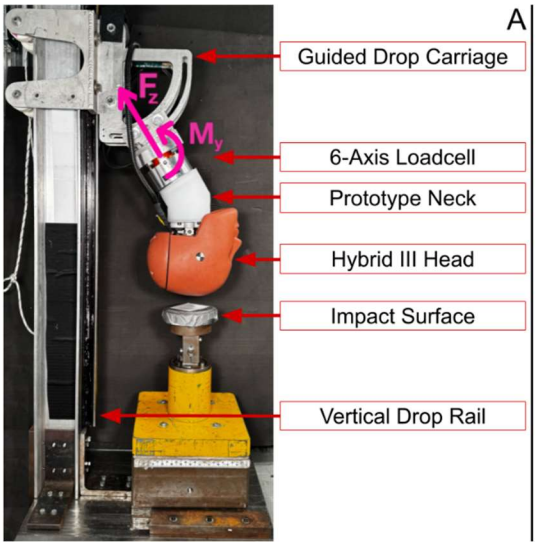
University of Victoria, Victoria, BC, Canada

Introduction

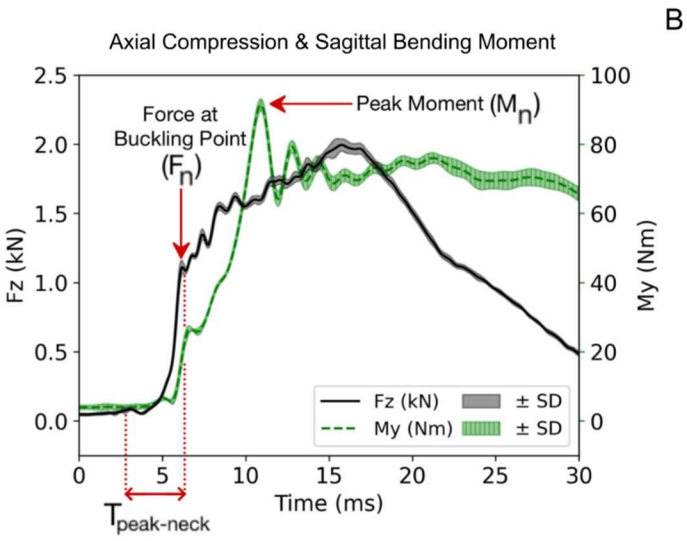
In the field of experimental headgear assessment, automotive head-neck surrogates are typically applied. Scrutiny is often leveled at the necks, as they are not typically validated for head impact studies. We have previously reported on a bespoke surrogate developed for biofidelic headgear assessment [1]. The present study is an extension of this past work because it tests the hypothesis that our neck exhibits a biofidelic kinetic response in a previously untested impact scenario; vertex head loading leading to neck axial compression [2], that can lead to both head-brain and neck injury.

Methods

A custom inverted drop experiment using SAE j211 compliant equipment and post processing techniques was applied (Figure 1.A). Impact speeds were 3m/s onto a rigid surface (n=10, $m_{carriage}$=11-12kg simulating following torso). Axial force and sagittal bending moments were collected at the neck base. Data was processed to identify key kinetics, including axial force at neck buckle, peak sagittal moment, and time to buckle.



Results



Referring to the nomenclature in Figure 1.B, peak compression force was 1.11±0.05kN (F_n), with buckling occurring at ~3.2ms ($T_{peak\text{-}neck}$). Buckling was followed by a sagittal moment maxima to 91.3±1.8Nm (M_n).

Discussion

Saari et al. [2] and Nightingale et al. [3] previously published cadaveric data from impacts we recreated in our study, and it is to this data we contrast. Saari et al. F_n were 1.91±0.73kN occurring ~4.2ms after carriage release, followed by M_n of 126.0±22.3Nm in 2.8m/s impacts (n=6, $m_{carriage}$=15kg) [2]. Select data from Nightingale et al. matching our impact parameters (n=2, $m_{carriage}$=16kg) showed F_n 1.90±0.06kN ~4.4ms after carriage release with M_n 124.9±26.9Nm (note: we equate T-injury to $T_{peak\text{-}neck}$ for the purpose of this comparison) [3]. We interpret these findings to suggest our neck can exhibit realistic buckling relative to cadavers, and offer an alternative to the Hybrid III neck that is known to be excessively stiff axially.

Velocity of Spinal Cord Injury Matters – Comparing Contusion and Dislocation in a Cervical Rat Model

MMr. Alexander Burden B.Eng, Dr. Jie Liu MD, Mr. Min Liu, Mrs. Nicole Janzen MSc, Mrs. Elizabeth Raffaele MSc, Ms. Haley Briggs BSc, Mr. Aidan Loong BSc, Dr. Oscar Seira PhD, Dr. Ward Plunet PhD, Dr. Thomas Oxland PhD, Dr. Wolfram Tetzlaff MD, PhD

UBC, Vancouver, BC, Canada

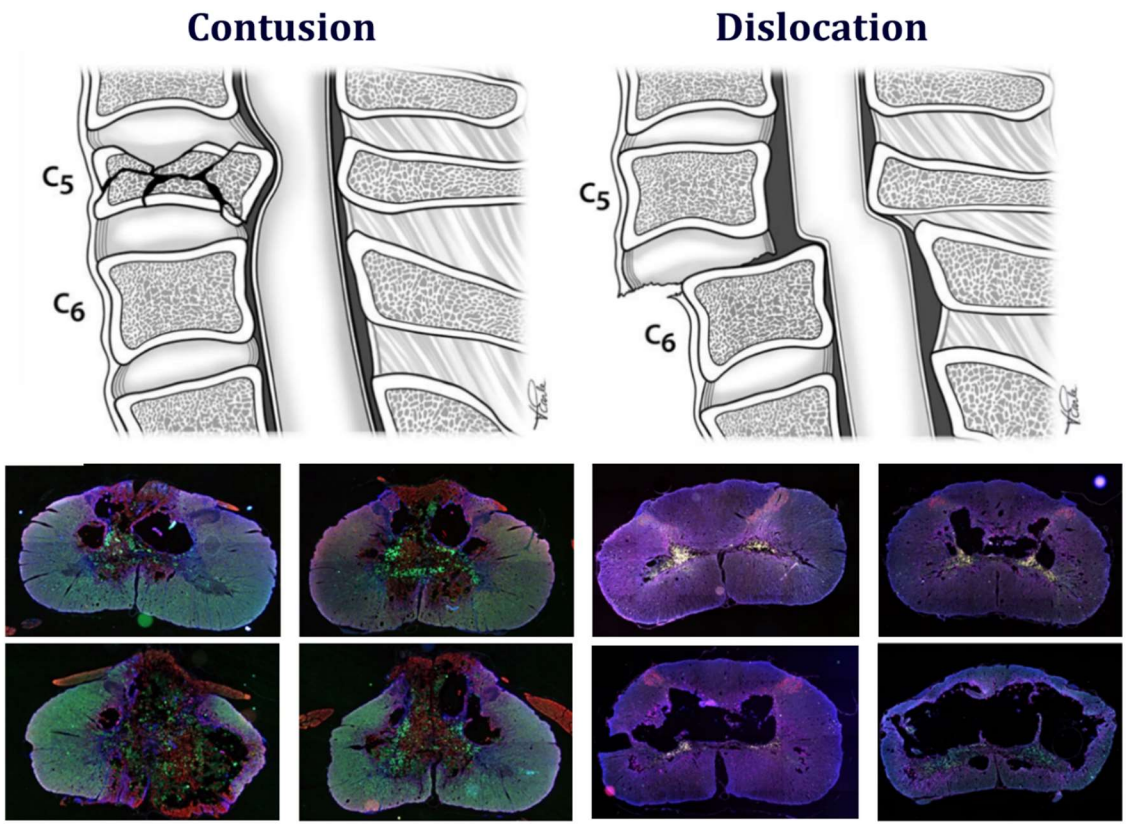
Introduction

Clinically, spinal cord injuries (SCI) are heterogeneous, occurring through various physical mechanisms, with different velocities, and depths of impingement. Cervical SCI are most common, with the majority of injuries occurring due to burst-fracture (9-35%) or dislocation (45-58%). Past pre-clinical experimental work has established that increasing velocity of contusion injuries results in greater functional deficits; however, the effect of velocity on dislocation injuries has not been clearly established. Additionally, while previous work has compared these injuries, relative severity of injury has not been controlled for, potentially conflating mechanism differences with differences in overall injury severity.

Methods

160 Sprague-Dawley rats were divided into six total groups; four contusion cohorts and two dislocation cohorts. Half of the cohorts were assigned low velocity (55mm/s) and the other half high velocity (550mm/s). Contusion cohorts (n=20) were further differentiated by two displacements; low (1.35mm depth) and high (1.45mm depth). Dislocation injuries (n=40) were conducted at 1.6 mm displacement of the C5/6 vertebrae, which were matched with the high displacement contusion groups (of low and high velocity) using the Martinez Open Field Locomotor scale. All SCI were conducted under aseptic surgery conditions using the UBC Multi-Mechanism Impactor and animals were kept for 6 weeks' post-injury for behavioral analysis, before being sacrificed and perfused for histological analysis.

Results



The Martinez Open Field, Irvine, Beatties, and Bresnahan (IBB) forelimb scale test showed significant differences ($p<0.001$) between mechanism and velocity cohorts, while the Grip Strength and Horizontal Ladder tests only showed differences between mechanisms ($p<0.001$). Motor Neuron counts at the injury epicentre were significantly lower in dislocation ($p<0.001$) than contusion, but were significantly higher in adjacent sections (-

1200μm and +600μm) indicating a more localized zone of injury. Myelin debris was significantly higher in dislocation ($p<0.001$) and showed an interaction effect with velocity.

Discussion

This is the largest study to directly compare contusion and dislocation injuries, and supports past work showing the differences in functional and histological outcomes between physical injury mechanisms. Velocity appears to affect injury severity in dislocation in a similar way and magnitude as it does in contusion, having significant effect on some behavioral tasks but not others.

A User-Centered Biomechanical Approach to Reduce Low-Back Load in Circus Russian Bar Porters

M.Sc.A. Pierre Schmidt[1,2,3], PhD Marion Cossin[1], PhD Eric Wagnac[4], PhD Anne-Laure Ménard[5], M.Sc.A. Gerald Parent[5], M.Sc.A. Flavie Gilet[4], M.Sc.A. Yves Mathieu[6]

[1]Centre HUPR, Montréal, Quebec, Canada. [2]Ecole nationale de cirque, Montréal, Québec, Canada. [3]École de technologie supérieure, Montréal, Quebec, Canada. [4]ETS, Montréal, Québec, Canada. [5]INEDI, Terrebonne, Québec, Canada. [6]CDCQ, St-Jérôme, Québec, Canada

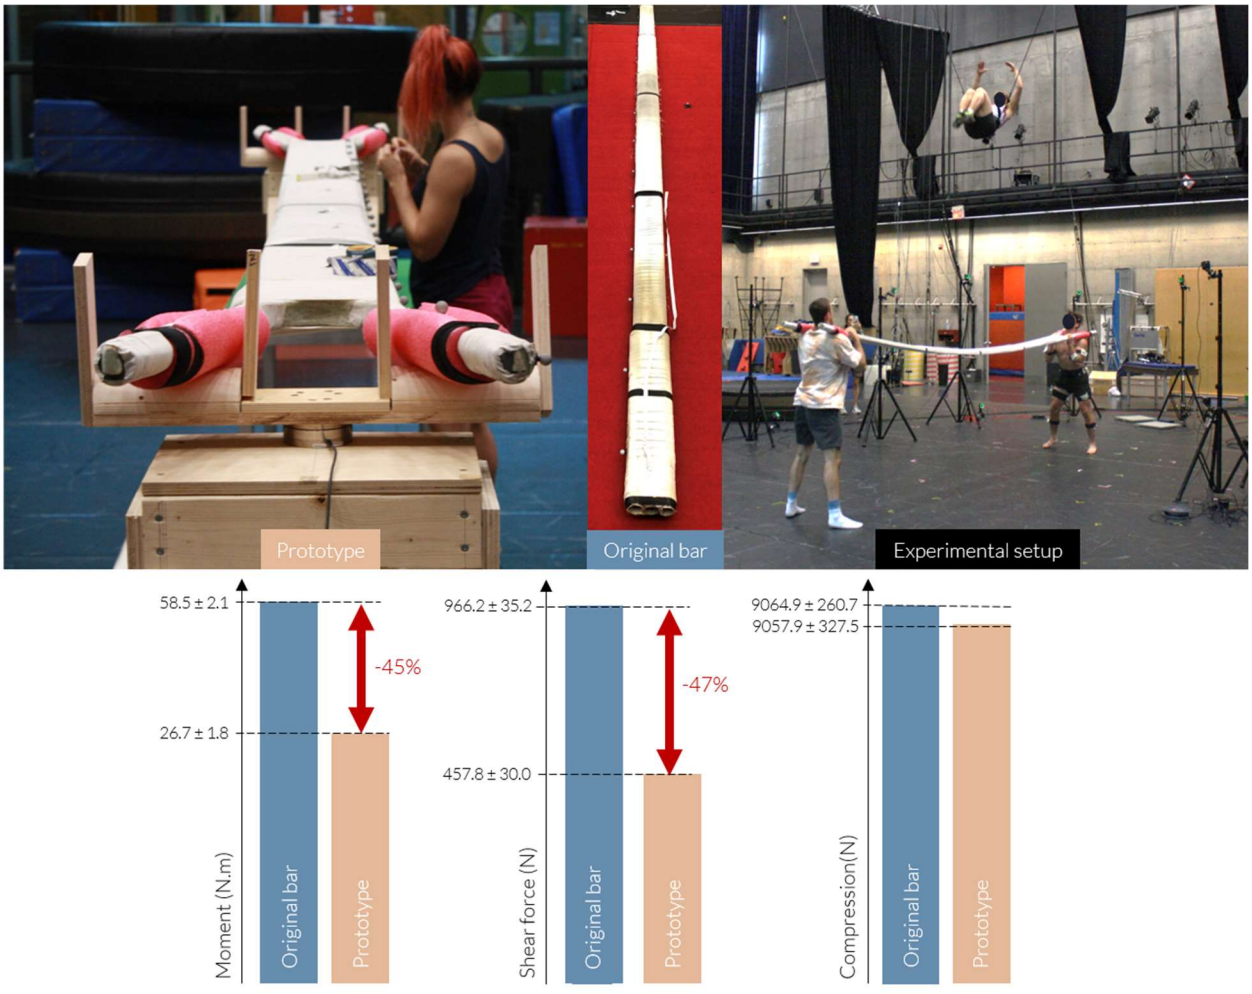
Introduction

In 2019, Cirque du Soleil reported chronic low-back pain among Russian bar artists, leading to substantial off-stage time and economic impact. Russian bar acts involve two porters supporting a flexible bar assembled with pole vaulting poles. A third artist, the flyer, performs acrobatic maneuvers by jumping on the bar. To address Cirque's concerns, a multidisciplinary transversal project involving five academic institutions and three industrial partners was conducted. This project demonstrates a new method for addressing biomechanics-related injury phenomena in the acrobatic community.

Methods

From 2019 to 2024, a multi-stage protocol was implemented after broader group of artists confirmed the prevalence of low-back pain among porters. Data were collected on two porters using motion capture, EMG, and force platforms to quantify spinal loads during typical Russian bar performances using a newly validated full-body musculoskeletal model [1]. Modeling data and iterative input from artists guided the development of several novel Russian bar concepts and ultimately, a Y-shaped prototype was selected. A fiberglass prototype was built with mechanical properties comparable to traditional bars. Using the validated model and a second data collection, spinal loads generated by the traditional and prototype bars were compared [2].

Results



The prototype significantly reduced lumbar loading, particularly in the frontal plane with a decrease in moments of about 45% and a decrease in shearing forces of about 47%. The new prototype did not reduce compression force on the lumbar column. Artists reported

improved comfort and perceived safety when using the Y-shaped bar, notably due to reduced slipping risk.

Discussion

Despite the small sample size, these results support the notion that design thinking along with biomechanical analysis can help reduce lower load on porters back. The findings open the door to evidence-based equipment design in the performing arts. Furthermore, to our knowledge, this is the first full-body musculoskeletal model developed specifically for circus artists, a population subject to high mechanical demands. This project demonstrates how a biomechanical protocol might, in the future, support injury mitigation in the circus and/or acrobatic community.

Influence of Intervertebral Disc Proximity on Hemorrhagic Severity in Porcine Spinal Cord Injury: A Biomechanical and Semi-Automated Imaging Assessment

Mr. Amirhossein Borjali PhD Candidate, Biomedical Engineering, Ms. Kitty So, Ms. Aysha Allard Brown PhD Candidate, Ms. Neda Manouchehri, Ms. Juliana Mitchell, Dr. Femke Streijger PhD, Dr. Brian Kwon MD, PhD, FRCSC, Dr. Peter Cripton PhD, P.Eng.

University of British Columbia, Vancouver, BC, Canada

Introduction

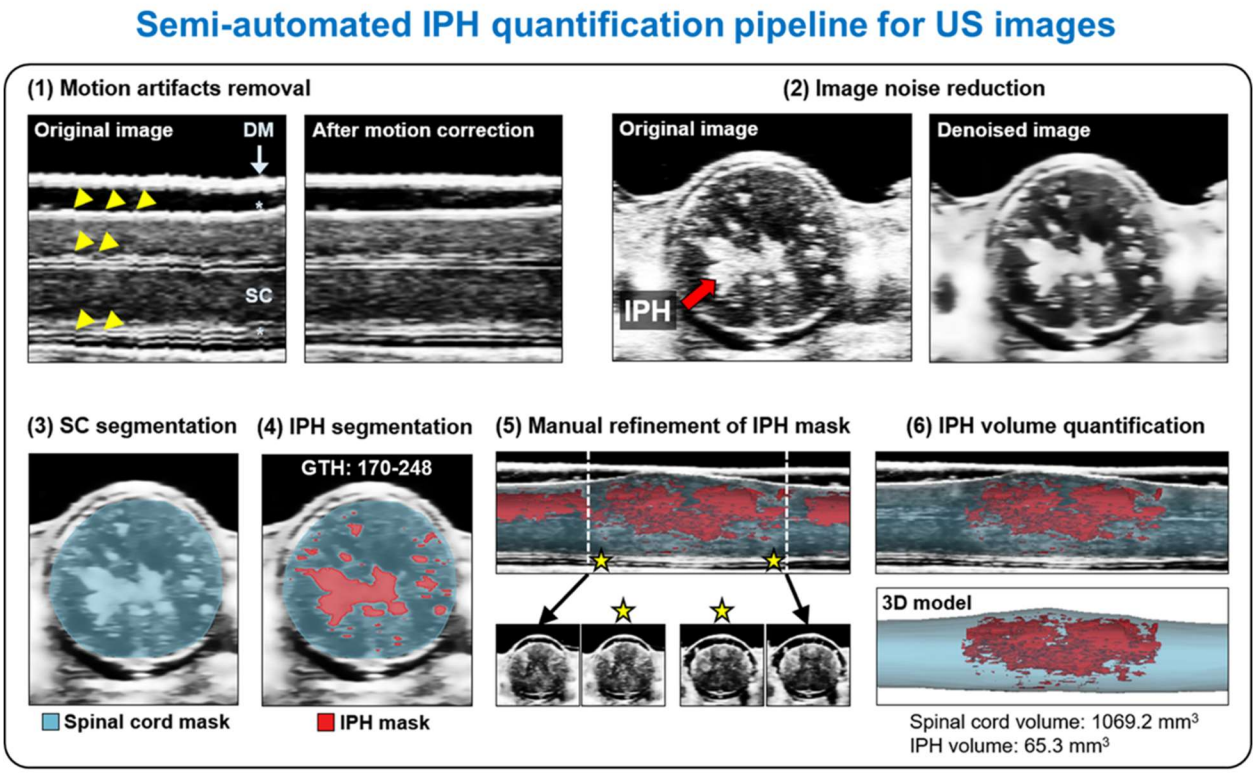
Animal models of spinal cord injury (SCI) are essential for understanding SCI biomechanics and evaluating therapies, yet substantial variability persists in the severity metrics in porcine SCI despite standardized impact parameters. One potential contributor is the stiffness of the anatomical region beneath the impact site. At the vertebral body, the ventral surface of the spinal canal is concave, providing more space beneath the spinal cord, whereas impacts over the intervertebral disc (IVD) interact with a protrusive surface formed by the endplates, annulus fibrosus, and posterior longitudinal ligament (PLL). These geometric differences may influence injury severity.

Intraparenchymal hemorrhage (IPH) is a recognized marker of injury severity, but the effect of impact proximity to the IVD has not been quantified. Manual IPH segmentation also introduces operator variability. This study evaluates whether injury–IVD distance predicts hemorrhage magnitude in a porcine SCI model and assesses a semi-automated ultrasound-based pipeline for IPH quantification.

Methods

SCI was induced at T2 using a weight-drop model while varying the distance between the impact epicenter and the nearest IVD, with impact energy held constant. Ultrasound imaging provided real-time visualization of acute IPH. A semi-automated segmentation pipeline was used for IPH quantification. Hemorrhage volume was normalized to spinal cord (SC) volume, and correlation analyses examined associations with injury–IVD distance.

Results



Injury–IVD distance showed a significant inverse relationship with absolute IPH volume (R^2 = 0.3181, $p < 0.01$). Injuries closer to the disc produced larger hemorrhage. Normalization to SC volume strengthened this relationship (R^2 = 0.5441, $p < 0.01$), indicating that relative hemorrhage severity increases consistently with greater IVD proximity and with greater cord size.

Discussion

The elevated hemorrhagic response near the IVD aligns with anatomical differences. The protrusion created by disc structures reduces available space and likely increases local strain in the spinal cord during impact compared with the concave ventral surface over the vertebral body. Accounting for injury–IVD distance may therefore reduce variability in porcine SCI studies.

In conclusion, proximity to the IVD significantly increases hemorrhagic severity in porcine SCI. Additionally, integrating anatomical context and objective imaging methods may improve reproducibility and translational relevance in large-animal contusion models.

More Bone, More Problems: Compromised Microarchitecture of Osteosclerotic Matrix in Prostate Cancer Bone Metastasis

Ms. Naomi Jung BASc[1,2], Dr. Felipe Eltit PhD[2], Dr. Qiong Wang PhD[1], Ms. Robyn Birch MASc[1], Ms. Bita Mojtahedzadeh BSc[1], Mr. Dennis Xie BSc[1], Mr. Samuel Xu MEng[1], Dr. Danmei Liu PhD[1], Dr. Eva Corey PhD[3], Dr. Colm Morrissey PhD[3], Dr. Lawrence True PhD[3], Dr. Rizhi Wang PhD[1], Dr. Michael Cox PhD[1]

[1]University of British Columbia, Vancouver, British Columbia, Canada. [2]Vancouver Prostate Centre, Vancouver, British Columbia, Canada. [3]University of Washington, Seattle, Washington, United States

Introduction

1 in 8 men will be diagnosed with prostate cancer (PC), and ~15% progress to an incurable metastatic state that primarily affects the bone. Patients with PC bone metastasis (PCBM) have three-fold higher fracture risk yet the biomechanical basis for this fragility remains unknown. We hypothesize that PCBM-affected bone has altered microarchitecture and organization which contributes to lower local mechanical properties and poorer fracture resistance.

Methods

We analyzed cadaveric vertebral trabecular bone samples from the thoracic/lumbar spine of patients who died of PC (n=12) and non-cancer donors (n=3). Quantitative backscattered scanning electron microscopy (qBSE) was used to quantify calcium weight percent (CaWt%) and lacunar density/shape using a custom MATLAB pipeline (5-9 ROIs per sample per bone type). We evaluated collagen organization with picrosirius red staining and polarized light imaging, and performed nanoindentation in matched ROIs (5 indents per ROI) to measure local elastic modulus and hardness. Bulk mechanical behavior was assessed by uniaxial compression to failure (7 PCBM; 3 non-cancer). Groups were compared using t-tests or one-way ANOVA with Tukey post-hoc testing (α=0.05).

Results

PCBM samples were predominantly osteosclerotic with elevated bone volume/total volume (BV/TV; Figure 1). Peak CaWt% did not differ between control, trabecular, and sclerotic regions, but CaWt% width was greater in PCBM (p=0.026). From nanoindentation, mean elastic modulus and hardness were not different between control (E =12.96 GPa, H=0.46 GPa) and PCBM sclerotic (E=11.47 GPa, H=0.46 GPa). BV/TV explained 77% of variance in elastic modulus from compression testing. PCBM osteosclerotic bone

exhibited poor collagen organization compared to trabecular regions with elevated lacunar density, area, and circularity, and poor lacunar alignment (all $p<0.001$).

Discussion

PCBM osteosclerotic bone demonstrates collagen disorganization and abnormal lacunar morphology despite similar peak mineralization and indentation metrics. Since bulk stiffness was largely explained by BV/TV, the elevated fracture risk in PCBM may reflect tissue-level damage accumulation and impaired toughening mechanisms that are not captured by modulus or hardness alone. Notably, increased mineral density heterogeneity in osteosclerotic regions may promote local strain concentrations that facilitate microdamage. Ongoing work will quantify crack initiation and propagation following compression to define PCBM-specific fracture mechanisms.

Images (Optional)

Ageing Increases Stiffness and Disrupts Strain Distribution in Human Lumbar Intervertebral Discs: Implications for Constitutive Modelling and Boundary Conditions Definition

Miss Margherita Pasini, Miss Gaia Youssef, Mr Davide Alberti, Prof Luca Cristofolini, Dr Marco Palanca

University of Bologna, Bologna, Italy, Italy

Introduction

Intervertebral discs (IVDs) undergo structural degeneration throughout life, leading to alterations of their biomechanical behaviour[1]. Yet, most available IVDs datasets come from the elderly, who exhibit marked age-related degeneration, and focus on apparent properties (stiffness, ROM, neutral zone). It remains challenging to determine how and to what extent degeneration affects IVDs mechanical behaviour, as well as to define credible specific boundary conditions for computational models across different ages.

A comprehensive biomechanical characterisation of the IVD across ageing is still missing. We aimed to provide an evaluation of age-related IVD mechanical changes to support the definition of constitutive laws.

Methods

Twenty-three lumbar IVDs were harvested from human donors and divided into age groups: young (n=11,33±2 years), adults (n=5,44±3 years), and old (n=7,63±1 years). Specimens underwent 3T-MRI and qCT to assess IVD degeneration[2] and exclude pathologies. The specimens were axially compressed within the elastic regime (up to 0.5% body weight) using a spine simulator (MIB4.0-MAS2-S) with a 6-axis load cell. A 3D-DIC system (Aramis Adjustable, Zeiss) was used to measure the full-field maximum and minimum principal strains (Eps_max, Eps_min) on the IVD surface.

The stiffness was obtained as the load-displacement slope between 20-80% of the maximum load. Strain variability was quantified using the Coefficient of Variation(CV) over the IVD surface. The age groups were compared (Kruskal-Wallis Test).

Results

Old IVDs were significantly stiffer than both young (+48%,p=0.025) and adults (+68%,p=0.050). They also showed larger Eps_min compared to young (+49%,p=0.012), and larger strain variability. Principal strains were consistently aligned over the surface of young IVDs, old IVDs showed scattered and irregular strain directions.

Discussion

The optimized architecture of the young IVDs enabled an efficient and homogeneous load transfer across adjacent vertebrae. In contrast, degenerated IVDs demonstrated strain concentrations and unpredictable mechanical responses. Age-related changes increased disc stiffness and impaired the capacity to distribute strain uniformly, thereby accentuating the mechanical difference between healthy and degenerated tissues. These findings highlight the limitations of relying on apparent material properties derived from a partially representative population and provide essential data for the development and validation of accurate vertebral computational models.

Lytic Lesion Size and Location Affect the Compressive Failure Load of Human Metastatic Vertebrae Calculated With Subject Specific Finite Element Models

Mr Robert Roger[1], Dr Rajdeep Ghosh[1], Dr Áron Lazáry[2], Dr Lingzhong Guo[1], Professor Damien Lacroix[1], Professor Enrico Dall'Ara[1]

[1]University of Sheffield, Sheffield, England, United Kingdom. [2]National Center for Spinal Disorders, Budapest, Central Hungary, Hungary

Mr Robert Roger

Dr Rajdeep Ghosh

Dr Áron Lazáry

Dr Lingzhong Guo

Professor Damien Lacroix

Introduction

Approximately 16% of cancer patients are clinically diagnosed with vertebral metastases [1], which present in different types of lesions depending on the primary tumour. Lytic lesions reduce bone mineral density and increase fracture risk. Lytic lesions form in a variety of locations and volumes, yet the biomechanical impact of these factors remains poorly quantified and is not considered in current clinical stability scores. Finite element (FE) modelling provides a means to systematically evaluate these effects. This study aimed to assess how location and volume of simulated lytic lesions influenced vertebral failure load using FE models derived from computed tomography (CT)-images.

Methods

Three radiologically healthy lumbar vertebrae from three cancer patients with spine metastases were semi-automatically segmented from CT-images. Heterogeneous isotropic elasto-plastic homogenised FE (hFE) models were created from each vertebra. Material properties were assigned from bone mineral density distributions of densitometrically calibrated CT-images. Spheroidal lesions with volume of 10%, 20%, or 30% of the vertebral body volume (VBV) were simulated by assigning an elastic modulus of 0.01 MPa. Lesion's centres are shown in Figure-1A. Compressive ultimate force (FU) was calculated for each hFE model at 1.9% of apparent axial deformation. Normalised FU was calculated with respect to intact control vertebra.

Results

The range of normalised FU was 7.3±1.7%-24.3±2.3%, 14.9±2.1%-37.8±1.4%, and 22.0±1.8%-48.8±4.1% for lesions occupying respectively 10%, 20%, and 30% of the VBV (Figure-1B).

Discussion

Both lesion size and location influenced the FU of the vertebra and should be considered in scoring systems to estimate vertebral stability. Larger lesions produced greater FU reduction. Substantial variability across locations indicates position is equally important for assessing vertebral stability. Lateral regions located close to the cortex were most detrimental, suggesting these areas represent biomechanically vulnerable regions.

Images (Optional)

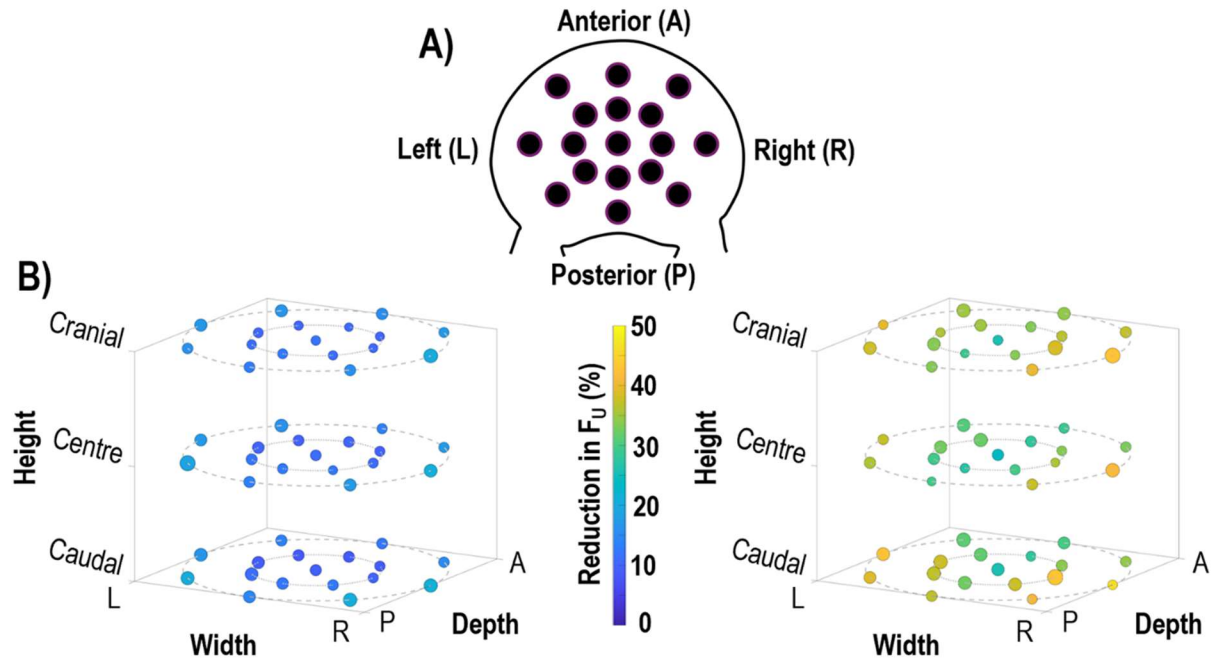

Figure 1: A) Cross section of a vertebral body displaying the location of the centre of virtual lesions at one axial location. B) Mean reduction in failure load across patients of simulated lesions with a volume of 10% (left) and 30% (right) of the vertebral body volume. Markers represent the location of the centre of the lesion, and the size of the marker represents the standard deviation of failure load reduction across patients.

Examining the mechanical contribution of elastin in the bovine annulus fibrosus

Ms Sabrina Sinopoli MSc, Ms Amber Swent BSc, Dr Diane Gregory PhD

Wilfrid Laurier University, Waterloo, Ontario, Canada

Ms Sabrina Sinopoli

Introduction

Low back pain, a common concern for the expanding aging population, emerges from various biomechanical disruptions of the spine often a result of damage to the intervertebral disc (IVD). It is therefore important to understand the mechanical contribution of the various structural components in the IVD. One such component is the protein elastin. Research has shown that elastic fibres are present in all parts of the IVD, but that their organization varies [1]. Elastic fibres are found between lamellae (perpendicular cross-bridges) and within lamellae (orientated parallel to collagen fibres) [1]. This study examined the mechanical contribution of elastin to the properties of the annulus fibrosus via enzymatic digestion of elastin.

Methods

Six bovine lumbar spines were used to obtain 18 IVDs. Following removal of the nucleus pulposus, samples were washed in PBS and randomly assigned to one of three conditions: 1) PBS only; 2) PBS+buffers which included protease inhibitors; 3) PBS+buffers+elastase (3U/mL). The submerged samples were then placed on a rocker plate at 40 rotations/minute and incubated for 36 hours (at 37°C). Following incubation, samples were washed with PBS and dissected to obtain two T-peel test samples to quantify lamellar adhesion and two bilayer test samples to quantify annular tensile properties.

Results

No significant effect of enzymatic digestion of elastin was observed. However, the group containing PBS+buffer required significantly less stress to reach 15% strain in the bilayer tests compared to samples in the PBS only group ($p=0.04$).

Discussion

The lack of mechanical effects following enzymatic digestion suggests elastin may not play a major role in overall IVD mechanical integrity, potentially due to its limited composition (less than 5% dry weight) [2]. The intact remaining collagen fibres may have had a greater responsibility for maintaining IVD strength in the absence of elastin. Additionally, as the mechanical tests performed measured overall annular tensile mechanics and lamellar adhesive mechanics, it is possible the intralamellar matrix (the connective matrix found within single lamellae), was independently affected by elastin digestion, which may have been overlooked.

OA195-02

Longitudinal Joint Mechanics in a Post-Traumatic Osteoarthritis Mouse Model Using I*n Vivo* image-Guided Mechanical Evaluation.

Ms Emma C. Boersma, Ms Annunzia M. Cagnoni, Dr Han Liu, Prof Kathryn S. Stok

The University of Melbourne, Melbourne, Victoria, Australia

Introduction

Image-guided mechanical evaluation combines mechanical testing with micro-computed tomography (microCT) to provide insight into joint loading at microstructural level [1]. Cross-sectional studies have shown that mechanical data can describe joint disease and serve as a fundamental basis for *in silico* models [1]. Longitudinal data would permit assessment of joint adaptation over time. The aim of this study was to longitudinally examine joint mechanics using *in vivo* image-guided mechanical evaluation of healthy and diseased mouse knee joints.

Methods

Destabilisation of the medial meniscus (DMM) or Sham surgery was performed on fourteen-week-old C57Bl/6 mice (n=10/group). The Mouse Actuating X-ray Imaging System (MAXIS) was used to perform stress-relaxation compression on the right knee during microCT scanning (10.4 µm, 70 kVp, 57-114 µA; vivaCT80, Scanco Medical) at three timepoints: before surgery (0-), 14- and 28-days post-surgery (Figure 1A). At each timepoint, two images were acquired during relaxation phases of the mechanical test. Steps were held at constant actuator displacement when the load cell reached (i) preload 200 mN, and (ii) loaded 300 mN. Images were processed as previously described, and joint space width (JSW), volume (JSV) and lowest voxel count (LVC) were calculated [2]. Actuator displacement at step ii (d_a) was analysed, and the effect of disease and time on imaging and mechanical measures were assessed using a mixed-effects model.

Results

Preliminary results show that following surgery, the actuator displacement required to reach the loads are smaller in DMM than Sham, with a significant difference at 4 weeks post-surgery (Figure 1B). Joint space data (not shown) suggests applied actuator displacements are larger than those experienced in the joint.

Discussion

In this first *in vivo* study using MAXIS, displacement in Sham and DMM knee joints was observed over time, demonstrating the sensitivity of MAXIS to joint health and disease progression. Displacements within the knee joint were only 1-2 voxels compared to those measured at the actuator. Further validation considering partial volume effects, must be conducted. This research leads to exciting possibilities, providing data for *in silico* models to explore links between material properties, tissue strain and cellular responses.

Images (Optional)

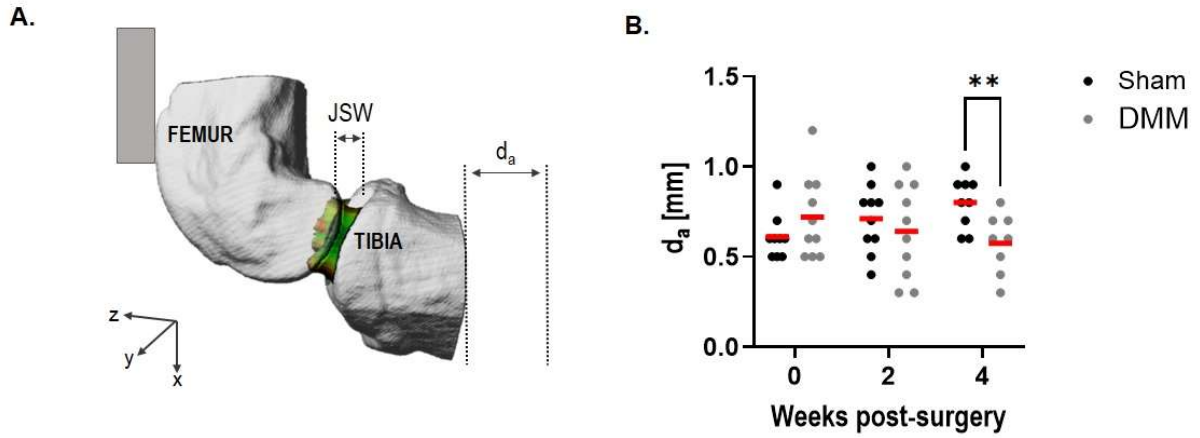

Figure 1. (A) Femur and tibia in sagittal plane and the direction of actuator displacement (d_a), along the z-direction, compared to joint space displacement, JSW and (B) showing the difference in actuation displacement over time in each group.

Ultrasound Evaluation of Acute Knee Cartilage Response After Walking in Patients with Knee Osteoarthritis

Dr. Derek Pamukoff PhD[1], Mr. Harry Battersby MSc[1], Dr. Richard Magony PhD[1], Dr. Hayden Atkinson PhD[1], Ms. Tamara Tompkins MSc[1], Dr. Richard Willy PT PhD[2], Dr. Tom Appleton MD PhD[1], Dr. Trevor Birmingham PT PhD[1]

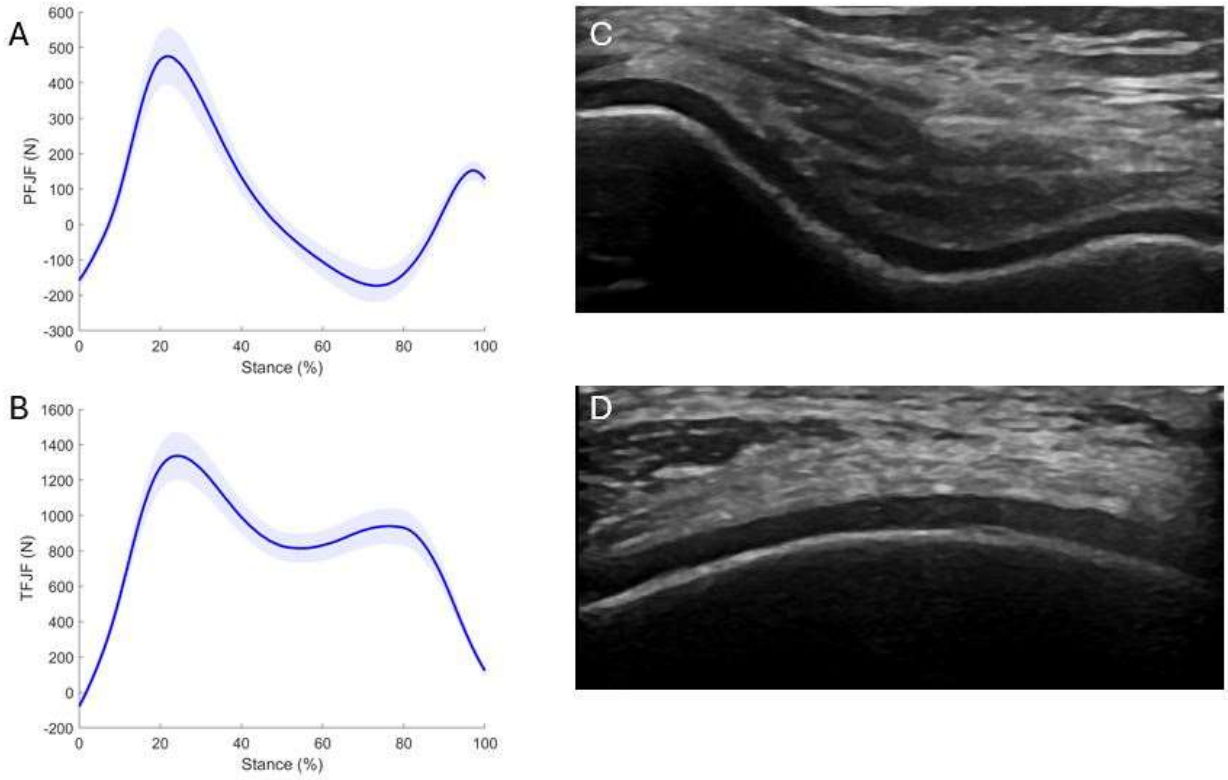
[1]Western University, London, ON, Canada. [2]The Ohio State University, Columbus, Ohio, United States

Introduction

Articular cartilage degradation is a primary feature of knee osteoarthritis (OA). Ultrasound imaging is used to evaluate cartilage outcomes that may be sensitive to loading paradigms. We evaluated acute knee cartilage response to a walking bout using ultrasound imaging.

Methods

35 patients with mild-to-moderate knee OA (19 male, 16 female; Age=62.8 (12) years; BMI: 26.6 (4.3) kg/m^2; Kellgren-Lawrence Grades 1-3 (n): 12, 10, 13) completed bilateral ultrasound imaging of the femoral trochlea and medial femoral condyle before and after 30 minutes of walking on a force-instrumented treadmill with motion capture at a self-selected speed (1.13 (0.14) m/s)). Gait biomechanics were sampled for 10 seconds at the end of every fifth minute. Peak patellofemoral (PFJF) and medial tibiofemoral contact force (TFJF) were derived and averaged across stances (Fig 1A-B). Thickness and echo-intensity (EI) were extracted from ultrasound images (Fig 1C-D). Participants self-reported their more symptomatic knee. 2 (limb) x 2 (time) ANOVA with repeated measures evaluated the change in cartilage thickness and EI. Multiple stepwise regression evaluated the association between absolute gait (TFJF and PFJF) and cartilage outcomes (thickness and EI) adjusting for age, sex, BMI, and prior injury in the symptomatic knee.



Results

There was a limb by time interaction for medial condyle cartilage thickness ($F_{1,33}$=4.94, p=0.03). Post hoc comparisons found thinner cartilage after walking in the more symptomatic knee (Mean Difference=-0.15 (-0.08, -0.21) mm, p=0.001), and cartilage was thinner in the more versus less symptomatic knee after walking (Mean Difference=-0.16 (-0.02, -0.30) mm, p=0.024). There was a main effect of limb indicating higher EI in the more symptomatic knee in the medial condyle ($F_{1,33}$=8.40, p=0.01; Mean Difference=4.34 (1.30, 7.40)) and trochlea ($F_{1,33}$=4.09, p=0.05; Mean Difference=3.22 (0.02, 6.42)). A larger medial TFJF (β=0.01, ΔR^2=0.15, p=0.021) was associated with higher medial condyle cartilage EI.

Discussion

There was an acute reduction in medial condyle cartilage thickness, but not within the trochlea. Patients with knee OA walk with less knee flexion, likely limiting patellofemoral loading. Higher medial TFJF was associated with higher cartilage EI on the medial condyle, which may provide a surrogate of cartilage composition that contributes to greater deformation in response to loading.

In Vivo Dynamic Stereo X-Ray Analysis Shows Medial and Lateral Tibial Slope are Correlated with Knee Mechanics after Anterior Cruciate Ligament Reconstruction

Ms. Kristen Seballos BS, MS[1], Mr. Austin Carcia BS[1], Dr. Armando Vidal MD[1,2], Dr. Jonathan Godin MD, MBA[1,2], Dr. Thomas Hackett MD[1,2], Dr. Matthew Provencher MD, MBA[1,2], Dr. Peter Millett MD, MSc[1,2], Dr. Johnny Huard PhD[1], Dr. Scott Tashman PhD[1], Dr. Colin Smith PhD[1]

[1]Steadman Philippon Research Institute, Vail, Colorado, United States. [2]The Steadman Clinic, Vail, Colorado, United States

Introduction

It is widely thought that anterior cruciate ligament (ACL) strain is increased by greater posterior tibial slope (PTS), which can contribute to ACL injuries and retears [1]. However, a recent study found peak ACL strain measured during single leg jumps with Dynamic Stereo X-ray (DSX) had no significant correlation with medial and lateral PTS [2].

Methods

Twenty-six patients (15 Female, 28.3±6.3 years) received unilateral bone-patellar tendon-bone ACL reconstruction (ACLR) in an IRB-approved clinical trial investigating the impact of orthobiologics on healing (IRB#2019-13, NCT04205656). All treatments groups are combined for this analysis. DSX assessments were performed during downhill running at 6- and 12-months post-surgery. CT-based bone models were registered to the DSX images to calculate knee kinematics from 0-30% of stance. Statistical Parametric Mapping (SPM) was used to analyze correlations for anterior tibial translation, internal tibial rotation, and ACL strain to medial, lateral, mean, and difference in PTS.

Results

At 6 and 12 months for all of early stance in downhill running, anterior translation was significantly correlated with medial, lateral, and mean PTS, and internal rotation was significantly correlated with PTS difference. At 6 months, ACL strain was correlated to medial (R=0.17–0.49, p=0.03), lateral (R=0.37–0 .61, p=0.005), and mean PTS (R=0.3–0.59, p=0.008) for 5-30% of stance. No significant ACL strain correlations were found at 12 months.

Discussion

Correlations with ACL strain were present at 6 months, but not 12, suggesting healing ACL grafts remodel and gain stiffness which reduces strain. Knee kinematics were still affected by PTS and lateral-medial differences at 12 months. Our results may differ from the prior DSX study because we included running, studied ACLR patients instead of healthy, and PTS was calculated in 3D instead of 2D [2]. Future studies will be needed to evaluate potential osteotomy patients with larger PTS. We will also perform PTS measurements on clinical X-rays to increase relevance in a clinical setting.

Images (Optional)

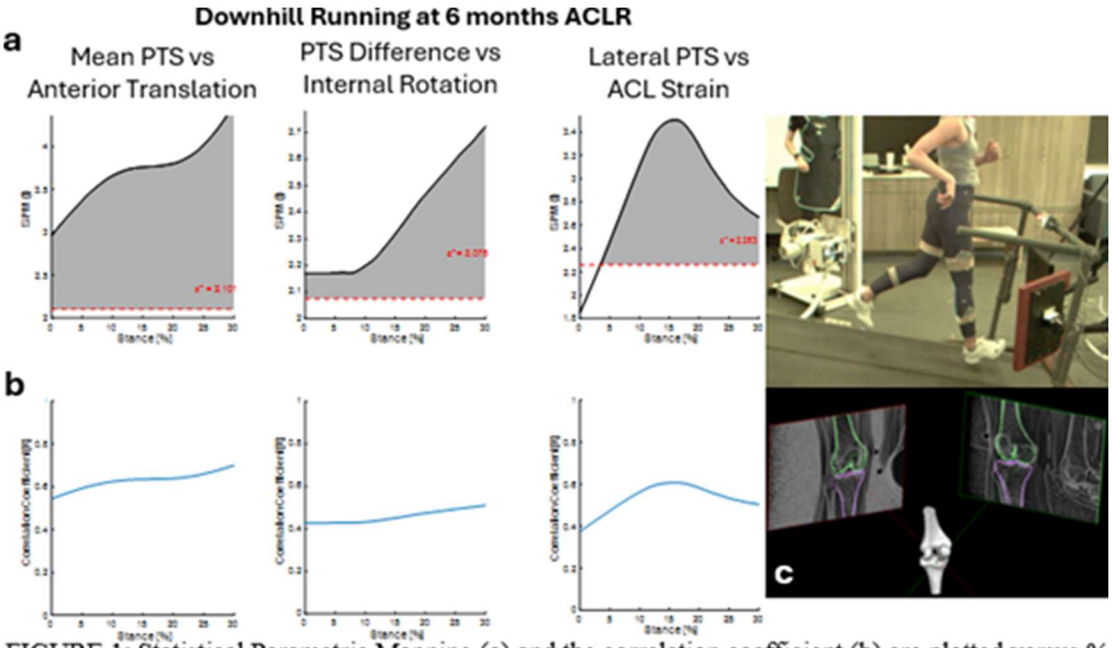

FIGURE 1: Statistical Parametric Mapping (a) and the correlation coefficient (b) are plotted versus % stance phase for downhill running at 6 months post-ACLR for PTS metrics and anterior translation, internal rotation, and ACL strain. (c) Participants performed downhill running while DSX imaging was collected to precisely measure knee kinematics.

The Effectiveness of Robotic Total Knee Arthroplasty on Restoring Knee Motion and Improving Clinical Outcomes

Dr. Shawn Robbins BscPT, PhD[1,2], Mr. Gabriel Zaccara BSc[1], Dr. David Zukor MD[3], Dr. Olga Huk MD[3], Dr. Adam Hart MD[4], Ms. Isabella Sierra BSc[1], Dr. John Antoniou MD[3]

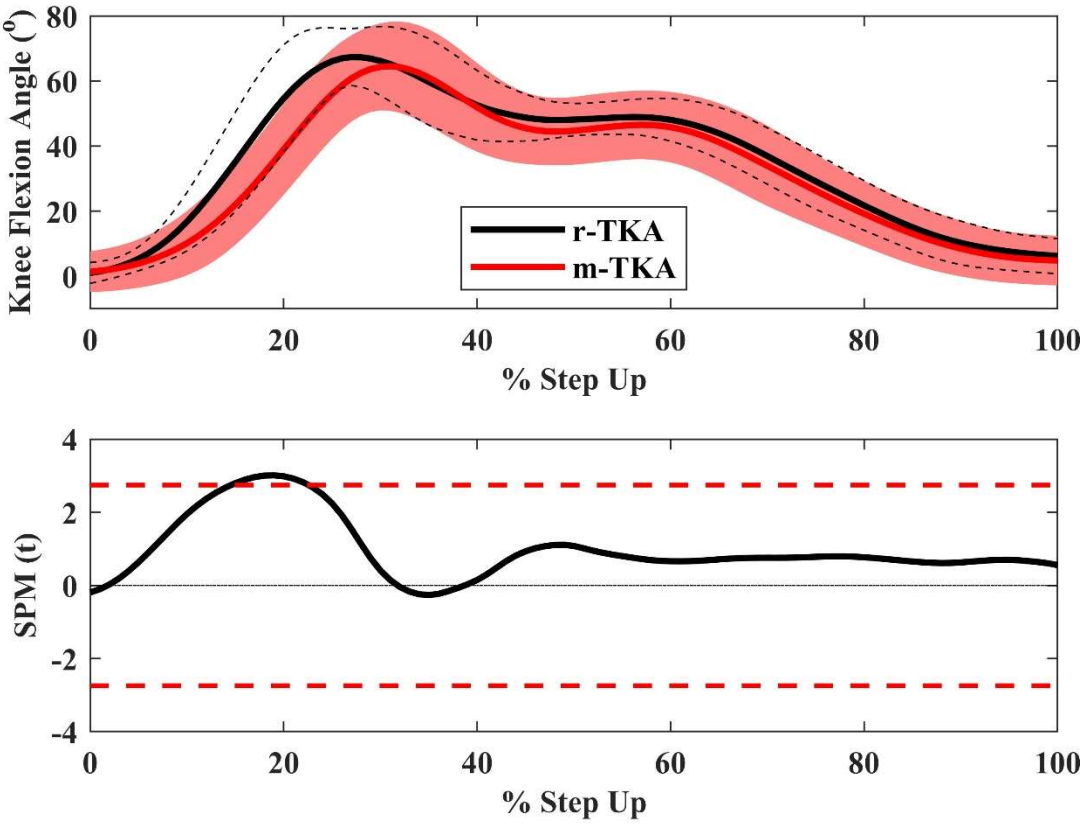
[1]McGill University, Montreal, QC, Canada. [2]Centre for Interdisciplinary Research in Rehabilitation of Greater Montreal, Montreal, QC, Canada. [3]Jewish General Hospital, Montreal, QC, Canada. [4]Montreal General Hospital, Montreal, QC, Canada

Introduction

Total knee arthroplasty (TKA) is an end-stage treatment for patients with knee osteoarthritis. However, 20% of patients report unfavourable outcomes post-surgery.[1] Robotic-arm assisted TKA (r-TKA) can improve the accuracy of implant positioning compared with conventional, manual TKA (m-TKA).[2] There is limited research evaluating newer generation robots and it is not clear if r-TKA improves knee motion during functional activities. The objective was to compare knee motion during gait and step up/down tasks between patients that underwent r-TKA and m-TKA at 1 year post-surgery.

Methods

This cross-sectional study recruited patients that underwent m-TKA (n=24) and r-TKA (n=12) for osteoarthritis and were assessed 1 year post-surgery. One surgeon performed r-TKA with the ROSA Knee System (Zimmer Biomet), while three other surgeons performed m-TKA using conventional manual techniques. Participants completed overground gait, and step up and down tasks on a 20 cm step. Kinematic data were recorded with an eight camera motion capture system (Qualisys) at 100 Hz and a cluster-based marker system. Knee angles were calculated using a Carden XYZ order of rotation and speed was determined from pelvis markers. Speed was compared using two sample t-tests. Knee flexion and internal rotation angles throughout the tasks were compared between groups using statistical parametric mapping (SPM).



Results

There were no significant between-group differences in speed during gait (mean difference=-0.09 m/s, p=0.190), step up (mean difference=-0.06 m/s, p=0.094), and step down (mean difference=-0.05 m/s, p=0.378). There were no significant differences (p>0.050) in knee flexion and internal rotation angles during gait and step down. The r-TKA group had greater knee flexion during the early stages of the step up task (15-23%, p=0.032) compared to the m-TKA group (Figure).

Discussion

Although the r-TKA had greater knee flexion angles during step up, differences between groups were small and there were no significant findings for gait and step down. Thus, there is no clear evidence that r-TKA leads to enhanced knee motion during functional activities. Future studies should enroll larger samples and consider pre-operative function.

Effect of Bone-Anchored Limb Use on Segmental Angular Momenta during Walking

Ms Grace Georgiou BS[1], Mr Mitchell Ekdahl BS[2], Mr Peter Thomsen-Freitas PT, DPT, MS[1], Dr Cory Christensen PT,PhD[1], Dr Jason Stoneback MD[1], Dr Brecca Gaffney PhD[2,1]

[1]University of Colorado-Anshutz, Aurora, CO, United States. [2]University of Colorado-Denver, Denver, CO, United States

Introduction

Transfemoral socket prosthesis users have a higher fall risk than able-bodied individuals. Bone-anchored limbs (BALs) are a promising alternative to socket prostheses shown to improve static and dynamic balance. However, past comparisons have mostly been limited to pre-implantation failed-socket use. Additionally, the mechanisms driving improved balance remain unknown. Segmental angular momenta (SAM) describe individual segment's contributions to body center of mass regulation during movement, providing mechanistic insight into dynamic balance. The objective was to determine how unilateral transfemoral BAL use affects SAM compared to successful socket users and healthy control participants without amputation (HC). We hypothesize: 1) HC will have the lowest range of SAM and 2) BAL users will have lower SAM than socket users

Methods

Whole-body kinematics were collected from 30 participants during level-overground self-selected walking (BAL: 7F/3M; 49.2±14.3 y/o; 26.2±4.3 kg/m^2; Socket: 2F/8M; 59.1±10.2 y/o; 30.2±4.7 kg/m^2; HC: 7F/3M; 24.9±3.6 y/o; 23.4±3.7 kg/m^2). Link-segment models for each participant were developed with differences in prosthesis mass and center of mass accounted for. Range of SAM during the amputated-limb gait cycle (dominant-limb for HCs) were compared across groups using an ANCOVA (covariate: gait speed) with a post-hoc Bonferroni correction.

Results

Frontal plane contralateral-limb SAM range was lower in HC (nondominant-limb) and BAL users compared to socket users (sound-limb) (Figure 1). Frontal plane head/trunk, sagittal plane pelvis, and transverse plane pelvis and contralateral-limb SAM range were larger in BAL and socket users compared to HC. Sagittal head/trunk SAM range was larger in socket users than HC.

Discussion

Larger frontal/transverse lumbopelvic SAM ranges in individuals with transfemoral amputation as compared to HC collectively indicates worse dynamic balance regardless of prosthesis type. Additionally, sagittal plane head/trunk SAM ranges were lower in HC than socket users but were not different from BAL users. This may indicate BAL users have some improvements in SAM regulation compared to socket users, although future work is needed to further explore this. Nonetheless, as SAM was more regulated (lower range) in HC than BAL and socket users, these results indicate the need for continued rehabilitation following transfemoral amputation.

Motor Module Generalization Across Walking and Standing Perturbations is Associated with Walking Balance Performance in Older Adults

Mr. Reece Lawrence, Mr. Grant Maddox, Ms. Kaitlyn Downer, Dr. Jessica Allen PhD

University of Florida, Gainesville, Florida, United States

Introduction

Balance ability is essential for safe walking, yet age-related declines in balance control increase the risk of falls among older adults. In relation to this risk, recent work demonstrates that neuromuscular control of walking and balance may share common structure. For example, we previously found that recruiting a common set of motor modules across walking and balance behaviors (i.e., motor module generalization) is associated with walking balance performance in both young adults and stroke survivors [1,2]. Based on these results, we hypothesize that motor module generalization represents a general control strategy for the maintenance of balance while walking. However, this shared structure has yet to be linked to walking balance performance amongst healthy older adults, which is the purpose of this study.

Methods

Motor modules were found using nonnegative matrix factorization from lower-limb electromyography while walking at self-selected speed and during a standing reactive balance task in 20 older adults (76.9±5.24 yrs). Motor module number for each behavior was chosen such that overall variance accounted for was >90%. The number of motor modules common to both behaviors were identified using Pearson's correlations. The relationship between the number of common modules and two metrics of walking performance were analyzed: walking speed (self-selected and fastest-comfortable) and distance walked on a narrowing beam.

Results

The median number of modules was 3.5 for walking (range:3-4), 3 for reactive balance (range:2-5), and 2 common between the two behaviors (range:0-3). The number of common modules correlated significantly with beam walking distance ($r=0.55$, $p=0.01$) but not with self-selected ($r=0.28$,$p=0.229$) or fast ($r=0.27$, $p=0.254$) walking speeds.

Discussion

The number of motor modules common between walking and standing reactive balance was positively associated with walking performance in older adults, but only when balance was specifically challenged. These findings are consistent with previous studies [1,2], further supporting the hypothesis that recruitment of reactive balance motor modules during walking may be a general neuromuscular strategy contributing to maintaining balance while walking and may serve as an effective target for design and/or prescription of gait rehabilitation.

Images (Optional)

The Mechanical Boundaries of Upright Standing Shape Our Preferred Posture

Mr. Amin M Nasrabadi M.Sc.[1], Dr. Calvin Kuo Ph.D.[2], Dr. Jean-Sébastien Blouin Ph.D.[1]

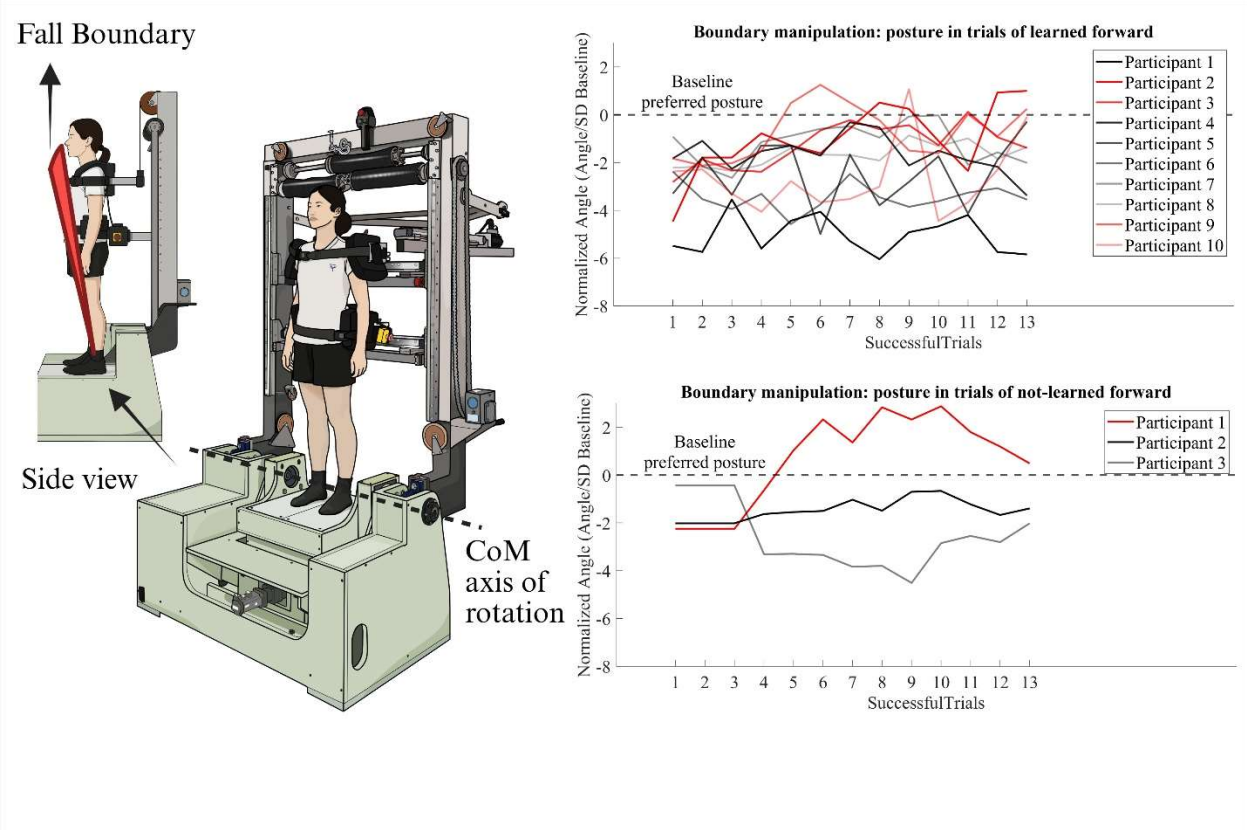
[1]The School of Kinesiology, University of British Columbia, Vancouver, BC, Canada. [2]The School of Biomedical Engineering, University of British Columbia, Vancouver, BC, Canada

Introduction

Standing is possible over a range of angles without losing balance. Although maintaining the centre of mass (CoM) above the ankle joint requires no moment, people typically prefer to stand with a 1-2° forward lean. Biomechanical and physiological factors, such as the size of the feet (determining the base of support) or the asymmetrical moment characteristics from the ankle-flexors, could contribute to preferred upright posture. Here, we used a novel robotic platform reproducing the dynamics of upright stance to manipulate the mechanical boundaries of standing balance.

Methods

Sixteen participants (8F, 64.9±9.6 kg, 169±7 cm, 26.9±5.3 years) stood on the robot for five 1-minute trials to establish their preferred posture (i.e. CoM average and SD of sway). Based on each participant's baseline, we changed the natural -3° backward to 6° forward balance boundaries (i.e. the foot base of support) to altered ones: −3° to $CoM_{preferred\ angle}$+0.25SD for participants who maintained a forward lean or $CoM_{preferred\ angle}$−0.25SD to 6° for those having a backward lean. In subsequent trials, participants had a 1.5° forward or backward free fall when they reached the altered boundary; and passively returned to a 0° upright posture to start the next trial. We hypothesized that exposure to the new boundaries would shift the participants' preferred posture away from the altered boundary. After participants successfully balanced for 60s in three consecutive trials with new boundaries or for up to ten minutes, we restored the natural boundaries and quantified whether participants' balance returned to their natural baseline preference.



Results

13/16 participants shifted their preferred posture, on average by 1.3°±0.3°, when exposed to the altered boundaries. Their new preferred posture was significantly different from the natural preferred posture (t-test, p-value < 0.001). When restoring their natural balance boundaries, only 4/13 participants returned to their initial preferred posture, on average after 391±22 seconds.

Discussion

Using a unique balance robot, our results showed that the mechanical boundaries of upright balance alter our preferred posture. Instead of aligning their CoM with their natural posture, participants preferred to stand away of their mechanical limits of stability.

Cognition–Perception Interplay in Postural Control Among Individuals with Diabetes Mellitus

Dr. Kai Cheng PhD[1], Dr. John Miles MD[1], Dr. Carl Luchies PhD[2], Dr. Hen-Yu Lien PhD, PT[3], Dr. Li-Ling Chuang PhD, PT[3], Dr. Chun-Kai Huang PhD, MS, PT[1]

[1]University of Kansas Medical Center, Kansas City, KS, United States. [2]University of Kansas, Lawrence, KS, United States. [3]Chang Gung University, Taoyuan City, Taiwan, Taiwan

Introduction

Diabetes Mellitus (DM), affecting over 11% of adults globally, is associated with balance deficits and cognitive impairments, particularly executive dysfunction, which heightens fall risk. Executive function is essential for managing cognitive workload and postural control. Under dual-task (DT) conditions, individuals with DM often exhibit greater postural instability and difficulty switching attention. The Sensory Organization Test (SOT) evaluates balance by challenging somatosensory, visual, and vestibular systems. Prior research suggests the impaired central processing observed in DM considered compromised sensory integration. This study examines the interaction between cognition and perception in regulating balance under sensory conflicts using a DT-SOT paradigm, hypothesizing that DM will exhibit degraded central processing and executive function.

Methods

Seventeen individuals with DM and 17 age-matched controls completed a virtual reality–based SOT under single-task and DT conditions. The DT included an auditory Stroop test. Postural sway was decomposed into rambling (central) and trembling (peripheral) components. Cognitive workload was assessed via pupillary dynamics using the Index of Pupillary Activity (IPA).

Results

DM participants exhibited significantly greater rambling and trembling components under sensory conflicts, independent of cognitive workload. Non-linear analysis using Sample Entropy indicated increased rigidity and predictability of postural control in DM with higher cognitive demands. Individuals with DM showed a tendency for higher IPA under sensory-conflict conditions, particularly during single-task trials. Both cognitive task performance and IPA did not differ significantly between groups.

Discussion

This study demonstrated impaired central processing in DM under sensory-conflict conditions by showing the increased rambling component in postural sway and its rigidity/predictability. The elevated IPA during sensory conflicts in DM suggests the increased cognitive workload. These findings underscore the complex interplay between perception and cognition in DM-related balance deficits. Future research should include larger cohorts and additional workload measures to validate these results.

Uneven Beginnings: Anticipatory Postural Adjustments and Muscle Quality Asymmetry During Gait Initiation at a Self-Selected Speed

Ms. Isabella Helm, Mr. Brandon Peoples MS, Ms. Bria Smith MS, Mr. Keven Santamaria-Guzman MS, Mr. Kenneth Harrison MS, Ms. Damaris Cifuentes MS, Ms. Silvia Campos-Vargas MS, Dr. Jaimie Roper PhD

Auburn University, Auburn, AL, United States

Introduction

Gait initiation relies on coordinated feedforward and feedback mechanisms to maintain posture as the brain prepares the body to transition from standing to stepping, known as anticipatory posture adjustments (APAs)[1, 2]. Longer APA durations can signal reduced postural control, increasing the risk of instability and impaired dynamic balance[1]. Because APAs require contributions from both limbs to stabilize the body before single-leg support, asymmetries in muscle quality may disrupt this process. Discrepancies in fat-to-muscle ratio (FMR) across the quadriceps, hamstrings, and gastrocnemius may compromise balance, neuromuscular response, and gait efficiency[3]. Although asymmetry in muscle quality has been linked to poor functional performance, its specific role in gait initiation and postural control remains poorly understood. Therefore, the purpose of the study is to evaluate the relationship between quadriceps, hamstrings, and gastrocnemius FMR asymmetry and APAs outcomes during walking.

Methods

Seven participants (2 males, 25 ± 6 years) underwent body composition assessments using dual-energy X-ray absorptiometry, with custom lower-leg segmentation to isolate the gastrocnemius, hamstrings, and quadriceps. FMR of the gastrocnemius, hamstrings, and quadriceps was determined to evaluate muscle quality. APAs were measured using inertial measurement units across two trials of the 40-meter walk test at a self-selected speed. Pearson correlation analyses were performed to examine the relationships between regional muscle compositions and APAs.

Results

Quadriceps FMR asymmetry showed strong negative correlations with first-step duration ($r = –0.911$) and first-step range of motion ($r = –0.832$), indicating that greater asymmetry may

constrain step execution and reduce movement amplitude. Hamstrings FMR asymmetry was positively correlated with APA duration (r = 0.780) and lateral acceleration (r = 0.779), suggesting that greater asymmetry in hamstring muscle quality may prolong postural preparation and increase lateral instability. No significant correlations were found between calf asymmetry and APA outcomes.

Discussion

In this pilot sample, our findings suggest that asymmetry in muscle quality influences postural control during gait initiation. These results underscore the importance of evaluating regional muscle composition when assessing balance and gait initiation strategies in populations at risk for muscle quality imbalances.

Images (Optional)

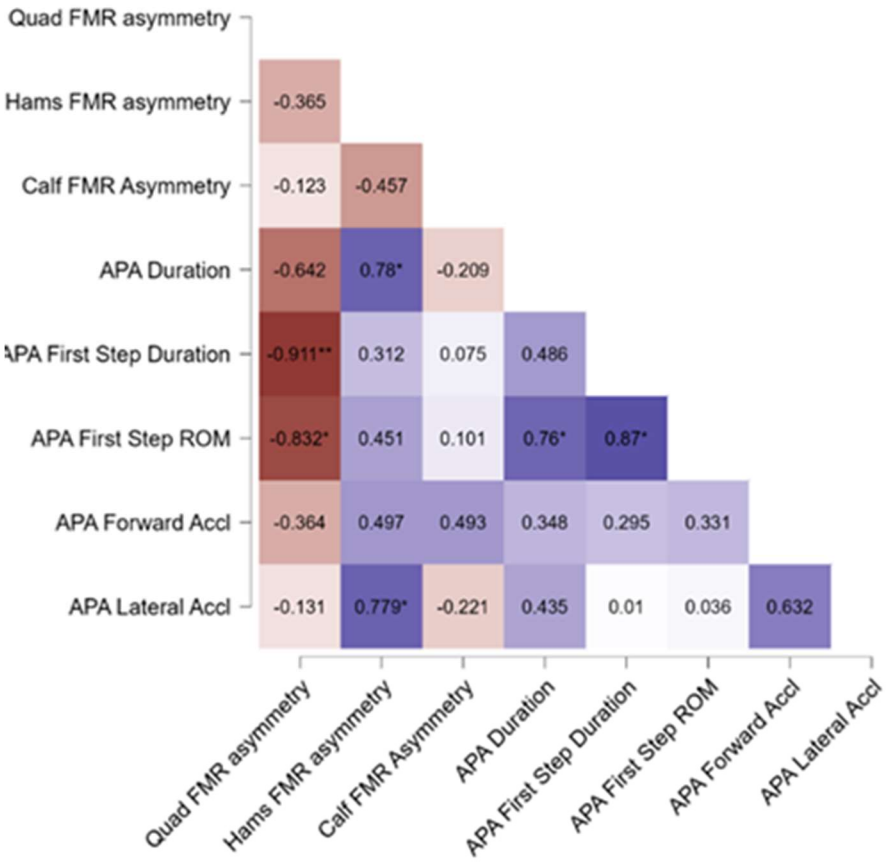

Figure 1: Correlation Heatmap Indicating the Association Between Muscle FMR Asymmetry and Anticipatory Postural Adjustment Outcomes. APA duration is the period from starting to the first measurable change in lateral acceleration and its return to baseline. APA first step duration is period between the of the APA duration to the initial contact of the first step. APA first step range of motion (ROM) is the angular displacement from the end of the APA to initial contact of the first step. APA forward acceleration (Accl) is the peak forward lumbar acceleration. APA lateral acceleration (Accl) is the peak lateral lumbar acceleration.

BD-Net: Bidirectional Distance Loss Function for Enhancing Vascular Structure Connectivity

Ms. Luyao Fan, Professor Bao Li, Professor Liyuan Zhang, Professor Youjun Liu, Professor Mingai Li

Beijing University of Technology, Beijing, Chaoyang District, China

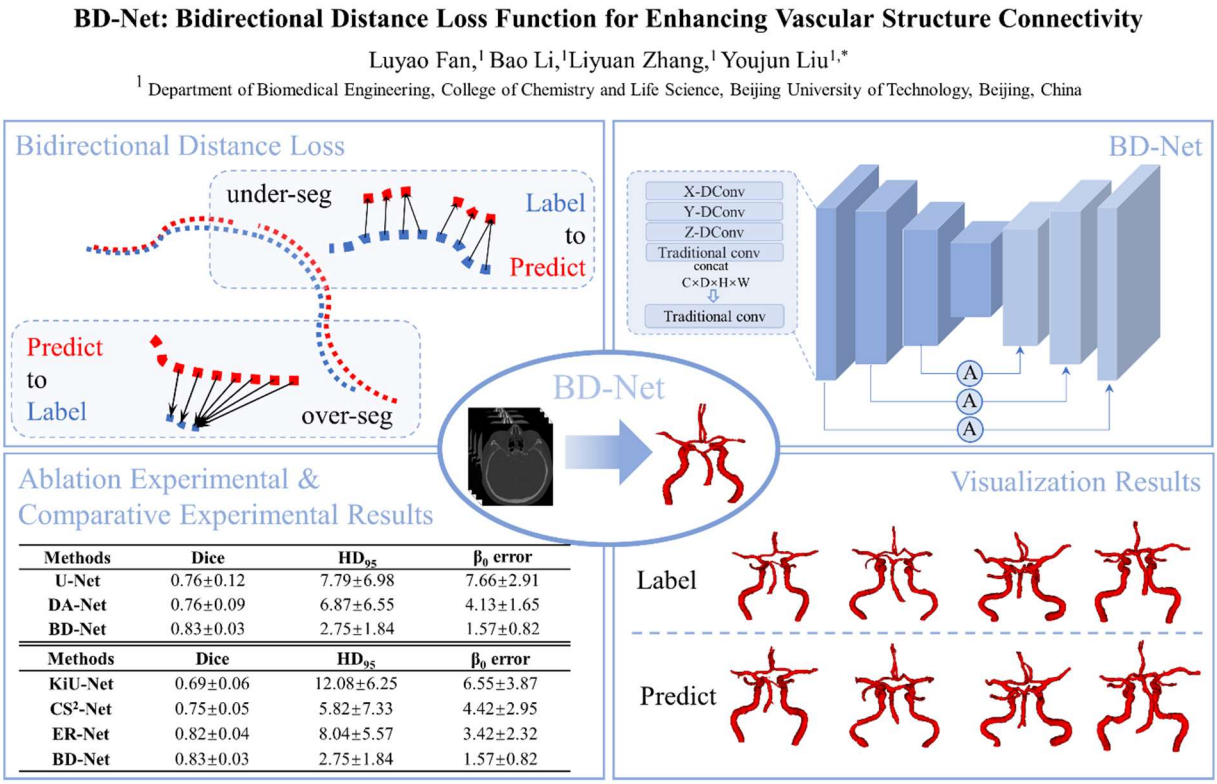
Introduction

Accurate segmentation of vascular structures in medical imaging is a crucial step in diagnosing cerebrovascular diseases and enabling precision medicine, particularly for downstream hemodynamic analysis. However, vascular segmentation often faces challenges due to the complexity of vascular anatomy and the low contrast between vessels and surrounding tissues, leading to over-segmentation and under-segmentation. These issues can reduce vascular connectivity, decrease segmentation accuracy, and ultimately affect subsequent analyses and diagnoses. To address these challenges, this study introduces BD-Net for cerebral artery segmentation, aiming to enhance vascular connectivity and improve segmentation accuracy.

Methods

To improve vascular connectivity, we propose an innovative bidirectional distance loss function. Specifically, this function predicts skeleton points and label skeleton points through bidirectional nearest-neighbor connections, quantifying the distances for each direction to compute over-segmentation and under-segmentation losses. This strategy promotes high consistency in both the number and spatial positioning of skeleton points, guiding the model to enhance vascular connectivity. Given the multi-scale features of vascular structures, we incorporate an axial dynamic convolution module based on the U-Net architecture, which adjusts the receptive field of the convolution kernels to capture fine details of vessel segments. Additionally, a multi-axis attention mechanism is embedded into the model to enhance its focus on spatial, channel, and temporal features, further improving the accuracy of cerebral artery segmentation. Finally, BD-Net was trained and tested on a dataset of 141 cerebral artery images.

Results



Ablation experiments demonstrated that incorporating bidirectional distance loss increased the Dice score to 0.83, reduced HD_{95} to 2.75, and decreased β_0 error to 1.57.

Comparative experiments showed that BD-Net outperformed ER-Net (Dice=0.82, HD_{95}=8.04, β_0 error=3.42) and CS2Net (Dice=0.75, HD_{95}=5.82, β_0 error=4.42).

Discussion

BD-Net effectively addresses the over-segmentation and under-segmentation issues, achieving precise cerebral artery segmentation and significantly enhancing vascular connectivity. This provides a solid foundation for subsequent hemodynamic analysis and plays a crucial role in the clinical diagnosis and precision medicine of cerebrovascular diseases.

Making the Most of 3D Ultrasound Data to Improve DDH Detection: Identifying the Posterior Lip and Greater Trochanter

Mrs Chloë Stiles MSc, BSc, Mr Adam McArthur BSc, Dr Abhilash Hareendranathan PhD, Dr Jacob Jaremko MD, PhD, FRCPC

University of Alberta, Edmonton, Alberta, Canada

Introduction

Developmental dysplasia of the hip (DDH) is more reliably detected by 3D ultrasound (3DUS) than conventional ultrasound (US) because image stacks more fully assess anatomy than single images, and analysis can be automated. Identifying consistent anterior-posterior slice order is a crucial initial step in automating hip US analysis since DDH indices vary significantly between anterior versus posterior hip. However, whether an image stack begins anteriorly or posteriorly depends on how the user performed the scan. Image orientation can be inferred based on the location of the Posterior Lip (PL) view within the stack relative to the Standard Plane (SP) view, which requires an awareness of the location of the Greater Trochanter (GT). We developed an AI model to correctly orient US image stacks antero-posteriorly for DDH by locating the PL and GT.

Methods

In 476 DDH 3DUS image stacks, a radiologist manually selected a central SP image and segmented ilium and femur. Retuve, an open-source framework for multi-modality DDH analysis, developed in-house, was used to segment the apex and PL (https://github.com/radoss-org/retuve). Stack orientation was inferred from relation of anatomic landmarks in images relative to the SP. Specifically, if the AI model detected the PL before SP, the stack was flipped. For automated localization of the GT, we developed a two-stage approach using the YOLO object detection model. Relevant GT-containing frames were identified before applying augmentation strategies to improve detection during training. The model then generated a video output.

Results

The AI model correctly oriented 98% of the remaining images antero-posteriorly with only one true fail. With the applied augmentations, the YOLO-based model achieved a Dice score of 0.997, indicating strong agreement with GT segmentations.

Discussion

The AI model reliably orients DDH US image stacks anterior-to-posterior through PL detection. The YOLO-based augmentation model successfully located the GT. These basic processing steps are needed to automate AI image analysis of DDH 3DUS. This novel approach opportunistically uses 3DUS images with minimal expert input. Future work will focus on completing automation by integrating GT detection with orientation for SP selection.

Trinity College Dublin, Dublin, Dublin, Ireland. [3]Neuroradiology Unit. Fondazione IRCCS Istituto Neurologico "Carlo Besta", Milano, Lombardia, Italy. [4]Department of Mechanical, Manufacturing and Biomedical Engineering. Trinity College Dublin, Dublin, Dublin, Ireland

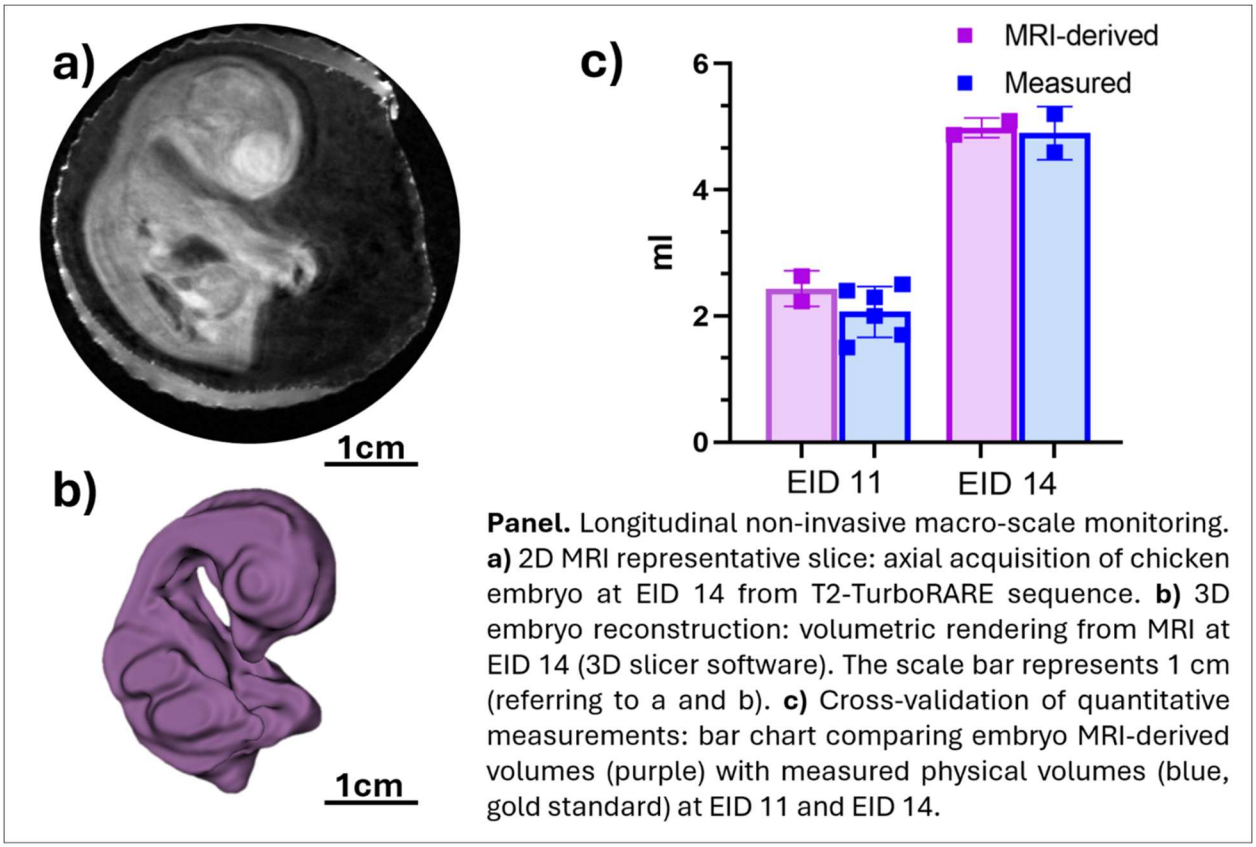
Introduction

The development of biomedical devices is hindered by the limitations of destructive animal models and the challenge of assessing material biocompatibility (ISO 10993-6) and foreign body reaction (FBR). To overcome this, we developed the EGGS&BEACON platform, an ex ovo system, which utilizes the avian chorioallantoic membrane (CAM) assay, offering a model for advanced imaging. Our aim is to establish the link between macro-scale Magnetic Resonance Imaging (MRI) and micro-scale cellular analysis through digital histopathology for quantitative characterization.

Methods

Intravitally, multimodal MRI was performed at embryonic incubation day (EID) 8-9-11-14 to reconstruct full embryonic volumes and major organ volumes using 7T Bruker Biospec (T2-TurboRARE sequence, 200x200x700 μm^3, voxel size) (Figure 1a, b). For *ex vivo* analysis, organs and CAMs were excised at EID 11 and 14 and processed for digital histopathology (formalin fixed, paraffin-embedded, FFPE). Sections were cut, hematoxylin–eosin (H&E) stained [1], and whole slide images (WSI) were digitalized (D-sigh 2.0, A. Menarini Diagnostic). A Machine Learning (ML) workflow, employing active learning, was used for automated cell segmentation, recognition and quantification.

Results



outcomes. Embryonic weight (5.82 ± 0.31 g) and measured volume (4.90 ± 0.42 ml) served as gold standards for non-invasive monitoring. A strong correlation was found between these measurements and full embryo MRI-derived volumes (5.09 ± 0.43 ml) at EID14, confirming the macro-scale acquisition's high accuracy (Figure 1c). CAM histopathology provided compartments' precise morphometrics (ectoderm: 9.49±1.3 μm; mesoderm:

68.61±9.5 µm; endoderm: 4.45±1.3 µm). The ML workflow classified and quantified cell types (red blood cells, fibroblasts, endothelial cells, and granulocytes), as cellular densities, establishing metrics for local innate immune activity [1]. Furthermore, we demonstrated the potential for recognizing organ volumes in longitudinal MRI of chicken embryos, and performing histological analysis on organs themselves, for systemic biocompatibility assessment, linking macro- and micro-scale.

Discussion

The EGGS&BEACON platform demonstrates high biocompatibility, and it is optimized for non-invasive monitoring, enabling repeated MRI acquisitions without compromising embryonic viability. The established integrated methodology (macro-scale MRI and micro-scale digital histopathology) provides robust multimodal and longitudinal characterization to assess the innate immune response and tissue mechanics for both systemic and local evaluation.

Classification of Bone Demineralization Patterns with HR-pQCT Texture Metrics and Derived Scores: Bone Microarchitectural Phenotypes as Indicators of Metabolic Disease?

Mr. Johannes Bereiter-Payr[1,2], Mr. Thomas Ausserer[1], Ms. Sonja Wagner[3,4], Ms. Martina Saretto[3,4], Dr. Heinz Zoller[3,4], Mr. Gerald Degenhart[1]

[1]Core Facility Micro-CT, University Hospital for Radiology, Innsbruck, Tirol, Austria. [2]VASCage - Centre on Clinical Stroke Research, Innsbruck, Tirol, Austria. [3]Medical University of Innsbruck, Department of Medicine I, Gastroenterology, Hepatology and Endocrinology, Innsbruck, Tirol, Austria. [4]Christian Doppler Laboratory on Iron and Phosphate Biology, Innsbruck, Tirol, Austria

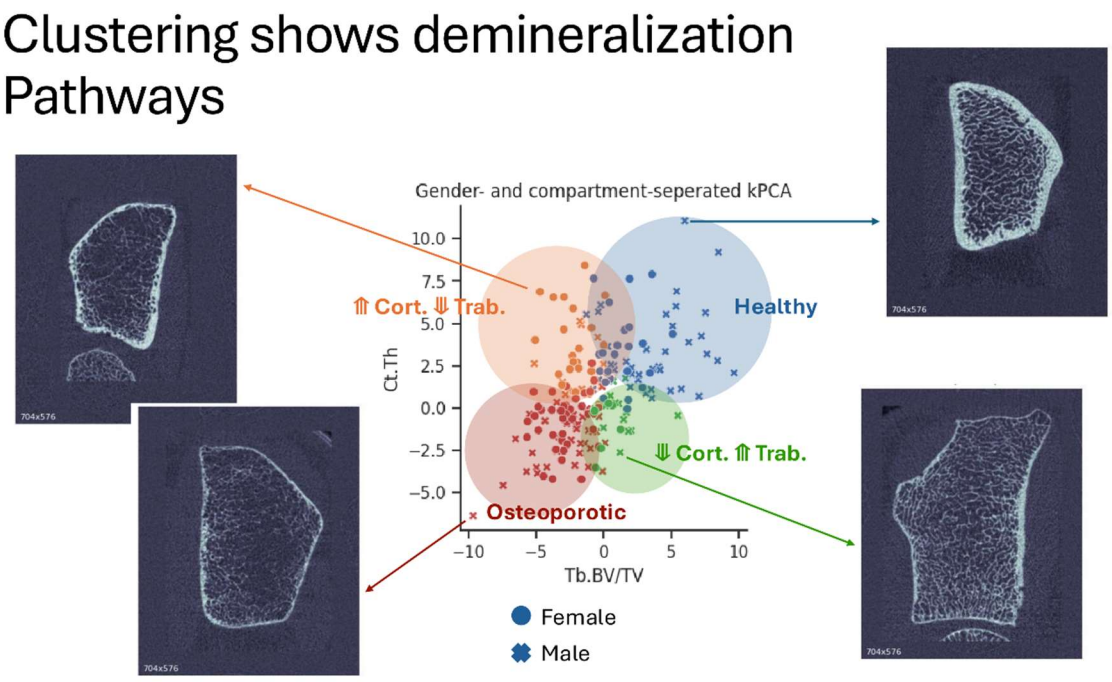
Introduction

We report ongoing work to quantify distinguishable patterns of bone demineralization in patients with metabolic and/or cardiovascular disease. This effort was motivated by (1) the consistent visual observation of distinct microarchitectural differences in HR-pQCT images of distal extremities within our study cohorts, and (2) previously published HR-pQCT phenotype classifications related to fracture risk by Whittier, Boyd and colleagues [1].

Methods

High-resolution peripheral quantitative CT (HR-pQCT) images of the distal radius were acquired in 192 patients from two clinical cohorts using an XCT-2 system (Scanco Medical AG), with 4–6 scans per patient over 12 months. Bone texture analysis (TA) was performed according to a standardized protocol provided by the manufacturer. For each patient, mean texture parameters across all examinations were normalized for age and sex using statistical models described by Warden et al. [2]. Normalized metrics were evaluated using principal component analysis (PCA) and fuzzy c-means clustering (FCM) to identify distinct (de-)mineralization patterns. Data were cross-referenced with areal BMD (aBMD) from DXA when available, or with projected mineral density derived from HR-pQCT.

Results



Among patients with aBMD values in the osteopenic range or showing early signs of demineralization, three potential phenotypes can be described:
(1) generalized demineralization,
(2) predominant trabecular deterioration, and
(3) selective thinning of the distal cortical compartment with relatively preserved trabecular structure.

Based on these findings, we propose a preliminary compartment-specific composite score to quantify individual demineralization patterns.

Discussion

HR-pQCT-derived structural markers can detect early alterations in bone mineralization prior to substantial changes in fracture risk. Some metabolic diseases appear to exhibit characteristic demineralization signatures. Accordingly, classification by the proposed scoring tool may serve as an indicator of bone involvement or may be useful to support the diagnosis suspected disease.

Robust Hip aBMD Measurement From Photon-Counting CT Projections: Overcoming DXA Positioning Constraints

Ms. Elena Paravisi[1], Dr. Jilmen Quintiens[1], Mr. Matthias Opsomer[2,3], Dr. Thomas Anijs[1], Prof. Kristl Claeys[2,3], Mr. Walter Coudyzer[4], Prof. Harry van Lenthe[1]

[4]Department of Radiology, University Hospital Leuven, Leuven, Flanders, Belgium

Introduction

Dual-energy X-ray absorptiometry (DXA) is the standard for diagnosing and monitoring osteoporosis. However, DXA measurements vary across manufacturers and depend heavily on patient positioning, potentially affecting T-score accuracy. This limitation is particularly problematic in patients with musculoskeletal contractures that prevent correct positioning in the DXA scanner. We hypothesized that 2D projections from digitally rotated 3D Photon-Counting CT (PCCT) scans can quantify areal BMD (aBMD). To test this hypothesis, we developed a semi-automated Python-based pipeline to compute hip aBMD from PCCT and evaluate its user-dependency.

Methods

Femoral PCCT and DXA scans from ten facioscapulohumeral muscular dystrophy (FSHD) patients were analysed. Three independent raters processed the PCCT scans ten times per patient over ten days. The pipeline automatically aligned the femur in the coronal plane, followed by user-guided placement of four anatomical landmarks to segment standardized DXA regions: femoral neck, intertrochanteric region, and trochanter, with total hip as their union. Correlation with DXA-derived aBMD was calculated. Intra-rater precision was assessed using root-mean-square standard deviation (RMS-SD) and coefficient of variation (RMS-CV), while inter-rater agreement was determined using the intraclass correlation coefficient (ICC) from each rater's final trial. The effect of DXA positioning errors on PCCT comparisons was tested by recomputing aBMD after applying rotations of 0–20° to the PCCT images.

Results

PCCT-derived aBMD showed strong correlation with DXA ($R^2 \geq 0.88$, Figure 1). No significant effect on the correlations was observed across the tested angles. Short-term

precision was excellent (maximum RMS-SD = 0.0121 gHA/cm^2, RMS-CV = 1.4%), and inter-rater reproducibility was high (ICC > 0.98).

Discussion

PCCT-based aBMD measurements demonstrated excellent precision and reproducibility, supporting PCCT as a robust alternative for patients unsuitable for DXA scanning as well as for opportunistic bone assessment with PCCT. However, PCCT consistently underestimated aBMD relative to DXA, as reported for other CT-based modalities[1,2]. This underestimation persisted across all tested angles, indicating that imprecise patient positioning does not fully explain the bias. Further investigations are required to determine how modality-specific imaging characteristics contribute to this systematic offset.

Images (Optional)

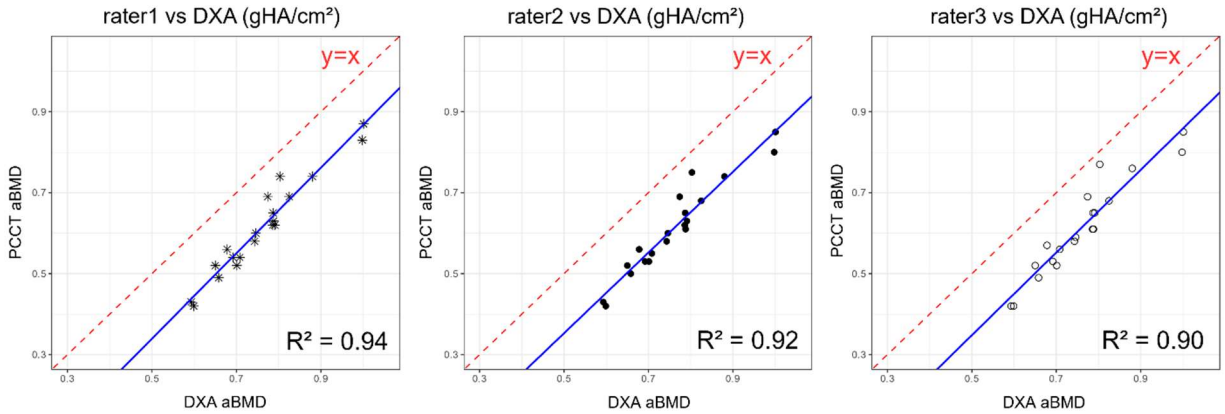

Figure 1. Scatter plot of femoral neck areal bone mineral density (aBMD) derived from PCCT scans using the proposed Python-based pipeline (final trial) compared with DXA measurements. Each plot represents one rater versus DXA. All raters demonstrate strong correlation with DXA.

[4]Department of Orthopedic Surgery and Orthopedic Research Institute, West China Hospital, Sichuan University, Chengdu, Sichuan, China

Introduction

Dynamic biplane radiography (DBR) is a gold-standard technique for measuring *in vivo* three-dimensional skeletal kinematics. Conventional image intensifier-based DBR systems are constrained by suboptimal image quality and limited imaging fields. We developed a customized DBR system equipped with large-format dynamic flat panel detectors capable of acquiring high-quality images over an extensive imaging area. Therefore, the objective of this study was to validate the accuracy of our customized DBR system across multiple joints.

Methods

Our customized DBR system is characterized by the following features: (1) a large-format dynamic flat panel detector providing an extensive high-quality imaging field with a maximum sampling rate of 90 Hz; (2) synchronization capability with an instrumented treadmill for simultaneous acquisition of images and ground reaction forces during walking; (3) an X-ray tube with a minimum pulse duration of 2 ms, effectively minimizing motion artifacts during high-speed movements. Three to six 1.6 mm stainless steel beads were embedded into each bone segment of three cadaveric specimens (one knee and two ankle specimens) and one synthetic cervical spine model. The DBR system was calibrated using a LEGO cube following the protocol developed at Brown University. Joint motion was simulated for each specimen within the imaging field of view. Marker-based tracking was performed using XMALab, whereas model-based tracking was executed using SlicerAutoscoperM. The accuracy of model-based tracking against marker-based tracking was assessed using root mean square error (RMSE).

Results

For translation, the mean RMSEs were 0.47 mm (knee), 0.21 mm (ankle), and 0.63 mm (cervical spine). For rotation, the mean RMSEs were 0.91° (knee), 1.50° (ankle), and 1.36° (cervical spine). The achieved accuracy is comparable to that reported in prior validation studies in all the three joints.

Discussion

The measurement errors of our customized DBR system of multiple joints are comparable to those reported in previous literature, demonstrating the high accuracy of our system. Critically, the capability of our customized DBR system to continuously capture images and ground reaction forces over multiple gait cycles enables more comprehensive biomechanical analysis, thereby supporting its future application in *in vivo* clinical research.

Advanced Humanised and Vascularized Bone Model Recapitulating Molecular and Functional Signatures of Osteoporotic Bone for Therapeutic Research

Mr. Muhammad Munam Mustafa Bukhari, Dr. Syeda Masooma Naqvi, Prof. Laoise McNamara

University of Galway, Galway, Galway, Ireland

Introduction

Postmenopausal osteoporosis causes bone loss, but also alters bone tissue composition, osteocyte activity and vascularisation. Anti-sclerostin therapy induces bone formation, decreases resorption and reduces fracture risk, but the effects are transient, and the mechanisms require further investigation. Animal and in vitro models of osteoporosis cannot reproduce human multicellular responses, limiting their potential for mechanistic and therapeutic studies. Thus, the objectives of this study are to 1) develop 3D multicellular vascularized and humanized bone mimetic models for studies of osteoporosis, 2) validate the transcriptomic profiles of the models against human bone and 4) apply the model to study anti-sclerostin therapy.

Methods

Vascularised bone-like models were developed by chondrogenic and osteogenic priming [1] and cultured in osteogenic media with estrogen (17 β-estradiol) until day 42, followed by estrogen withdrawal until day 49. Next, human mononuclear cells (pre-osteoclasts) were incorporated and the models were cultured until day 63 under continued estrogen (E), estrogen withdrawal (EW), or EW+sclerostin antibody (EWS) (Fig. 1 A). Immunostaining, ELISA and rt-PCR were conducted for validation and compared to human bone samples.

Results

We have successfully developed the first humanized 3D bone mimetic model that accounts for osteocyte differentiation, mineralization and vascularization over extended culture. By inducing estrogen deficiency within the model, we recapitulated the osteoporotic phenotype with respect to sclerostin production (WNT inhibitor), mineral heterogeneity, hypertrophy (collagen X) and vascularization (CD31) (Fig.1 A). Metabolic markers separated the estrogen group (E) from the estrogen withdrawal (EW). Our models captured transcriptomic features of healthy osteogenesis (TNFRSF11B (OPG), RUNX2, ALPL) and recapitulated osteoporotic catabolic gene expression, which was validated

against human osteoporotic bone (TNFSF11, MMP1) (Fig.1C), supporting the physiological relevance of the model. Treatment with sclerostin inhibitory antibody restored WNT/β-catenin signalling and reduced osteoclastogenic signalling (Fig.1 D, F).

Discussion

This study provides a humanized bone model that recapitulates key molecular and functional signatures of osteoporosis, which are necessary for evaluation of therapies. The model was applied to reveal that sclerostin inhibition could partially restore WNT signalling under estrogen deficiency.

Investigation of Long-Term Culture of a Placental Organoid-on-a-Chip for Modeling Pregnancy Hypertension

Ms. Kinoka Kubo[1], Prof. Kenichi Funamoto PhD[2], Prof. Daisuke Yoshino PhD[1]

[1]Tokyo University of Agriculture and Technology, Koganei, Tokyo, Japan. [2]Tohoku University, Sendai, Miyagi, Japan

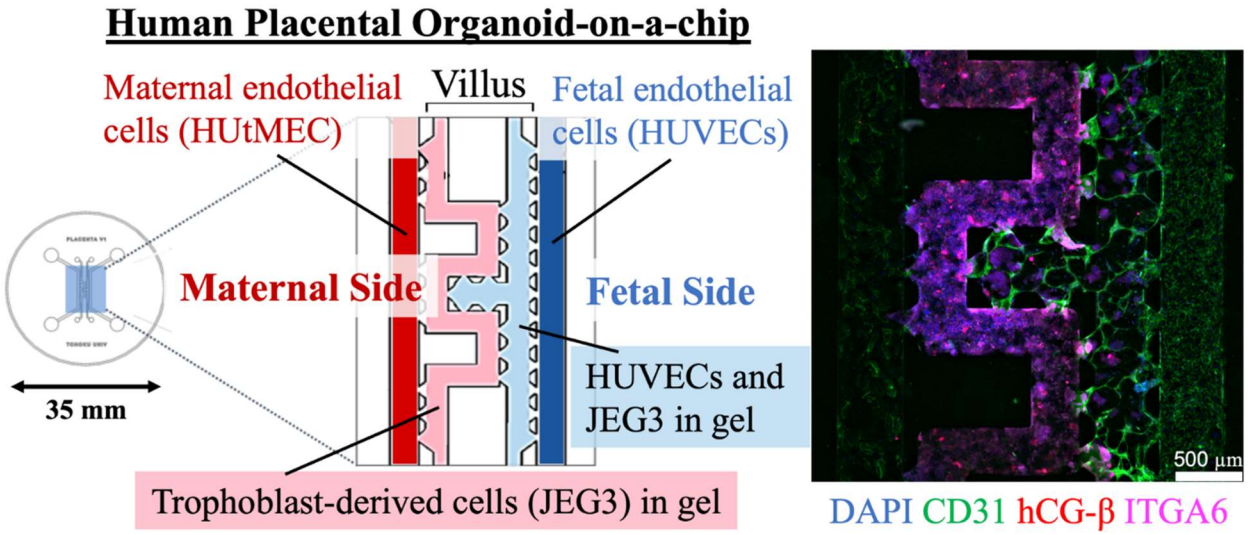
Introduction

Pregnancy hypertension is closely linked to maternal vascular dysfunction and impaired placental morphogenesis. Although elevated blood pressure is known to disrupt endothelial barrier integrity, the biomechanical mechanisms connecting hypertensive stress to placental and fetal vascular impairments remain unclear. To address this issue, we developed a placental organoid-on-a-chip capable of long-term culture and mechanical stimulation. This platform is designed to model the biomechanical progression from maternal hypertensive loading to pathological placental villus and umbilical vascular development.

Methods

A microfluidic device was fabricated by bonding polydimethylsiloxane to a glass substrate. The microchannels were coated with poly-D-lysine and type I collagen to enhance cell adhesion and mechanical stability. A fibrin hydrogel containing Matrigel, fetal endothelial cells, and trophoblast-derived cells was polymerized within a central gel compartment. Maternal and fetal endothelial cells were seeded into the perfusion channels located on the periphery of the tissue sample. The continuous perfusion generated by using a peristaltic pump maintained a steady flow rate, shear stress, and hydrostatic pressure. The behavioral patterns of the cultured cells were assessed by live imaging, and the structural organization and marker expression were evaluated by immunofluorescence microscopy.

Results



The system successfully reconstructed an in vitro placental villus unit under biomechanically relevant conditions. The endothelial cells formed a three-dimensional vascular network in the hydrogel and a confluent monolayer on the channel under shear flow. Trophoblast-derived cells demonstrated fusion and exhibited pregnancy-associated markers, thereby demonstrating functional differentiation within the engineered microenvironment. The optimization of gel stiffness, matrix composition, and seeding density has enabled the stable, long-term culture without structural collapse of the gel–channel interface. The implementation of continuous perfusion ensured the preservation

of vascular integrity, thereby facilitating real-time observation of cell–cell and cell–matrix interactions.

Discussion

The application of controlled hydrostatic pressure within the perfusion circuit provides a unique platform for modeling hypertensive loading on maternal–fetal interfaces. This system establishes a foundation for biomechanically driven disease modeling of pregnancy hypertension, enabling quantitative analysis of endothelial barrier disruption, villus deformation, and vascular morphogenesis. The platform also has the potential to facilitate mechanobiology-based therapeutic screening targeting hypertensive placental dysfunction.

Research Assistant Amélie Dufeil

Introduction

Articular cartilage is important for load-bearing and pain-free joint articulation. In osteoarthritis (OA), cartilage quality is degraded. Medical intervention is required to restore cartilage functional properties. Low molecular weight methacrylated HA (HAMA) has been shown to penetrate cartilage and produce intra-tissue mechanical reinforcement after photo-polymerisation, a process requiring a photoinitiator. The Ru/SPS photoinitiator system is preferred as it uses visible light that reduces cytotoxicity and improves crosslinking depth. Previous studies have used high light intensity (25–30mW/cm^2) for photocrosslinking, casting doubts on its phototoxicity. This study aimed to determine a photocrosslinking protocol that minimizes cell death and evaluate the effect of HAMA on the viscoelastic properties of healthy and degraded cartilage.

Methods

Porcine cartilage samples were assigned to one of the four groups: (1) healthy, (2) OA simulated by collagenase treatment, (3) healthy+HAMA, and (4) OA+HAMA. A 4% HAMA solution (25kDa, 40% substitution) with Ru/SPS (0.5/5mM) was applied for 10min, then photocrosslinked under 400nm light. For phototoxicity test, healthy+HAMA samples were photo-crosslinked by 20 or 25mW/cm^2 for 3 or 10min. For mechanical tests, samples from Group 3–4 were photo-crosslinked by 20mW/cm^2 for 3min. Cell viability in the top 100µm tissue was assessed by confocal imaging. Tissue mechanical properties were measured by a three-step unconfined stress relaxation compression test. A 2% cyclic loading was

applied at 100–0.1Hz during the hold phase. Force-displacement data were processed for mechanical properties.

Results

Photocrosslinking at 25mW/cm^2 for 10min caused a 50μm-deep zone of death (region with >50% dead cells). This depth was reduced to 20μm at a lower dosage (20mW/cm^2, 3 min). Collagenase treatment decreased equilibrium, instantaneous and storage moduli by 55–73% compared with healthy controls. In OA-like tissue, HAMA restored all moduli to healthy levels; whereas HAMA stiffened healthy cartilage by 44–77%.

Discussion

High light intensity caused significant cell death. A reduced photo-crosslinking dosage improved cell viability while recovering the viscoelastic properties of degraded cartilage. However, off-target over-stiffening of healthy tissue was observed. This suggests a narrow photocrosslinking window balancing mechanical reinforcement and biocompatibility. Future studies will focus on further optimisation using longer wavelengths and lower photoinitiator concentrations.

Images (Optional)

[4]Bone and Dental Bioengineering Lab, CIR-Dental School, Dept. of Surgical Sciences, University of Torino, Torino, Piemonte, Italy

Introduction

In vivo, the periodontal ligament (PDL) undergoes combined compression, tension and shear, fundamental for regulating cell growth, differentiation and tissue development [1]. Reproducing these cues *in vitro* through biomimetic materials and controlled mechanical stimulation is essential to elucidate stem-cell mechanobiology. Here, we developed and validated a bioreactor platform to study cyclic uniaxial stretch on human PDL stem cells (hPDLSCs) cultured on 2D and 3D substrates.

Methods

A previously developed stretch bioreactor [2,3] (Fig.1A) was employed to apply controlled tensile strain to hPDLSC cultures. To evaluate the influence of the environment structure, hPDLSCs were seeded either on 2D polydimethylsiloxane (PDMS) flexible substrates or on 3D electrospun polycaprolactone (PCL) aligned nanofibrous scaffolds. PDMS substrates were designed to provide homogeneous deformation to cell monolayers [4], while 3D PCL scaffolds were fabricated to reproduce the fibrous and anisotropic architecture of the native extracellular matrix. Cells were cultured under intermittent uniaxial stretch regimes (strain up to 15%, frequency = 1 Hz, applied with different intermittent protocols: 90s every 6h, 5min every 6h and 5 min every 1h) and compared to static controls.

Results

Intermittent stretch stimulation did not affect cell viability and induced hPDLSC alignment along the stretch direction in both configurations (Fig.1B). On PDMS substrates,

intermittent stretch promoted the expression of osteogenic (*ALP*) and ligament-related (*COL XII*) markers. This effect was markedly amplified when intermittent stretch stimulation was applied to 3D cell-seeded PCL constructs: enhanced alignment, improved matrix organization, and increased expression of key PDL-associated genes and proteins (*COL XII, Decorin, Periostin, OCN, and COL I*) were observed (Fig.1C), indicating a synergistic influence of mechanical stimulation and 3D microarchitecture.

Discussion

Overall, the study demonstrates a synergistic interplay between intermittent stretch and 3D microenvironment in directing hPDLSC organization and differentiation, paving the way for further mechanobiology investigations.

Images (Optional)

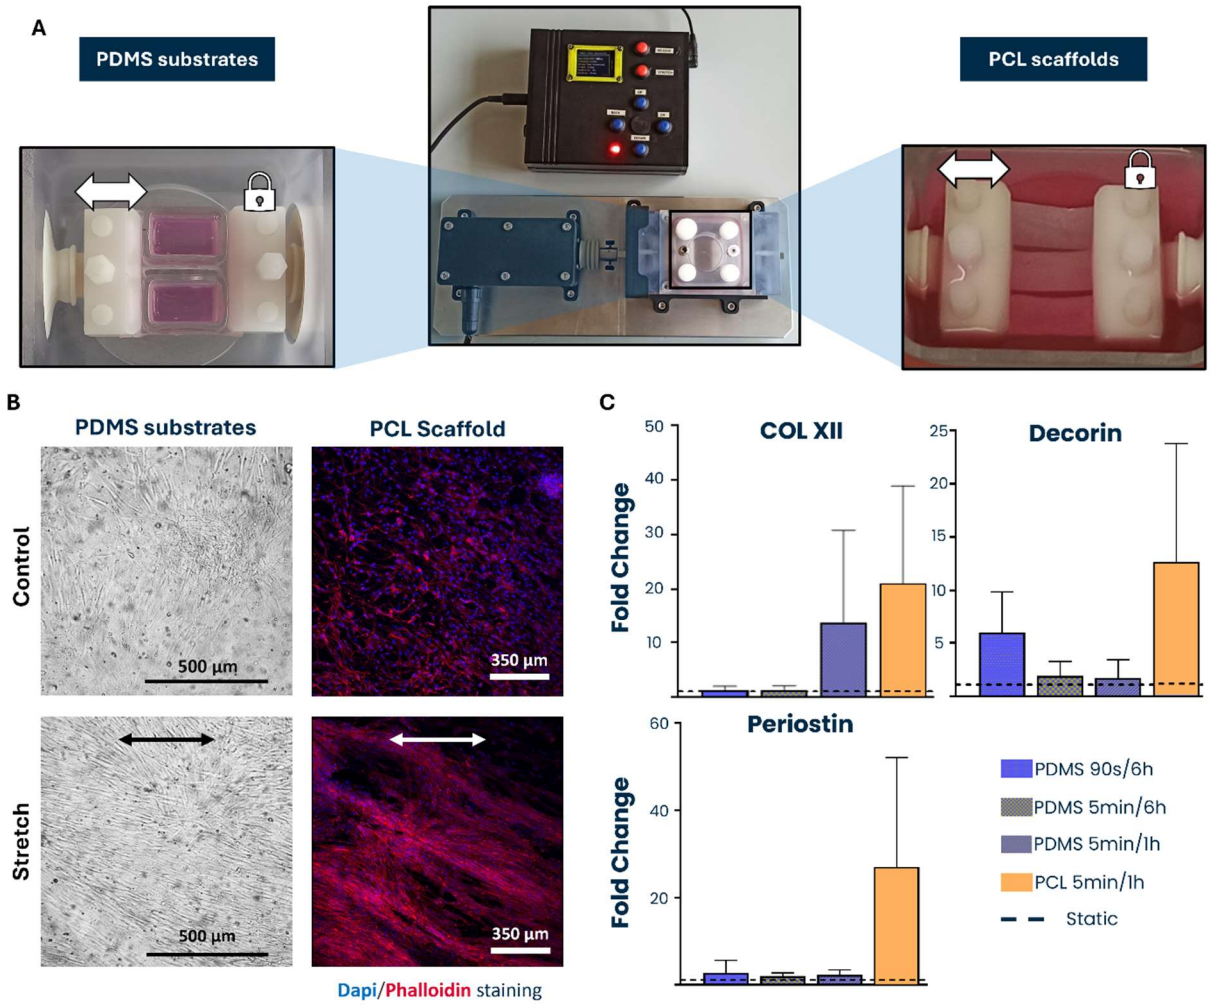

Figure 1. **A)** Overview of the stretch bioreactor, including a close-up of the PDMS substrate (left) and the PCL scaffolds (right) within the culture chamber. **B)** Bright-field images and DAPI/phalloidin staining of cells cultured on PDMS substrates and PCL scaffolds, respectively, under static (top row) and stretching (bottom row) conditions; arrows indicate the direction of the applied strain. **C)** Gene expression profiles presented as fold changes relative to the static condition (dashed line). The graphs depict comparisons among the different intermittent stretching protocols and between cultures grown on PDMS substrates and those on PCL scaffolds (n = 3).

Breast Cancer Fibrotic Microenvironment Architecture Controls Doxorubicin Diffusion: A Multiphysics Computational Study in an Avian Chorioallantoic Membrane Model

Dr. Alberto Bocconi, Dr. Claudio Conci, Mr. Leonardo Cherubin, Dr. Chiara Martinelli, Ms. Giada Mainieri, Mr. Marco Vigneri, Dr. Emanuela Jacchetti, Dr. Manuela T. Raimondi

Department of Chemistry, Materials and Chemical Engineering "Giulio Natta", Politecnico di Milano, Milano, (MI), Italy

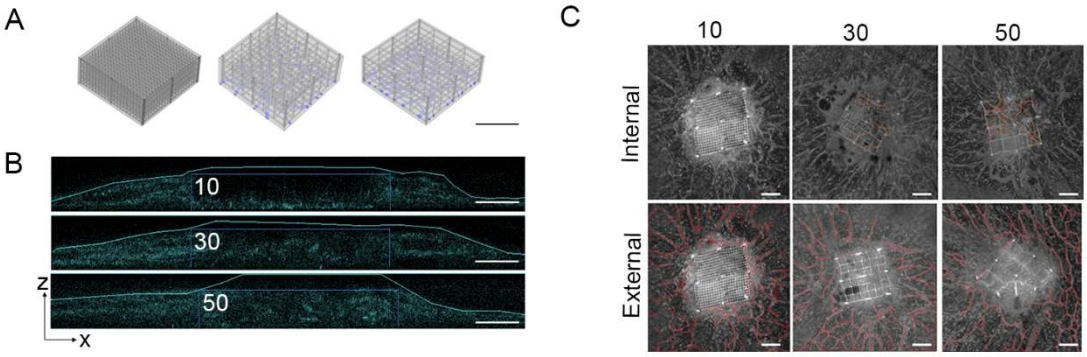
Introduction

In breast cancer, progressive collagen deposition stiffens the tumor microenvironment, imposing physical barriers to drug penetration and reducing therapeutic efficacy. To reproduce this progressive fibrotic remodeling in vivo, a chick embryo chorioallantoic membrane (CAM) model was implanted with three micro-scaffold architectures with distinct pore sizes, each generating different levels of vascularization and collagen deposition [1]. On this basis, a three-dimensional multiphysics model was built and calibrated on imaging-derived geometric parameters, blood flow velocities and experimentally measured transport coefficients from the CAM platform. The model is used to test how changes in fibrotic microenvironment architecture modulate doxorubicin distribution and efficacy within the platform.

Methods

COMSOL Multiphysics simulations coupling Computational Fluid Dynamics and Transport of Diluted Species were used to model doxorubicin transport within SZ2080 micro-scaffolds (10×10×15, 30×30×20, 50×50×20 μm^3 pores) implanted on the CAM. For each architecture, vascular morphology and density were quantified by two-photon intravital microscopy and used to define the three-dimensional vascular geometry and inlet flows, together with blood velocities from red blood cell tracking. Fibrotic architecture, including collagen density and fiber orientation, was quantified by second-harmonic generation imaging, and CAM stiffness was measured by atomic force microscopy. Doxorubicin transport coefficients were measured experimentally and used as inputs to the model.

Results



Doxorubicin concentration profiles were predicted over 120 minutes post-injection using an experimentally measured diffusion coefficient of 7.85×10^{-11} m^2/s in CAM tissue. Pore size distinctly modulated drug diffusion: 50×50×20 μm^3 scaffolds exhibited ~1.5-fold higher accumulation compared to 30×30×20 μm^3 pores, whereas 10×10×15 μm^3 pores showed

substantially reduced delivery throughout the scaffold region. Spatial concentration gradients revealed geometry-dependent diffusive resistance within the fibrotic compartment, with steeper gradients and extended low-exposure zones in the most fibrotic condition.

Discussion

This combined computational and experimental method shows that scaffold geometry regulates fibrotic microenvironment architecture by modulating vascularization and collagen deposition, hence affecting doxorubicin distribution across three fibrotic stages mimicked in the platform. By evaluating multiphysics predictions across three different pore topologies, the platform quantifies how fibrosis influences drug diffusion and may ultimately impact therapeutic efficacy.

Elucidating Mechanical Mechanisms of Alzheimer's Disease With Human Brain Models

Dr Xun Wang[1,2,3], Dr. Zhengyu Zhang[1], Ms. Annabel Tiong[1], Dr. Seunggyu Kim[1], Dr. Maria Proestaki[1], Prof. Zhengpeng Wan[1], Prof. Rudolph Tanzi[2,3], Prof. Ming Guo[1], Prof. Sehoon Choi[2,3], Prof. Roger Kamm[1]

[1]MIT, Cambridge, MA, United States. [2]Massachusetts General Hospital, Boston, MA, United States. [3]Harvard Medical School, Boston, MA, United States

Introduction

Alzheimer's disease (AD) involves the dysfunction of the blood–brain barrier (BBB) and meningeal lymphatics (ML), the brain's vascular system, which accelerates toxic protein buildup, including amyloid β (Aβ) accumulation, driving AD progression. Yet how BBB and ML interact and break down in AD remains unclear due to limited human tissue access and poor translation of animal models. Emerging evidence suggests that physical forces and mechanical properties of cells and tissues also play a role in AD, but tools to study these factors in human systems are scarce. Microfluidic engineered living systems offer a transformative solution to these limitations and reveal mechanical mechanisms of AD in the human environment.

Methods

We developed a novel 3D in-vitro human brain model that integrates perfusable BBB microvasculature, sprouting ML vessels, and AD-mimicking neurons within a single microfluidic platform. Our model recapitulates key structural and functional features of the human brain, enabling quantitative assessment of BBB permeability, ML drainage, and Aβ clearance under AD conditions. Built on top, we incorporated mechanical tools to explore therapeutic targets, including Piezo1, a mechanosensitive channel, and employed optical tweezers and force-spectrum microscopy to assess cellular mechanical changes during AD progression.

Results

Using our unified 3D human brain model, we showed increased BBB permeability, disrupted ML sprouting, reduced ML drainage, and abnormal Aβ accumulation in the AD condition. ML sprouts exhibited impaired growth and reduced clearance capacity. Mechanical measurements showed that Aβ exposure increased astrocyte stiffness and altered intracellular mechanical activity. Ongoing work is mapping similar mechanical

changes across other brain cell types, including microglia, to define AD-associated cell mechanics.

Discussion

Our physiologically relevant human model enables simultaneous analysis of Aβ dynamics, barrier function, fluid drainage, and cellular mechanics. It provides a platform to dissect neurovascular–lymphatic crosstalk and to identify mechanosensitive pathways such as Piezo1 that may regulate AD progression. Future efforts include developing fully stem-cell-derived isogenic models to reduce variability and expanding integrated mechanical measurements to characterize biomechanical dysfunction across cell types. Together, this system offers new insights into mechanical mechanisms in AD and supports the discovery of mechano-biomarkers and mechano-therapy strategies for human brain diseases.

Numerical Simulation of Atherosclerosis Development Following the Outside-in Hypothesis

Dr. -Ing. Meisam Soleimani[1], Prof. Peter Wriggers[1], Prof. Axel Haverich[2], Prof. Christian Gasser[3], Prof. Philipp Junker[4]

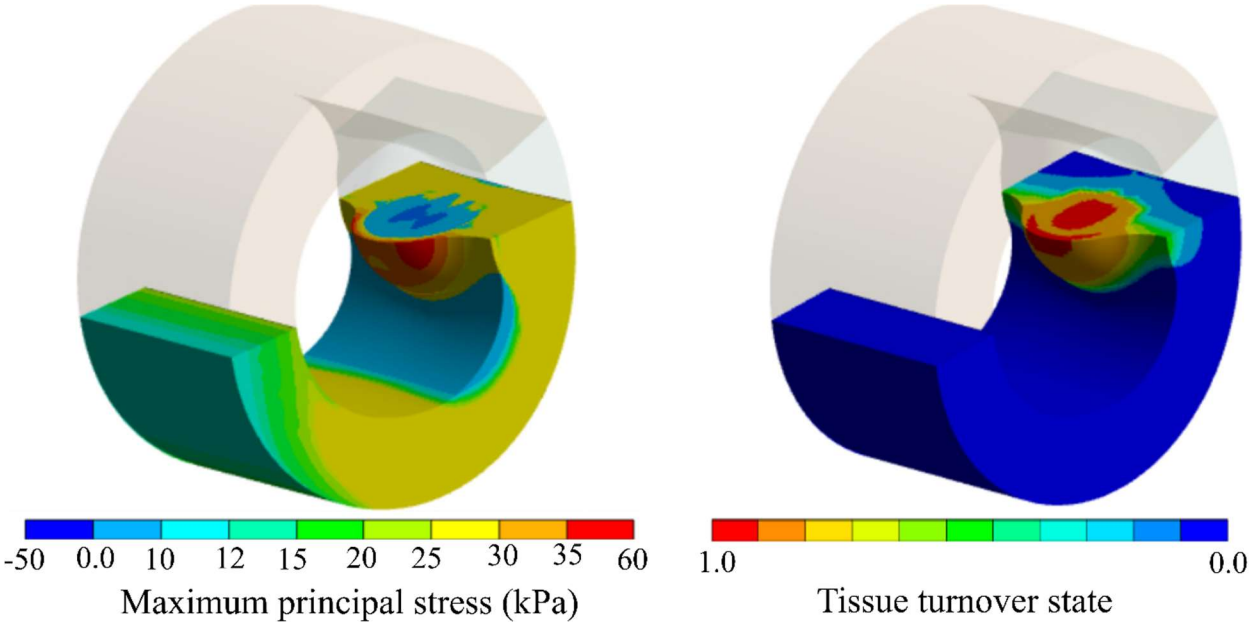
[1]Leibniz University Hannover, Hannover, Lower Saxony, Germany. [2]Medical School Hannover, Hannover, Lower Saxony, Germany. [3]KTH Royal Institute of Technology, Stockholm, Stockholm, Sweden. [4]Leibniz University Hannover, Hannover, Lowersaxony, Germany

Introduction

Atherosclerosis remains the leading cause of cardiovascular disease, yet its initiation and progression are poorly understood. Emerging evidence suggests a key role of the vasa vasorum (VV), whose impaired perfusion may trigger inflammation and plaque formation through an outside-in mechanism. We present a multi-field computational model that couples tissue turnover, inflammation, and growth [1]. Perfusion is described by a diffusion–reaction equation accounting for VV dysfunction, while inflammation is represented using a phase-field formulation that tracks the evolving inflamed region. Tissue growth results from the combination of inflammation-induced swelling with stress-regulated turnover. Simulations reveal strong coupling between perfusion deficits, inflammation, and mechanical stress, illustrating how VV impairment can initiate a pathological condition.

Methods

This work refines a previously developed multi-field model that captures deformation, perfusion, and inflammation in the arterial wall using an isotropic Yeoh hyperelastic law, diffusion–reaction–based nutrient transport, and a phase-field formulation to track inflammatory interfaces. Multiplicative kinematics govern atherosclerosis-related wall thickening through inflammation-induced swelling and stress-regulated tissue turnover. The model is extended by coupling perfusion with mechanical stress. We propose two interacting disease mechanisms: (i) reduced perfusion initiates inflammation when nutrient levels drop below a critical threshold, particularly under VV dysfunction; and (ii) chronic inflammation combined with ongoing tissue turnover leads to irreversible wall thickening and plaque formation. Simplifications include homogeneous isotropic mechanics, lumped blood-borne factor transport, constant boundary nutrient supply, and a regularized phase-field description. The framework is implemented using a fully implicit, monolithic finite element formulation.



Results

One can see in Fig.1 how the model predicts artery wall thickening as a result of spreading tissue inflammation and tissue turnover. Cauchy stress in the wall (left column) and the inflamed spatial tissue domain (right column). Elevated blood pressure further amplifies peak stresses, underscoring its role in the progression of disease.

Discussion

Our model highlights the importance of VV dysfunction in driving outside-in plaque growth and reveals how mechanical, inflammatory, and perfusion processes interact during disease progression. Despite necessary modeling simplifications and the challenge of patient-specific validation, the framework provides a foundation for future AI-supported vascular simulations.

Rectus Femoris Tendon as an Alternative ACL Graft: A Biomechanical Comparison with Standard Graft Configurations

MS Julian André, MS Samuel Bachmaier

Arthrex GmbH, Munich, Bavaria, Germany

MS Julian André

Introduction

Anterior cruciate ligament reconstruction (ACLR) remains the most common treatment method for ACL injuries [1], with graft choice and fixation technique being key determinants of clinical success [2]. While hamstring tendon (HT), bone-patellar tendon-bone (BTB), and quadriceps tendon autografts are commonly used [3], the rectus femoris tendon (RFT) recently gained attention due to its favorable anatomy and low donor-site morbidity [4]. However, biomechanical data on RFT grafts in ACLR remains limited. Therefore, the purpose of this study was to biomechanically evaluate the RFT as a viable graft alternative for ACLR.

Methods

Tendons were dissected from human cadaveric knees (54.9±12.6 years) and divided into four groups (n=8 per group): four-strand hamstring tendon (4HT), four-strand rectus femoris tendon (4RFT), doubled rectus femoris tendon (2RFT), and BTB graft. Specimens underwent four loading conditions (1,000 cycles each of position-controlled loading and force-controlled loading between 10-100N, 10-200N, and 10-300N), followed by a pull-to-failure (50mm/min). Residual graft force, dynamic elongation, dynamic stiffness, and ultimate failure load were evaluated. Group differences were analyzed using a one-way ANOVA with Tukey post-hoc test ($p<0.05$).

Results

The BTB group exhibited significantly greater residual graft force compared to both RFT groups ($p\leq0.046$). Dynamic elongation in the 200N load block was significantly greater in the 2RFT group compared to all other groups ($p\leq0.015$). No significant differences were observed between groups in the 100N and 300N load blocks. The dynamic stiffness of the BTB group was significantly lower compared to the 2RFT and 4HT groups ($p\leq0.019$).

Moreover, the 4HT group showed significantly greater dynamic stiffness than the 4RFT group ($p \leq 0.047$). The ultimate failure load of the 2RFT group was significantly lower than that of the 4HT and BTB groups ($p \leq 0.034$).

Discussion

This study's results confirm the RFT as a viable autograft alternative for ACLR, demonstrating comparable biomechanical performance to standard grafts. Despite increased elongation and lower failure loads, 2RFT grafts may be suitable for patients relying on preserved quadriceps function.

Unicortical Quadriceps Tendon Repair With All-Suture Anchors Results In Less Gap Formation Than Traditional Hard-Body Suture Anchors

Dr. Brian Werner MD[1], Mr. Marcos Tejada BS[2], Dr. Jocelyn Wittstein MD[3], Dr. Rachel Frank MD[4], Dr. Mary Kate Evans PhD[5], Dr. Anthony Khoury PhD[2], Mr. Benjamin Smith MS[2]

[1]UVA Health, Charlottesville, Virginia, United States. [2]Arthrex, Naples, Florida, United States. [3]Duke Health, Durham, North Carolina, United States. [4]UCHealth CU Sports Medicine, Denver, Colorado, United States. [5]Artrhex, Naples, Florida, United States

Introduction

Current quadriceps tendon repair techniques following rupture include transosseous patellar bone tunnels (TO) and suture anchors (SA); however, documented failure rates range from 0-16% [1]. Adjustable all-suture anchors (ASAs) may provide better tendon footprint restoration; however, there are currently no studies that have examined ASA use for unicortical fixation. The authors hypothesized that unicortical ASA fixation would reduce gap formation and exhibit comparable stiffness, yield load, and ultimate load to the conventional unicortical hard-body suture anchor approach.

Methods

Eight matched male cadaveric knee pairs were dissected and randomized to ASA (2.6-mm) or hard-body suture anchor repairs, with medial/lateral Krackow sutures on the quadriceps tendon (1.3-mm tape). For ASA repair, two ASAs were inserted into two 2.6-mm sockets, respectively. For the control repair, two hard-body anchors were inserted into two tapped 4-mm sockets, respectively. Krackow sutures were loaded through anchors to reduce the quadriceps tendon. Knees underwent 10 native preconditioning cycles (5° to 90° of flexion) on a materials testing system, followed by 250 post-repair cycles (0.1 Hz, 150 N peak) and load-to-failure (50mm/min) [2]. Outcomes: gap formation (mm) during cyclic loading and stiffness (N/mm), 0.2% offset yield load (N), and ultimate load (N) during load-to-failure. Paired t-tests were used for statistical analyses ($p < 0.05$).

Results

ASA repair had significantly less gap formation at cycle 250 (mean Δ=4.2 mm; $p<0.001$). Mean control displacement surpassed the defined critical threshold for gap formation (5.0 mm) within the first 50 cycles; mean ASA displacement approached this threshold at cycle

200. No significant differences in stiffness or ultimate load. Yield load was significantly higher in the control group (mean Δ=54.7 N; p=0.002).

Discussion

ASA repair significantly reduced gap formation by 43%, suggesting unicortical ASA repair may lead to improved clinical outcomes. While only the yield load was significantly lower for the ASA repair, this may not result in clinical deficiencies when the post-operative healing is complete. Despite the inherent limitations of a time-zero biomechanical study, the results provide robust data to biomechanically support ASA viability for unicortical quadriceps tendon repair.

Repeatability of Shear Wave Tensiometry in Tendons With and Without Pathology: A Comparison of Normalization Methods During Countermovement Jump Phases

Ms. Lucia Hockerman[1,2], Ms. Elizabeth Schmida MS[3,2], Dr. Darryl Thelen PhD[4], Dr. Bryan Heiderscheit PT, PhD, FAPTA[3,2], Dr. Naoaki Ito DPT, PhD[3,2]

[1]University of Wisconsin-Madison Department of Biomedical Engineering, Madison, Wisconsin, United States. [2]University of Wisconsin-Madison Badger Athletic Performance Program, Madison, Wisconsin, United States. [3]University of Wisconsin-Madison Department of Orthopedics and Rehabilitation, Madison, Wisconsin, United States. [4]University of Wisconsin-Madison Department of Mechanical Engineering, Madison, Wisconsin, United States

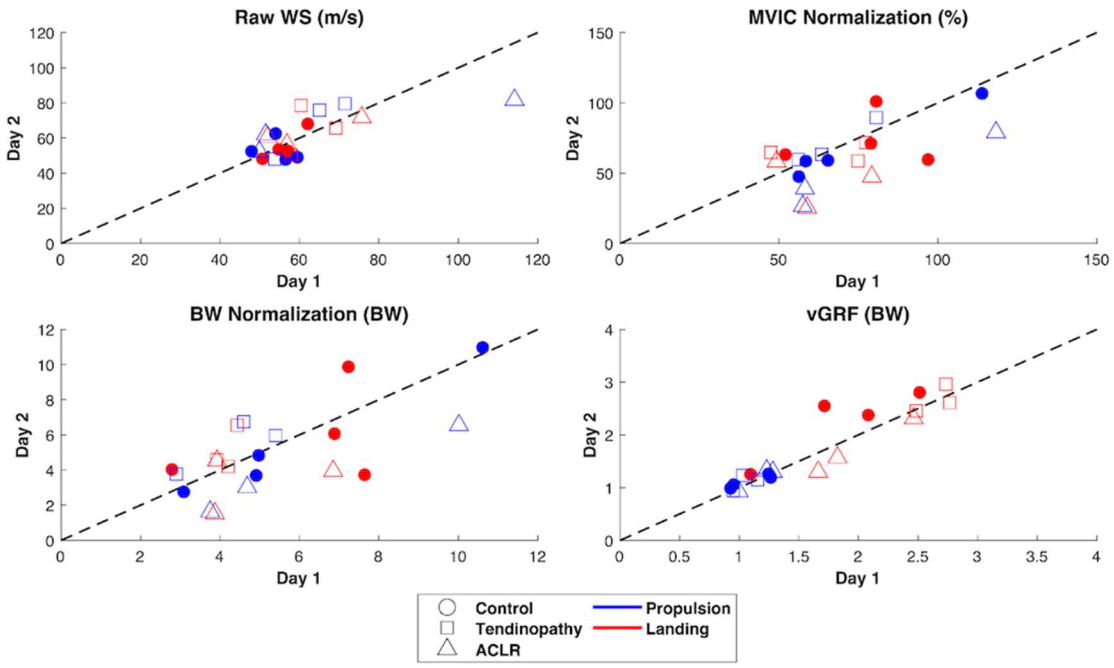
Introduction

Heavy tendon loading through exercise therapy is the recommended approach for treating patellar tendon injuries [1]. Disconnect between exercise and internal tendon loading during rehabilitation,
however, makes optimal dosing difficult. Shear wave tensiometry (SWT) is a skin-mounted sensor that measures tendon shear wave propagation speed (equivalent to axial stress [N]) [2], but its repeatability is unknown. This study aimed to assess the repeatability of SWT during propulsion and landing phases of countermovement jumps (CMJs) using different normalization methods in healthy and pathological patellar tendons.

Methods

Adults with patellar tendinopathy (n=3), anterior cruciate ligament reconstruction with a bone-patellar tendon-bone autograft (n=3), and healthy controls (n=4) participated. SWT was simultaneously recorded with (1) vertical ground reaction forces (vGRFs) during CMJs, and (2) knee extensor torque during maximum voluntary isometric contractions (MVICs) performed on an electromechanical dynamometer positioned at 60° of knee flexion. Data were collected twice within a 7-day period. The involved limb (weaker limb for controls) was analyzed. During propulsion and landing phases, peak CMJ wave speeds (WS, m/s) were identified and normalized to (1) peak WS at MVIC (%) and (2) scaled to units of body weight (BW) using a standard 4.5 cm patellar tendon moment arm. Intraclass correlations (ICCs) assessed the reliability of each normalization method and peak vGRF.

Results



SWT ICCs during CMJ propulsion were greater than landing, with MVIC and BW normalization values comparable to vGRF. SWT ICCs during landing phase were poor (Figure 1).

Discussion

SWT was most repeatable between days during the propulsion phase of CMJ when normalization methods were implemented. Propulsion SWT was more reliable than landing, likely reflecting the propulsion phase being performed with more consistent knee biomechanics than the landing phase. Hence, the low SWT ICCs during landing may be due to normal movement variability. SWT was applied at the patellar tendon across different pathologies during CMJs with promising repeatability results. Larger cohorts with various tendon pathologies and testing in alternative movements may be needed to further determine ideal normalization methods.

Preliminary Data Suggest that Human Tendinopathic Tendons Do Not Contain More Denatured Collagen than Healthy Controls

Mx. Margaret Capalbo[1], Dr. Spencer Szczesny[1,2]

[1]Pennsylvania State University, University Park, PA, United States. [2]Penn State College of Medicine, Hershey, PA, United States

Introduction

Despite tendinopathy accounting for 30% of all musculoskeletal disorders, its pathogenesis is unclear. We previously found minimal collagen damage (i.e., denaturation) in mouse Achilles tendon (AT) explants cyclically loaded to failure, suggesting that collagen denaturation may not initiate a degenerative cellular response leading to tendinopathy. However, it is unclear whether collagen denaturation occurs in human tendinopathic samples. Additionally, HIF-1a has been measured in higher quantities in human tendinopathic tissue, suggesting a role for hypoxia as well. However, the relationship between collagen damage and hypoxic signaling is unknown. Therefore, the purpose of this study was to measure the amount of collagen denaturation and HIF-1a in tendinopathic and healthy human tendon samples. We hypothesize that both markers will be greater in tendinopathic samples than in healthy controls.

Methods

Tendinopathic tissue from the long head of the biceps tendon (LHBT) and AT were collected during surgical repairs with IRB approval. Healthy tissue was obtained from the National Disease Research Interchange. Cryosections (10um) were incubated with a collagen hybridizing peptide (CHP) to measure collagen denaturation or a HIF-1a anti-body. Fluorescence images were used to determine the percentage of tissue positively stained by CHP and HIF-1a. tatistical significance was determined using a Wilcoxon test.

Results

In the LHBT (n=3), percent area of CHP was not statistically significant between healthy (5.3% ± 4.0%) and tendinopathic (0.7% ± 1.2%) tissue (Fig. 1A,B). For the AT (n=1), the percent area of CHP was 25.8% in the healthy and 1.0% in the tendinopathic sample. For the LHBT stained for HIF-1a (n=2), the staining in healthy (0.4% ± 0.3%) and tendinopathic (0.6% ± 0.002%) samples was similar (Fig. 1C,D).

Discussion

While no statistical difference was determined between the healthy and tendinopathic samples for either tendon and marker, the amount of collagen denaturation tended to be higher in healthy tissue. This unexpected trend may be explained by ambiguous determination of the healthy and tendinopathic portions of the LHBT tissue or differences in collection methods for the AT samples. Still, our preliminary data suggest that human tendinopathic tendons do not contain substantial collagen denaturation and, therefore, may not be characteristic of tendinopathy.

Images (Optional)

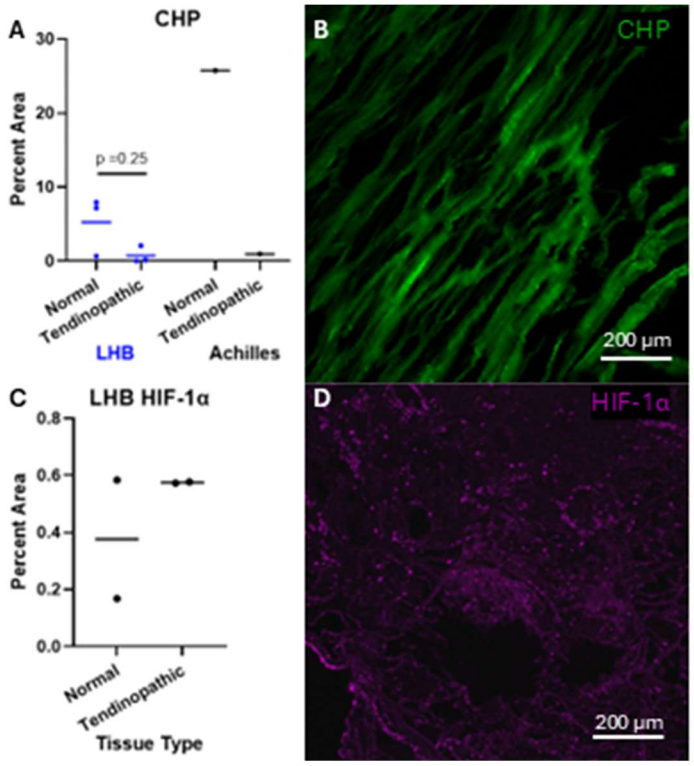

Figure 1: (A) Percent area of collagen denaturation (CHP) LHBT and AT. (B) Representative image of healthy AT for CHP staining. (C) Percent area of HIF-1α staining in LHB tendons. (D) Representative image of diseased LHBT for HIF-1α staining.

Evaluating Animated and Interactive Learning Tools for Strength Training Biomechanics Education

Assistant Teaching Professor Breanne Carlson MS[1], Associate Professor Erich Petushek PhD[1], Research Associate Oliver Faul MS[2], Professor Tron Krosshaug PhD[2]

[1]Michigan Technological University, Houghton, MI, United States. [2]Norwegian School of Sports Sciences, Oslo, Oslo, Norway

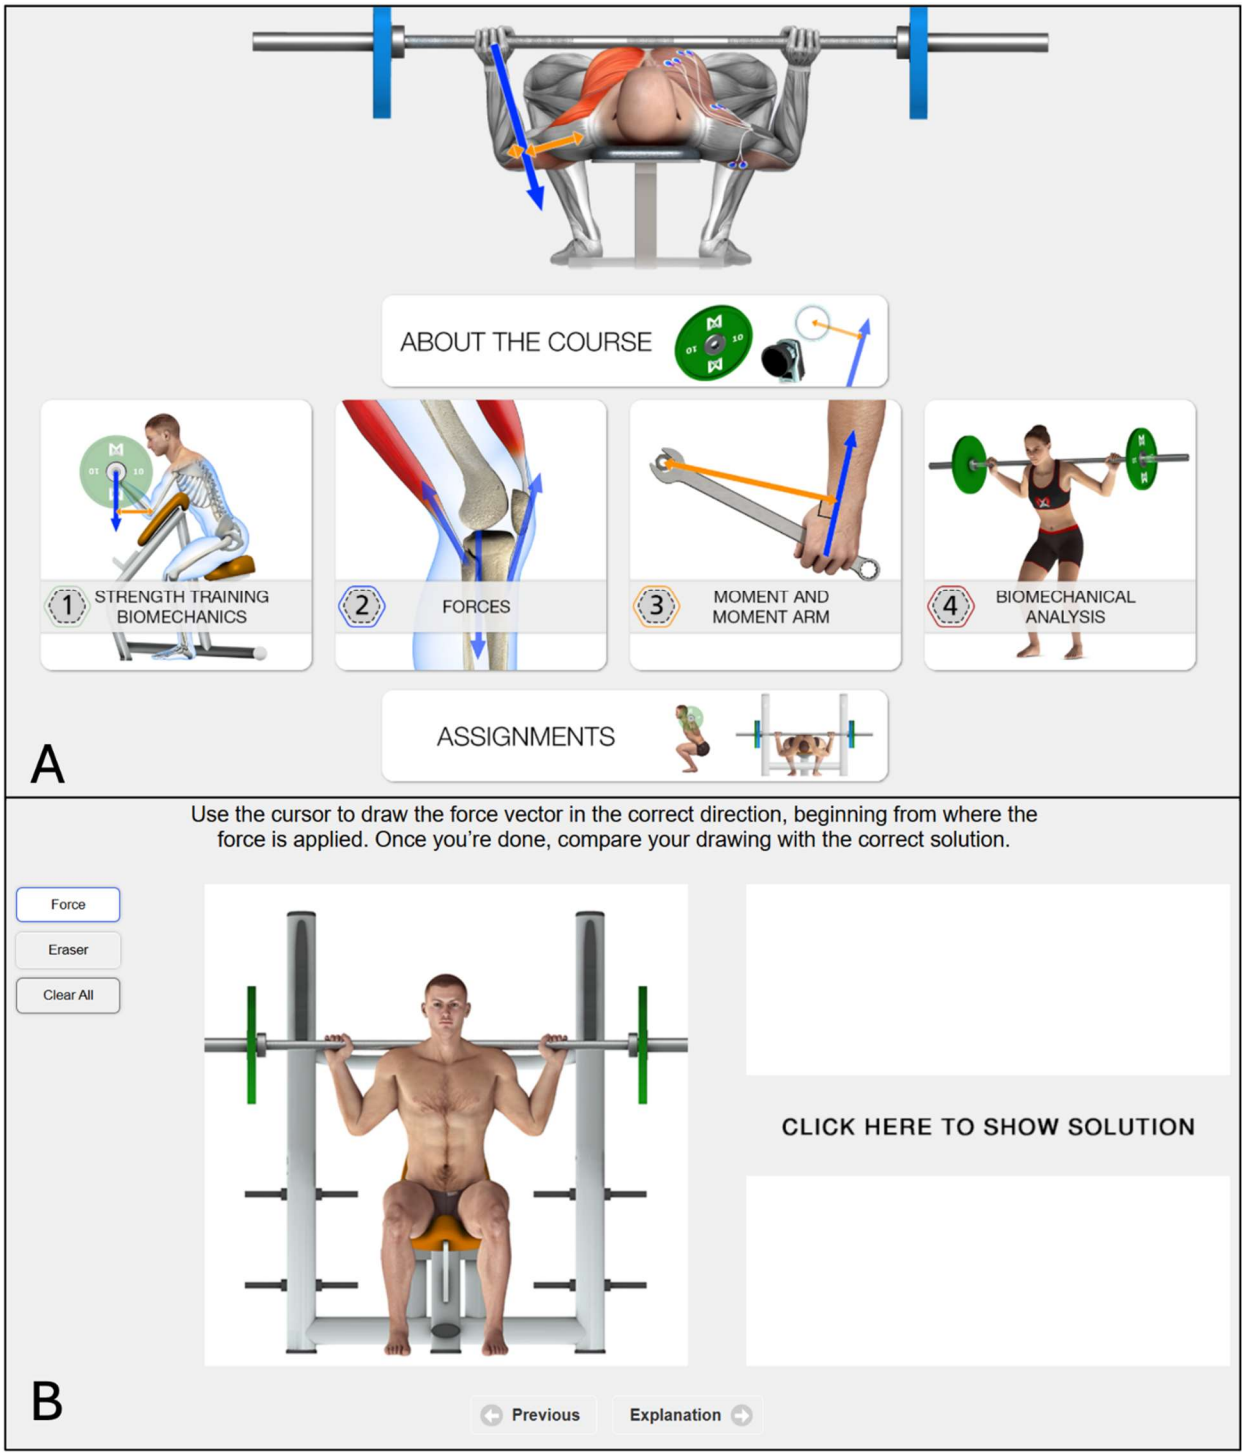
Introduction

Teaching biomechanics of strength training requires students to integrate anatomy, force vectors, moment arms, and joint moments within applied resistance-exercise contexts. Traditional lecture approaches may inadequately support this applied conceptual learning. Interactive digital platforms that combine animated demonstrations and hands-on manipulation tools may enhance understanding, yet research examining student perceptions, usability, and potential motivational bias remains limited. This study evaluated student perceptions of an instructional platform designed specifically for strength-training biomechanics and examined whether platform endorsement was related to baseline enjoyment of strength training.

Methods

Eighteen undergraduates in an exercise assessment course completed a mixed-methods survey evaluating the Muscle Animation instructional platform (see Figure 1 for example screenshots). Quantitative measures included likelihood of recommending the platform to a peer (modified Net Promoter Score; 1–5 scale) and enjoyment of strength training (1–5 scale). Descriptive statistics and 95% CI were calculated, and correlations tested associations between enjoyment and endorsement ($\alpha = .05$). Qualitative item responses assessing platform likes, dislikes, and improvement suggestions were analyzed using content analysis. Two researchers independently coded responses and resolved themes by consensus. Frequency counts estimated thematic prevalence.

Results



Mean likelihood of recommending the platform was 3.56 (95% CI: 2.92–4.21). Students reported high enjoyment of strength training (M = 4.06, 95% CI: 3.53–4.59). No significant association was found between enjoyment and endorsement ($r = .30$, $p = .26$). Thematic analysis identified animated visualizations of joint forces and moment arms as the most valued feature (≈50%). Interactive vector manipulation during exercises was noted by 33% as enhancing active learning and conceptual understanding. Modular lesson structure and

quiz practice were cited by 20–30%. Usability concerns were most common, including navigation difficulties (25–30%), lack of progress tracking (22%), and quiz formatting issues (22%). Approximately 28% reported no dislikes or suggestions.

Discussion

Results indicate that animated and interactive tools are highly valued for teaching strength-training biomechanics and that endorsement is independent of students' intrinsic interest. Findings emphasize usability refinements—particularly navigation workflows and progress monitoring—while retaining strong visual and interactive design elements. Future work will evaluate learning outcomes and conduct usability testing to optimize training-specific biomechanics instruction.

FA.RE.MO: A Non-profit Platform to FAcilitate REsearch MObility in Biomechanics

Dr Cecilia Monoli[1], Dr Monika Colombo[2]

[1]Department of Health and Kinesiology, University of Utah, USA, Salt Lake City, Utah, United States. [2]Department, Aarhus, Jutland, Denmark

Introduction

International research mobility is a cornerstone for scientific and career development, fostering knowledge exchange, innovation, and personal growth. Globally, 6.9 million students engaged in international mobility in 2022, with graduate students forming the largest share in programs like Erasmus+ and U.S. exchanges [1]. For example, the U.S. hosted nearly 488,000 international graduate students in 2024/25, while NSF's IRES program supported 5,000 graduate researchers since 2006. International students are particularly concentrated in doctoral programs and STEM fields, highlighting the relevance for graduate-level mobility [1]. Despite this demand and impact, accessing international research opportunities remains challenging.

Methods

Addressing current limitations in accessing international research opportunities, we are developing **FA.RE.MO** [2], a web-based platform designed to centralize and streamline research mobility in biomechanics. As illustrated in **Fig. 1**, the platform is structured into several key components. It introduces users to the mission and provides curated information on research opportunities organized through a keyword-based system. A dedicated section compiles funding and fellowship programs. The platform hosts a growing network of international biomechanics labs, including details on research focus, equipment, contacts, and openness to hosting students. A story-sharing space, and a resources and contacts section offers templates for emails, application materials, and cultural/practical guides. FA.RE.MO is currently in active development and will be available for use at the time of the congress.

Results

FA.RE.MO aims to increase engagement by creating a dynamic, user-friendly environment for research mobility planning. Expected outcomes include:

i) A growing database of researchers and institutions across disciplines.

ii) Outreach through social media and academic channels to reach graduate students globally.

iii) Improved matching accuracy, reducing administrative burden and accelerating collaboration setup.

Discussion

By connecting researchers and institutions, FA.RE.MO is positioned to transform how research mobility is managed. The platform promotes inclusivity, transparency, and efficiency, addressing current limitations in fragmented systems. Ultimately, FA.RE.MO supports career development for graduate students and strengthens international collaboration networks, contributing to a more interconnected scientific community.

Integration of Quantitative Biomechanical Analysis in Non-Research Settings via an Automated Pipeline

Ms Kaley Pagnotta, Dr. Cherice Hill

University of Rochester, Rochester, NY, United States

Introduction

Biomechanical analysis is increasingly desired in athletic settings, but the necessary expertise creates a barrier to broad utilization; automated pipelines can reduce the expertise necessary, decreasing this barrier. Collaborating with coaches and athletic trainers to create a system for motion analysis that, after development, can be used independently of a biomechanics expert would allow for biomechanical analysis to be integrated in routine injury prevention and training. This study aimed to develop and pilot such a system for motion analysis in a non-research setting by non-experts.

Methods

Following consultation with an athletic program, a Qualisys Track Manager PAF pipeline was coded to automate marker-less motion capture and force plate data processing through Theia3D and Visual3D (Figure 1A). A coach was trained (~2 hours) to set up and calibrate a marker-less motion capture system and portable force plates, follow a collection protocol, process data (automated), and interpret the generated report. After training, the coach independently used the protocol and pipeline to collect and interpret data from 8 athletes at 3 timepoints across 3 months. The coach completed surveys reflecting their perception of and comfort with the biomechanical data and collection method before training, after training, and after each data collection session.

Results

The developed pipeline automated processing comparably to manual processing. The coach consistently viewed motion analysis data as “very important”. Before training, the coach had low confidence in using the equipment and collecting data, but confidence improved and remained high after training (Figure 1). All data collected by the coach was research-grade quality, with appropriate lighting and all 8 cameras having the athlete in full view. Over time, the coach set up more quickly, and the coach only had questions for the monitoring researcher at the initial data collection session.

Discussion

These findings demonstrate the potential for integration of an automated biomechanical pipeline for use in an athletic training space by a coach. Coaches demonstrated increased comfort after training and consistently expressed importance of incorporation of this data relative to training goals. As interest in biomechanical data continues to grow, future work should continue to explore ways to improve accessibility of robust biomechanical analysis.

Transferring Anatomical Models From Medicine to Engineering: Derivation of Requirement Categories for Anatomical Models Supporting the Development of Medical Devices Using the Example of the Lumbar Spine

Ms. Marisa Ritter M.Sc., Dr.-Ing. Robin Remus, Dr.-Ing. Marc Neumann

Biomedical Engineering Lab, Department of Mechanical Engineering, Ruhr University Bochum, Bochum, NRW, Germany

Introduction

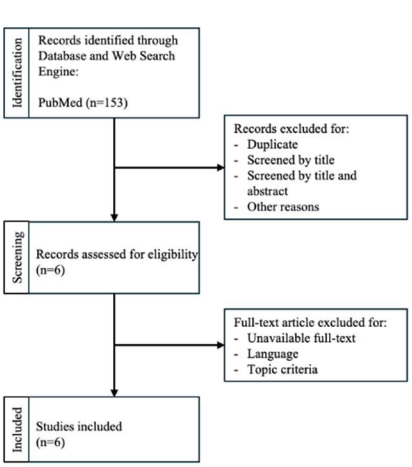
Developing medical devices, such as spinal implants, requires a deep understanding of anatomy and biomechanics [1]. Physical models can enhance this understanding by providing visual and tactile insights into complex structures [2, 3]. This study reviews anatomical spine models used in educational settings to derive requirement categories for a physical anatomical model to impart anatomical and biomechanical knowledge and to support the development of medical devices.

Methods

A literature review was conducted in PubMed to identify publications on the educational applications of physical lumbar spine models published between 2020 and 2025. The articles were screened by title and abstract, followed by full-text assessment of eligible studies (Figure 1a). Studies were included if they described a physical spinal model and reported details on its design, fabrication, and educational application.

Results

The literature review identified six spinal teaching models used primarily in surgical training (Figure 1b). The models varied in anatomical extent, ranging from single spinal segments (L4/5) to multi-segment constructs (L1–S1). Extended versions included the pelvis and rib cage. Five of the six models targeted novice learners, typically surgical residents. All models featured clearly defined applications and learning outcomes. They were manufactured using cost-effective approaches, with reported costs not exceeding $500 per model.



Discussion

The results indicate that existing models are primarily designed for medical residents, raising the question of whether they can be directly transferred to use in the development of medical devices. Identifying engineers' specific needs is essential to determine which anatomical or functional features require modification, simplification, or expansion.

Integrating engineers' feedback into a subsequent development phase could help ensure that the resulting requirement categories reflect actual needs. Overall, the findings provide an initial foundation for a structured requirements framework that balances anatomical realism with functional biomechanical representation and supports the design of effective anatomical models to enable engineers to gain deeper insights into anatomy and biomechanics knowledge and, later on, transfer this knowledge to degree programs of engineers for the development of medical devices.

Leveraging Game-based and Blended Learning to Support Students with Heterogeneous Linguistic, Cultural, and Academic Backgrounds in a Lecture Series on Traffic Accident Biomechanics and Polytrauma Pathophysiology

M.Ed. Raphael Grau[1], M.A. Ann-Kathrin Steiner[2], Dr. Luke West[2], M.Ed. Matthias Mann[1], Dipl.-Ing. Katharina Bause[1], Univ.-Prof. Dr.-Ing. Tobias Düser[1]

[1]IPEK – Institute of Product Engineering, Karlsruhe Institute of Technology (KIT), Karlsruhe, Baden-Württemberg, Germany. [2]Eberhard Karl University of Tübingen, Tübingen, Baden-Württemberg, Germany

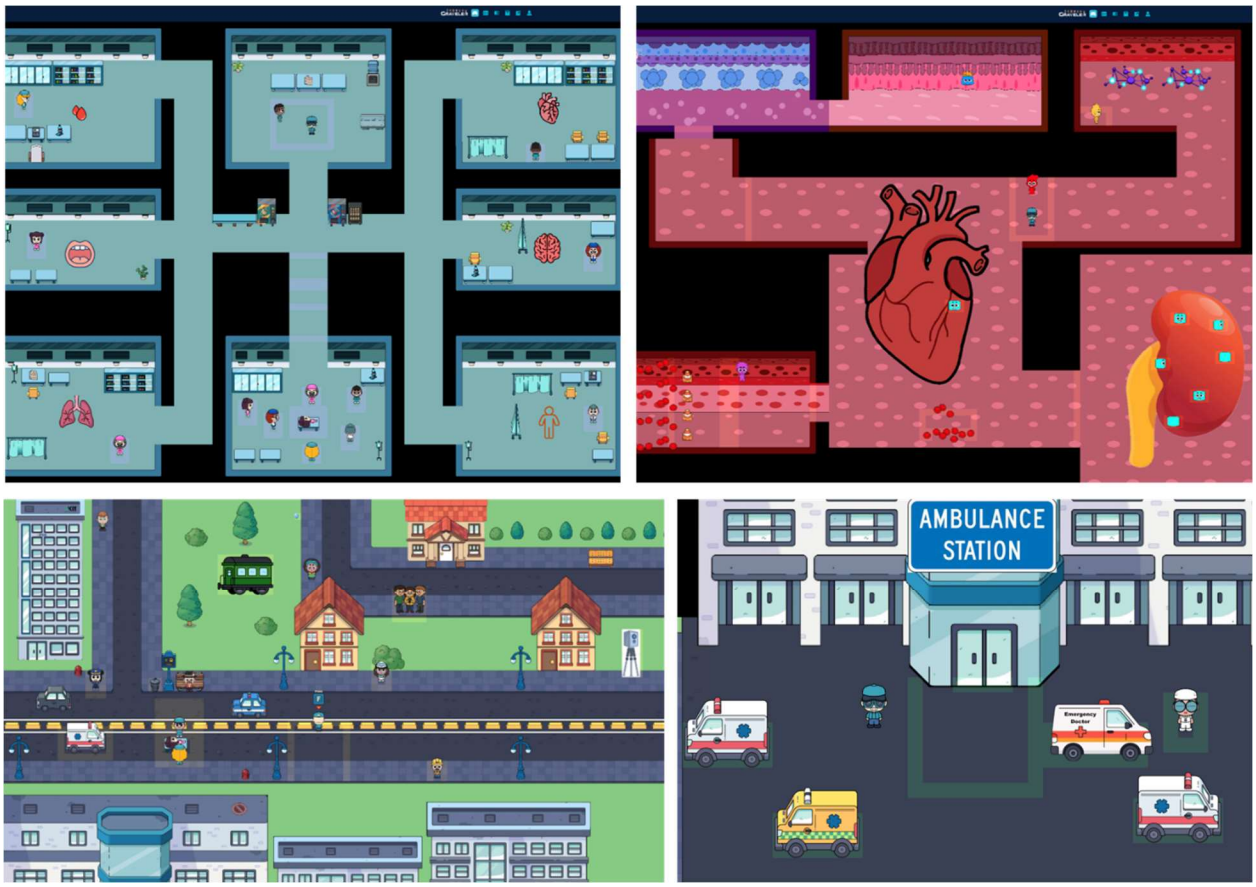
Introduction

A new international Master's program in Biomedical Engineering, brings together students from diverse linguistic, cultural, and academic backgrounds with varying prior knowledge and learning needs. To support their entry into the sensitive topics of biomechanics and pathophysiology of injured patients, a serious game was developed and implemented within a teaching course. It enables students to grasp fundamental mechanisms of traffic accidents and related injuries while learning at their own pace and focusing on individual interests. Embedded in a blended learning framework, the course bridges a research gap by combining serious gaming, adaptive learning, and inclusive access for diverse learners.

Methods

This study develops and evaluates a media-pedagogical intervention through a serious game. The learning environment follows the Technological Pedagogical Content Knowledge (TPACK) framework to ensure meaningful integration of digital tools. Principles of situated learning, complete action, and the Four-Component Instructional Design Model (4C/ID) guide the design of competence-oriented, practice-relevant tasks. Using a qualitative approach, learning processes are explored through continuous reflection, a research journal, and structured feedback with instructors and peers. Standardized questionnaires, including the User Experience Questionnaire, the Questionnaire on Learning with Serious Games, and the Questionnaire for Assessing Current Motivation, are used for student evaluation. The data collection is ongoing, but will be completed before WCB.

Results



A two-dimensional online multiplayer role-playing game with integrated collection and problem-solving elements was developed, comprising six interconnected game worlds.

Students assume the role of a trainee and progress through scenarios addressing biomechanics and accident research, preclinical and clinical trauma management, and the pathophysiology of injuries. Preliminary data analysis indicates positive outcomes across all applied questionnaires. Results suggest that participants experienced enhanced motivation, engagement, and perceived learning effectiveness through the serious game intervention.

Discussion

The preliminary findings suggest that the developed serious game offers a promising approach to supporting learners with heterogeneous disciplinary backgrounds in acquiring core competencies in trauma biomechanics and emergency care. However, the ongoing evaluation will be essential to more precisely determine the magnitude of these effects and to identify design components that contribute most strongly to learning outcomes. Further iterations may refine usability, narrative integration, and alignment with curricular learning objectives.

Does Stiffness Really Matter?The Role of Substrate Stiffness in the Mechanoresponse of Dermal Fibroblasts In Vitro

Ms. Daniela Kromer[1], Dr. Costanza Giampietro[2], Prof. Dr. Edoardo Mazza[1,2]

[1]ETHZ, Zurich, Zurich, Switzerland. [2]Empa, Duebendorf, Zurich, Switzerland

Introduction

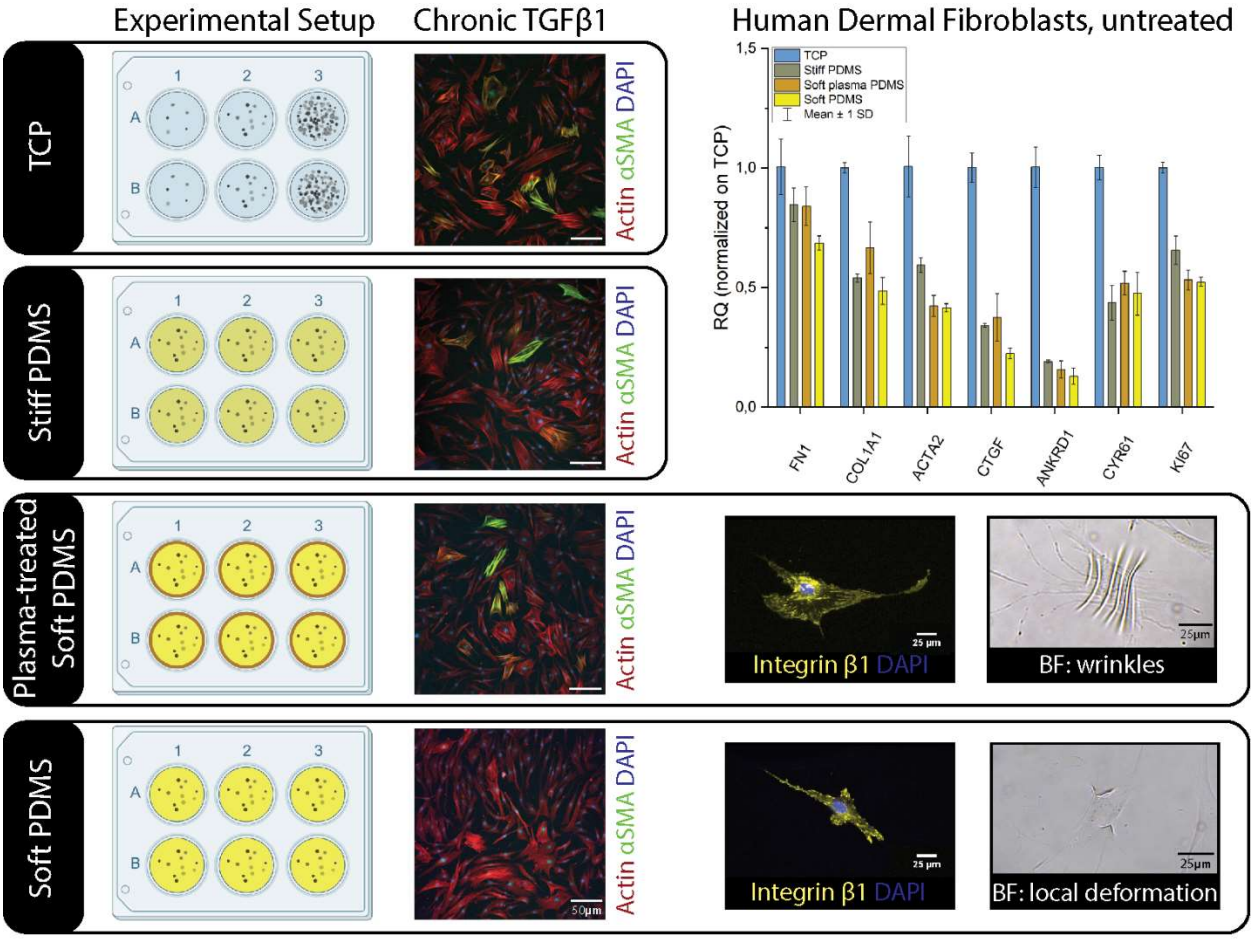
Fibroblast mechanotransduction is widely studied using engineered substrates, yet the stiffness contribution relative to other microenvironmental factors remains unclear(1). Here, we investigate how substrate stiffness, material, surface treatment, and cell density shape the mechanoresponse of dermal fibroblasts compared with endothelial cells.

Methods

Human dermal fibroblasts and human umbilical vein endothelial cells were cultured on collagen-coated substrates of varying materials and stiffnesses. Substrates included soft (0.2kPa) and stiff (64kPa) polydimethylsiloxane (PDMS), and tissue-culture-plastic (TCP). In selected experiments, cells were activated with TGF-β1. Samples were analyzed by qPCR for mechanoregulated gene expression and immunofluorescence for morphology, cell-substrate adhesion, stiffness-responsive nuclear YAP and smooth muscle actin (α-SMA) expression.

Results

Fibroblasts displayed similar morphology, adhesion and low α-SMA levels (<2% of all cells) across all substrates. Gene expression indicated that fibroblasts respond only mildly to stiffness. Matrix-remodeling genes showed no significant stiffness-dependent changes. ACTA2 and YAP-target genes trended towards upregulation with increasing stiffness, while comparison between stiff PDMS and TCP showed a threefold upregulation, highlighting the influence of substrate material composition over stiffness.



To potentiate the mechanoresponse, fibroblasts were treated with TGF-β1. Chronic TGF-β1 increased α-SMA stress fiber assembly to ~20% on TCP and ~10% on stiff or plasma-treated soft PDMS, whereas no α-SMA was assembled on soft PDMS. This suggests that under supraphysiological conditions, the stiffness-dependent response is amplified. Apart from this, fibroblasts were still able to locally deform the soft PDMS which was shown further through wrinkle formation of a stiffer surface layer added by plasma functionalization.

Compared to fibroblasts, sparse and confluent endothelial cells induced smaller mechanically deformations of soft PDMS yet displayed a faster and stronger transcriptional response to substrate stiffness. Studying sparse and confluent fibroblasts revealed cell density as a strong regulator. Together, these results reveal distinct stiffness-sensing sensitivities between fibroblasts and endothelial cells.

Discussion

Matrix stiffness plays a major role in skin pathophysiology including tissue stiffening during wound healing or fibrosis. Our results show that in vitro, substrate stiffness does not robustly activate dermal fibroblast mechanotransduction. Instead, substrate material, surface functionalization, and cell density exert stronger effects, suggesting that fibroblasts mechanoresponse in vitro is multifactorial.

Introduction

Mechanotransduction enables cells to convert physical forces into biochemical signals, a process dependent on both the organization and dynamics of the actin cytoskeleton. Actin networks not only generate contractile tension but also transmit forces to the extracellular matrix (ECM) through focal adhesion complexes that couples stress fibers to the cell-matrix interface [1]. In articular cartilage, the ability of chondrocytes to sense and transmit mechanical forces directly governs cartilage homeostasis, matrix turnover, and degeneration. Here, we investigate how actin-binding and -bundling proteins such as plastin-3 (PLS3) modulate cytoskeletal architecture and force transmission.

Methods

Primary chondrocytes were isolated from newborn mice globally lacking (*Pls3*KO [2]) or overexpressing (*PLS3*OE [3]) PLS3 in comparison to C57BL/6N (WT) mice. 2D traction force microscopy (TFM) was performed on chondrocytes cultured for 48h on 5kPa polyacrylamide substrates embedded with fluorescent beads. Live-cell imaging simultaneously captured the cell body and bead positions in stressed and reference states, allowing to measure cell-induced displacements and to calculate cell tractions. To quantify cell-substrate deformation volumes on a nanometer-scale level, Elastic Resonator Interference Stress Microscopy (ERISM) [4] was applied. ERISM provides high sensitivity and enables stiffness comparison across 5kPa and 34kPa as well as measurements on two

different time-points (after 48h and 72h), offering a complementary assessment of chondrocyte force transmission.

Results

*Pls3*KO cells generated significantly ($p<0.05$) higher traction forces compared to WT chondrocytes, while displaying smaller traction foci. Cell area was similar across genotypes and stiffnesses after 48h, after 72h *Pls3*KO cells exhibited the largest reduction in cell area shifting from soft to stiff ($p=0.07$). In contrast, normalized indentation volume in *Pls3*KO chondrocytes was significantly higher than for WT and *PLS3*OE cells on soft (5kPa) substrates at both 48h and 72h, while this difference was lost on stiff (34kPa) substrates after 48h due to reduced indentation volume in *Pls3*KO cells under higher stiffness.

Discussion

PLS3 appears essential for early focal adhesion organization and initial force transmission, while compensatory mechanisms likely override its role in mature cytoskeletal states.

Strain-Dependent Gene Expression and Remodeling by Tricuspid Valve Interstitial Cells

Dr. Devin Laurence Ph.D., Dr. Stanley Stachelek Ph.D., Mrs. Emily Hall M.S., Ms. Xiaoqiu Yang M.S., Dr. Matthew Jolley M.D., Dr. Robert Levy M.D.

Children's Hospital of Philadelphia, Philadelphia, PA, United States

Introduction

The tricuspid valve is the primary functioning heart valve for children with hypoplastic left heart syndrome (HLHS). These patients undergo surgical palliation to transition the right ventricle to handle oxygenated blood flow. This significantly increases the transvalvular pressure, and at least 40% of patients will develop tricuspid valve regurgitation (highly associated with heart failure) within 20 years of birth [1]. Our group has demonstrated aberrant serotonin (5-HT) receptor (HTR) signaling contributes to mitral valve degeneration [2] and mechanosensitive ion channels mediate these processes (under review). We hypothesize that the elevated pressure resulting from surgical palliation of HLHS triggers tricuspid valve remodeling via HTR.

Methods

Human tricuspid valve interstitial cells obtained with IRB approval were cultured on a commercial tension bioreactor system (FlexCell FX6000) at user-defined strain (0%, 10%, 20%) for 72 hours. Following a preliminary screening, we included an antagonist for the TRPC6 mechanosensitive ion channel. Specific endpoints included qRT-PCR of 5-HT signaling genes and pro-collagen 1 ELISA. Statistical comparisons were made via one-way ANOVA following Shaprio-Wilk normality test, with $p<0.05$ deemed significant.

Results

Our results (Figure 1) showed that elevated strain led to increased collagen gene expression and pro-collagen 1 secretion. Interestingly, TRPC6 antagonism mitigated these processes and resulted in a significant reduction in HTR2B gene expression, suggesting functionality up-stream of HTR signaling.

Discussion

This is the first investigation to demonstrate the strain-dependent response of tricuspid valve interstitial cells. Our findings have implications for children with HLHS and adults with pulmonary hypertension, in which the tricuspid valve experiences increased transvalvular pressures. Specifically, we showed larger strains elicit elevated

COL1A1/COL3A1 gene expression and pro-collagen secretion that would stiffen the leaflets and may lead to the development of tricuspid regurgitation. Furthermore, we demonstrated TRPC6 mechanosensitive ion channels contribute to these observations. This agrees with prior renal studies [3] and warrants further investigation. We are expanding this study to characterize the presence and role of TRPC6 (and other mechanosensitive ion channels) and to dissect the pro-fibrotic signaling pathways.

Calibrating Hyper-Compliant Microparticles to Quantify Microscale Forces in 3D Tissues

Mr. Dongwon Ha Ph.D. Student, Ms. Graylen Chickering Ph.D. Candidate, Professor Eric Darling Ph.D., Professor Haneesh Kesari Ph.D.

Brown University, Providence, Rhode Island, United States

Introduction

Understanding the mechanical forces that emerge within developing tissues is essential because these forces regulate how cells proliferate, migrate, and organize, ultimately shaping tissue architecture and governing key developmental and morphogenetic processes. To quantify these forces, we employed hyper-compliant microparticles (HCMPs) as force sensors to measure microscale pressure distributions [1]. To reliably use HCMPs as force sensors, it is necessary to first characterize their mechanical behavior.

Methods

HCMPs were fabricated using an inverse polymerization protocol [2]. Because the sensors are hydrogel-based, they were modeled as hyperelastic materials, and a Neo-Hookean constitutive model with two unknown parameters was selected for simplicity and parameter identifiability.

To determine these parameters, we performed two independent experiments: (1) atomic force microscopy (AFM) indentation and (2) osmotic pressure testing. AFM indentation was carried out using a spherical bead tip to compress the HCMPs, and the resulting force–displacement curves were analyzed using both the classical Hertz contact model and finite element methods (FEM). For the osmotic pressure experiments, polyethylene-glycol (PEG) solutions of varying concentrations were prepared to generate controlled osmotic pressures [3]. HCMPs were immersed in each solution and equilibrated for 12–24 hours. Following equilibration, confocal microscopy was used to measure the deformation of individual HCMPs. 3D finite element meshes were constructed by stacking 2D images. These 3D meshes used as inputs to FEM, which predicted the pressure exerted on the HCMPs. The predicted pressures were compared with the known osmotic pressures, which served as the ground-truth values for calibration.

Results

By jointly calibrating the indentation and osmotic pressure datasets, we determined that the force sensor possess a Young’s modulus of 890 Pa and a Poisson’s ratio of 0.3. The

calibrated model accurately reproduced the experimentally observed pressure–stretch behavior. Notably, the measured Poisson's ratio contradicts the common assumption that polyacrylamide hydrogels behave as nearly incompressible materials.

Discussion

These calibrated, ultra-soft force sensors enable precise quantification of cell-generated traction forces in microtissues while allowing microscale measurements with minimal disturbance to overall tissue structure.

Investigating Bone Cell Mechano-sensitivity in Breast and Prostate Cancer Patients

Miss Eisha Hashmi BEng[1], Dr Stefaan Verbruggen BEng, PhD, FHEA[1,2]

[1]Queen Mary University of London, London, Greater London, United Kingdom. [2]The University of Sheffield, Sheffield, South Yorkshire, United Kingdom

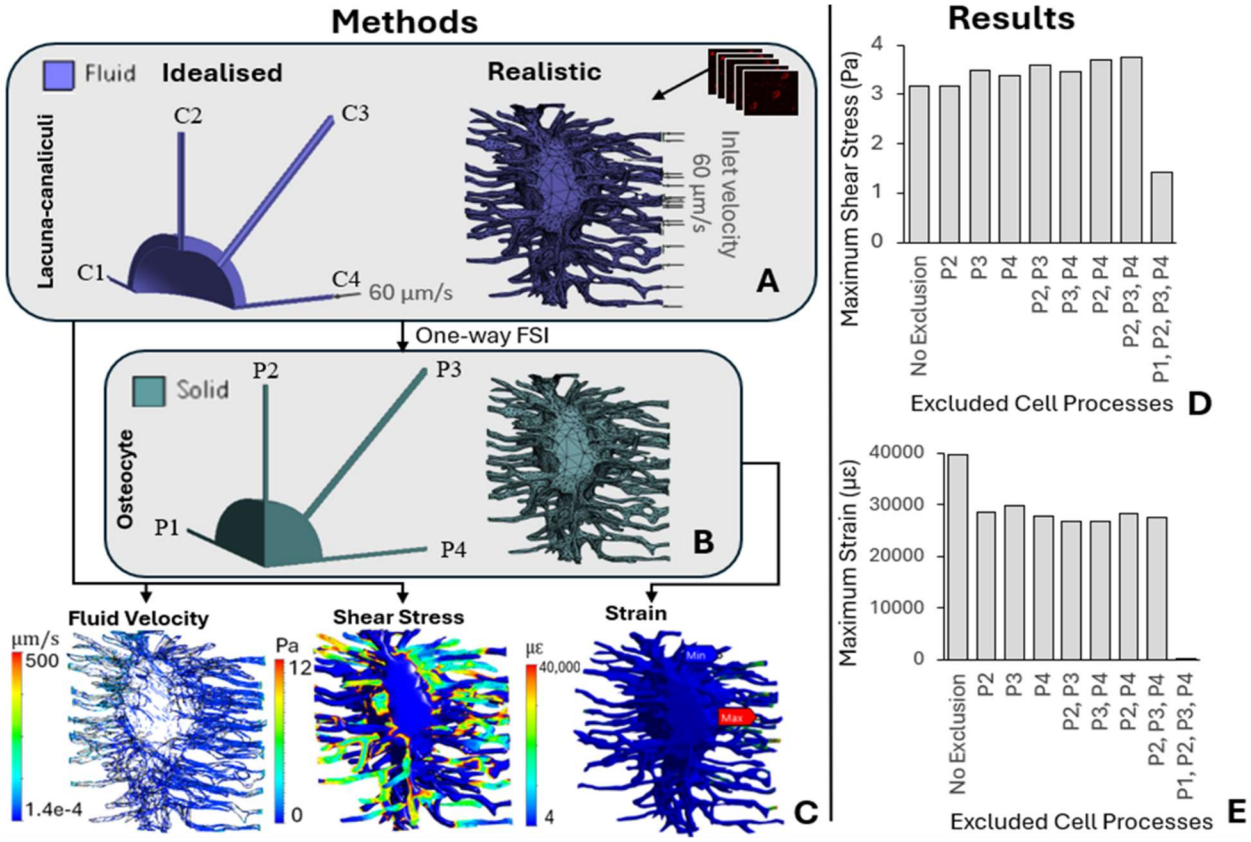
Introduction

Bone metastasis is a major cause of pain in advanced breast and prostate cancer. Although interactions between metastatic cells and the bone microenvironment are recognised [1], the role of osteocytes—most abundant bone cells and primary mechanosensors—remains underexplored. Osteocytes regulate mechanical environment through peri-lacunar remodelling, which may be disrupted in cancer [2] and alter osteocyte mechanics (preliminary work). Metastatic progression is also marked by dendritic loss and reduced lacuno-canalicular connectivity [2]. As dendrites are primary mechanosensory sites [3], we hypothesise that their progressive loss alters mechanotransductive signalling in cancer-altered bone.

Methods

Idealised multiphysics models were developed with osteocyte and lacuna modelled as ellipsoids (7.5×13.5μm;9×15μm), and processes and canaliculi as branching channels (Ø=0.44μm;Ø=0.6μm)–reduced by symmetry to the layout in Fig1A–B. The cell was defined as a linear elastic solid (E_{cell}=4.47kPa;ν_{cell}=0.3) and the pericellular matrix (PCM) as viscous fluid (μ_{PCM}=0.000855kg/m·s;ρ_{PCM}=997kg/m3) [4]. Metastatic deterioration was simulated by removing single, paired, triple, or all processes, with voids replaced by PCM. Interstitial flow was applied at 60μm/s, and mechanical response assessed using one-way fluid–structure interaction.

Results



Membrane shear stress remained 3-4Pa under partial deletions but decreased to ~1.5Pa without processes. Maximum strain dropped from ~40,000 to ~30,000με after single deletion, with minimal further decline until complete removal, which reduced strain to near-zero.

Discussion

This study examined how process loss alters osteocyte mechanical cues. Shear-based mechanotransduction remained preserved—even with complete process removal—as osteogenic responses occur at ~0.8Pa [6], whereas strain-mediated signalling was

abolished; suggesting that dendrites are more critical for strain amplification than shear sensing, and osteocytes may be more mechanically robust than previously assumed. Limitations include idealised geometry and pressure-driven flow. Ongoing work incorporates realistic osteocyte geometries and two-way FSI to better predict mechanosensory failure thresholds and inform strategies to preserve osteocyte connectivity in metastatic bone.

Impact of Simulated Microgravity on Chorioretinal Cell Fate and Epithelial-to-Mesenchymal Transition

Ms. Emily Formella, Dr. Kristan Worthington, Mr. Richard Cliver

University of Iowa, Iowa City, Iowa, United States

Introduction

Spaceflight-associated neuro-ocular syndrome (SANS) is a condition seen in long-duration astronauts that is characterized by increased intracranial pressure, retina structural changes, and visual impairment. Exposure to microgravity has been identified as a primary risk factor of SANS, but the underlying cellular mechanisms are not fully understood. Microgravity is known to disrupt biomechanical signaling in many human cell types, and comparable disruptions are associated with pathological changes in retinal pigmented epithelial (RPE) cells and potentially in choroidal vascular endothelial cells (ChEC) in other ocular diseases. In this study, we aim to characterize the impact of simulated microgravity on the fate of RPE cells and investigate the role of epithelial to mesenchymal transition (EMT) in this response.

Methods

ARPE-19 cells were seeded onto Cytodex3 (C3) microcarrier beads in a low-attachment plate at a density of 200,000 cells/cm2 of C3 surface area. After allowing 24 hours for attachment, cell-coated beads were transferred to a rotating wall vessel bioreactor to simulate microgravity. Cells were cultured in simulated microgravity for a maximum of seven days with samples collected at periodic intervals to assess viability and gene expression. Viability was assessed via fluorescent staining with Calcein AM and Ethidium Homodimer-1, and gene expression was analyzed by qPCR targeting RPE genes (e.g., RPE65, CDH3, KRT18, TJP1) and mesenchymal markers (e.g., ACTA2, CDH2, SNAI1, VIM) of interest.

Results

RPE cells grown on microcarrier beads (Fig.1A) maintained high viability (>80%, Fig.1B) and cell number over seven days under standard gravity and simulated microgravity conditions. In our preliminary experiments, simulated microgravity elicited significant upregulation of RPE65 compared to standard Earth gravity (Fig.1C) but did not substantially impact EMT gene expression.

Discussion

These findings demonstrate the feasibility of using a rotating wall vessel bioreactor to study RPE cells in a mechanically altered environment. In our ongoing studies, we are replicating these conditions for additional rigor. At the same time, we recognize that the use of immortalized cells may contradict the expected biomechanical response. Thus, we are applying the same approach to iPSC derived RPE cells and expanding the study to include iPSC derived ChECs.

Images (Optional)

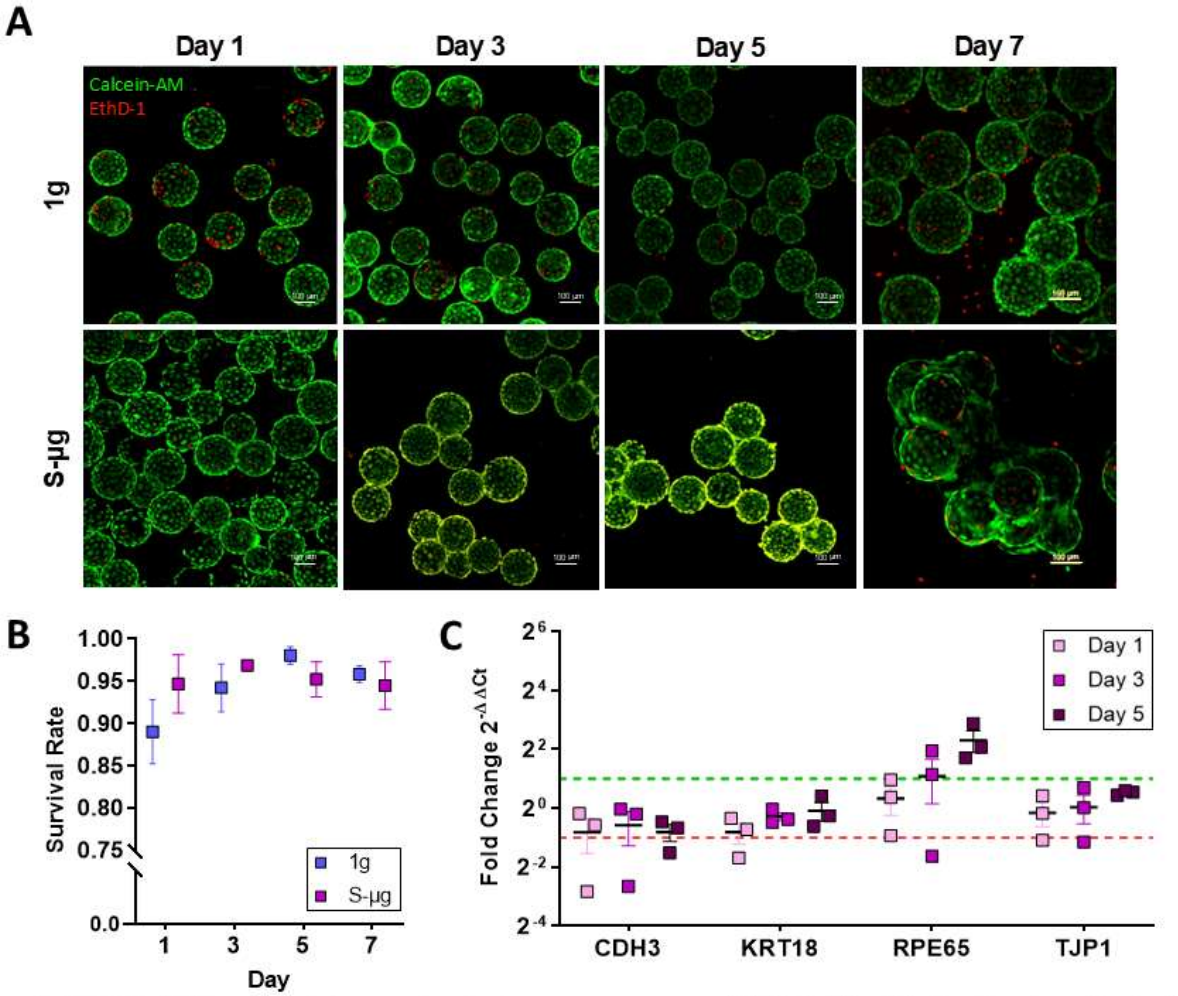

Figure 1. A) Representative confocal microscopy images of ARPE-19 cell-laden beads subjected to standard gravity (1g) and simulated microgravity (S-µg); Scale bar = 100 µm. Average cell density increased from 38.5 ± 18.5 to 172.7 ± 38.3 cells/bead across a 7-day culture period. **B)** Mean cell viability in 1g and S-µg groups (error bars show 95% CI). **C)** Relative expression of target RPE genes across five days in S-µg, normalized to 1g controls (mean ± SEM, n = 3).

Multimodal Imaging Enables Functional Characterisation of Gene Mechanoregulation During Bone Regeneration

Dr Francisco Correia Marques[1], Dr Neashan Mathavan[1], Mr Jack J. Kendall[1], Dr Amit Singh[1], Dr Dilara Yilmaz[1], Ms Denise Günther[1], Dr Gisela A. Kuhn[1], Dr Friederike A. Schulte[1], Dr Esther Wehrle[1,2], Prof. Dr Ralph Müller[1]

[1]ETH Zürich, Zürich, Zürich, Switzerland. [2]AO Research Institute, Davos, Davos, Switzerland

Introduction

Multimodal imaging approaches reveal mechanobiological processes across spatial scales. In bone, 3D micro-computed tomography (micro-CT) images can be correlated with 2D spatial transcriptomics data from the same sample using Spatial µProbe [1], linking gene expression with the mechanical environment determined by micro-finite element (micro-FE) analysis. In highly dynamic processes like bone regeneration, mechanical loading strongly influences healing outcomes [2]. However, molecular effectors involved in this response are still poorly understood. Here, we evaluate the expression of functionally-relevant genes under mechanical loading in a preclinical model of bone regeneration.

Methods

Four 12-week-old female BCR mice received mid-diaphyseal femoral defects, and individualised cyclic loading via an external fixator (n=2, Loaded) or 0N-loading (n=2, Control) from three weeks post-surgery [1-3]. Weekly *in vivo* micro-CT (10.5 µm, vivaCT80) was performed until sacrifice five weeks post-surgery. Structurally intact sections (n=1/group) were processed using the 10x Genomics Visium FFPE protocol [2-3]. 2D Visium sections were optimally positioned in 3D using Spatial µProbe and bone pixels were labelled with bone formation timepoints identified with micro-CT (Fig.1a). Time-lapsed gene expression was modelled with generalised additive models (GAM), followed by clustering per dataset. Functional characterisation was performed with g:Profiler [4] to genes that clustered together on both Loaded and Control samples (min. 3). Correlation between GAMs was assessed using Spearman coefficient ρ.

Results

Agglomerative clustering successfully identified groups of genes involved in vital musculoskeletal functions during healing. Leveraging time-lapsed information, our data suggests that muscle-related processes (e.g., aerobic respiration) are maintained

(ρ=0.837, Fig.1b) upon mechanical loading. Comparably, biological functions directly linked to bone mechanobiology showed stronger variations, including skeletal system development and oxygen transport (with lower ρ=0.687 and 0.561), and reduced cell migration from week 3 (ρ=0.475), indicating controlled remodelling activity.

Discussion

Mechanical loading targets functionally-relevant processes in multiscale bone mechanoregulation. These temporally and spatially distinct events can only be captured via multimodal imaging approaches. Spatial µProbe unlocks 2D-3D multimodal registration of time-lapsed data, enabling the quantification of these changes, inferring potential drivers and advancing our understanding of mechanical signalling and molecular biology towards novel healing therapies.

Images (Optional)

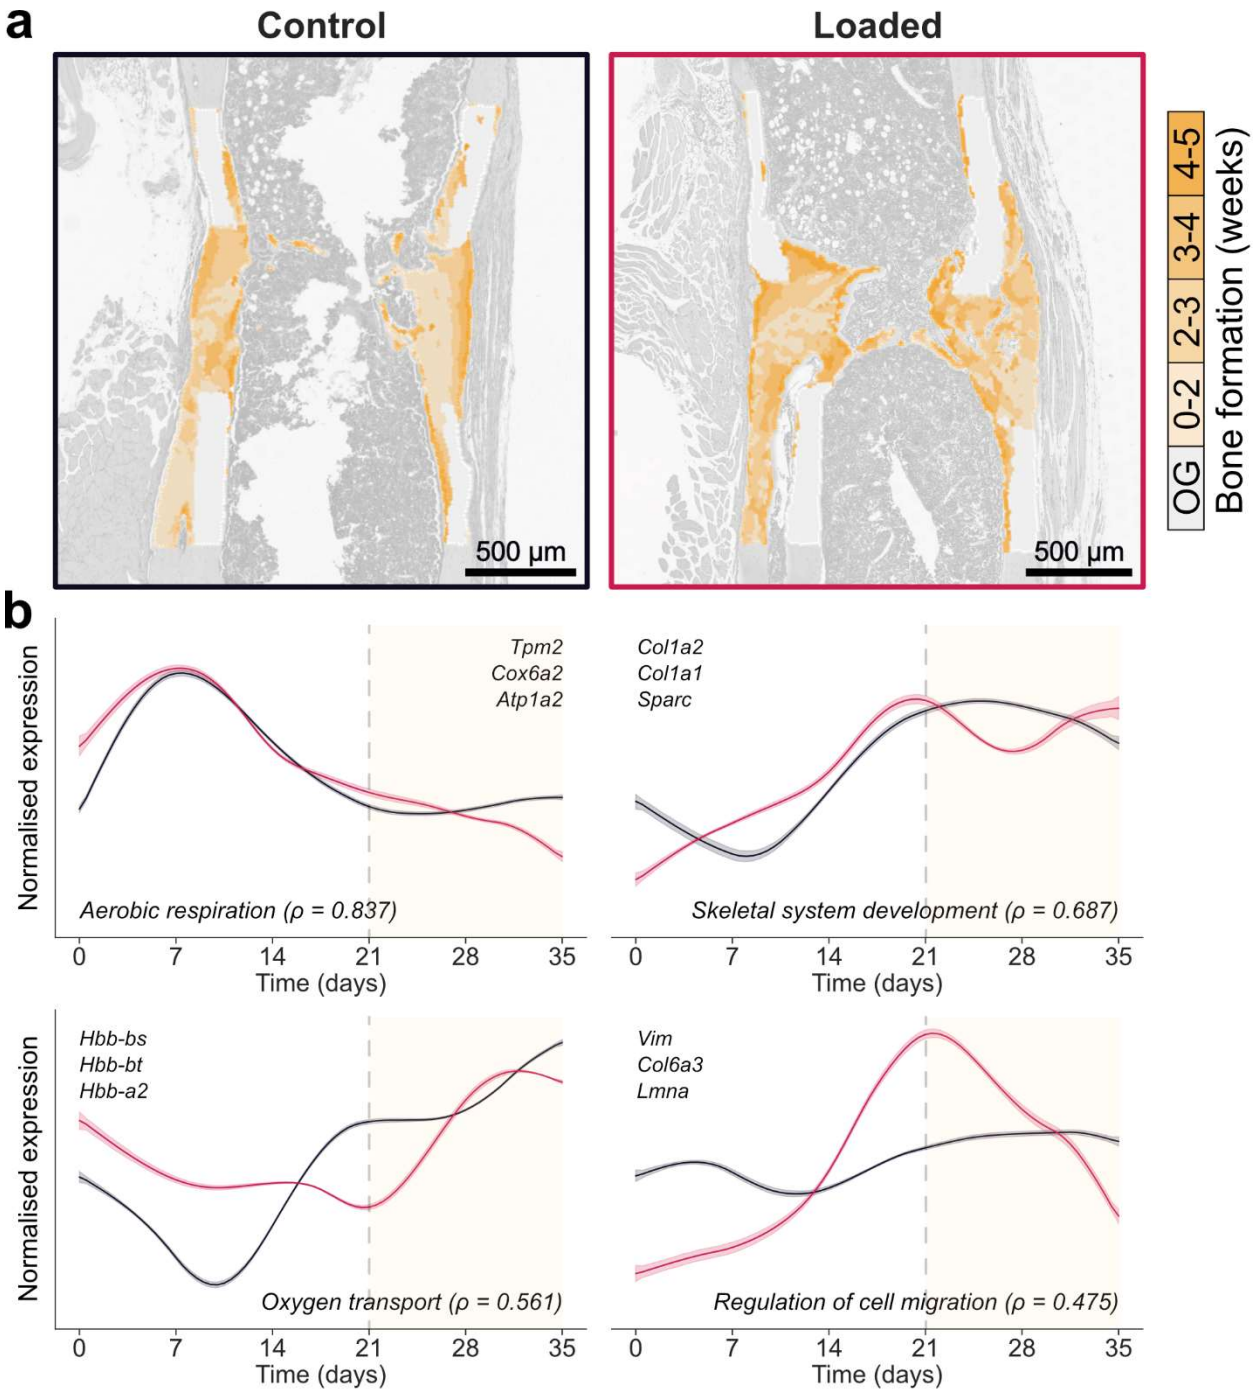

Figure 1: Functional gene mechanoregulation analysis. a) Bone formation regions identified with time-lapsed *in vivo* micro-CT and mapped to the 2D-3D registered ST section of the Control and Loaded samples. b) Comparison between the normalised expression of gene-sets between Control (black) and Loaded (red) samples. The top three most expressed genes are listed. A functionally-relevant significant enrichment term identified with g:Profiler is indicated. Spearman correlation coefficient between the curves obtained for both samples is indicated as a proxy for the change in expression trends resulting from cyclic mechanical loading.

Cholesterol Depletion Disrupts Cortical Actin Organization, Rewires Metabolism, and Overcomes Drug Resistance in Cancer Cells Within 3D Microstuctured Scaffold

Mr Giovanni Buccioli[1], Ms Cristina Cortesi[1], Dr Chiara Martinelli[1], Dr Claudio Conci[1], Dr Alessandra Nardini[2], Dr Rebeca Martínez Vázquez[2], Prof Manuela Teresa Raimondi[2], Prof Emanuela Jacchetti[1]

[1]Department of Chemistry, Materials and Chemical Engineering "Giulio Natta", Politecnico di Milano, Milan, MI, Italy. [2]Institute for Photonics and Nanotechnologies, CNR, Milan, MI, Italy

Introduction

Multidrug resistance (MDR) in tumours is often sustained by efflux pumps whose activity is dictated by plasma-membrane organisation and mechanics, governed by cholesterol within lipid rafts and by the architecture of the cortical actin network [1]. Moreover, a glycolytic metabolic programme is a well-recognised hallmark of MDR, supplying the ATP demanded by these pumps. However, conventional 2D cultures fail to recapitulate native membrane structure and tumour metabolism. Here, using 2D and 3D substrates, we investigate whether cholesterol depletion disassembles the cortical actin network and thereby rewires cellular metabolism to enhance chemosensitivity.;

Methods

The custom-made 3D scaffold, named the Niche, consists of a lattice of cubic pores ($15\times15\times15\ \mu m^3$) fabricated via two-photon polymerization in biocompatible resin SZ2080 onto glass coverslip [2]. MCF7 and MDA-MB-231 cells were cultured on 2D glass coverslips and the 3D Niche. Cell viability was assessed after 24h under a Doxorubicin concentrations (4.4 μM on glass, 103.5 μM on Niche) with/without Lovastatin (1 μM). Cortical actin organization was assessed by immunofluorescence images; fluorescence-lifetime (FLIM) imaging microscopy inferred cell metabolism.

Results

Only cells cultured within the 3D microstructured scaffold and treated with Lovastatin showed a clear disassembly of the cortical actin network (Fig. 1) together with a reduced reliance on glycolysis. Under these conditions, cells displayed increased chemosensitivity to Doxorubicin, consistent with decreased efflux pump capacity in the 3D setting.

Discussion

These findings identify plasma membrane and cortex mechanics as central regulators of multidrug resistance, with cholesterol dependent membrane organisation and cortical actin integrity emerging as key control points for efflux pump function. The 3D scaffold does not simply provide a culture support, but recreates tumour relevant architectural cues that make this mechanotransduction axis measurable and drug responsive, in contrast to 2D substrates. By better approximating the structural context in which resistance is maintained, the Niche enhances the predictive value of *in vitro* testing and supports mechanistic, scaffold based screening of strategies that target cholesterol and the actin cortex to restore chemosensitivity.

Images (Optional)

Rescue of Plasma Membrane Localization of Mislocalized Pendrin Mutants by Low-Dose Lasalocid a Sodium

Mr. Goki Nagasaki, Hisashi Sugimoto, Tomokazu Yoshizaki, Michio Murakoshi

Kanazawa University, Kanazawa, Ishikawa, Japan

Introduction

Pathogenic mutations of pendrin (SLC26A4), which is an anion exchanger expressing in the inner ear, thyroid gland and kidneys, often result in misfolding and intracellular mislocalization, being responsible for Pendred syndrome and non-syndromic hearing loss. In our previous studies, pharmacological chaperones have been proposed as a therapeutic approach; however, only limited small molecules such as salicylate derivatives have been reported, and their effective concentrations were relatively high. In the present study, Lasalocid A sodium, one of the salicylic-acid derivatives, was examined whether it can rescue plasma membrane localization of mislocalized pendrin mutants at lower concentrations and evaluated its cytotoxicity.

Methods

Human embryonic kidney(HEK)293 cells were transfected with FLAG-tagged wild-type pendrin or eight mislocalized mutants. Cells were treated with Lasalocid A sodium at 1 mM, 0.1 mM, 0.01 mM or 1 μM for 12–24 h, and plasma membrane localization was assessed by Wheat germ agglutinin (WGA) staining and FLAG immunofluorescence using a confocal microscope. Cell viability was measured by Cell Counting Kit-8 (CCK-8), and cytotoxicity was assessed by LDH release.

Results

Three responsive mutants showed relocation from the cytoplasm to the plasma membrane by treatment with 1-mM Lasalocid A sodium. Notably, 0.01-mM Lasalocid A sodium also induced plasma membrane localization in these mutants, whereas 1-μM dose did not show such changes in localization. The remaining mutants could not be restored by Lasalocid A sodium at 1mM, 0.1mM, 0.01mM and 1μM.

In toxicity assays, cell viability sharply decreased above 0.005 mM, and cell toxicity increased above 0.02 mM. Concentrations of 1-mM and 0.1-mM Lasalocid A sodium markedly reduced viability, whereas 0.01 mM maintained high viability (85–82%).

Discussion

In previous studies, differences in substituent patterns around the benzene ring and the presence of a 1,3-propanediol moiety were shown to markedly influence the activity of salicylate derivatives used to improve pendrin localization. Notably, Lasalocid also possesses a 1,3-propanediol moiety, and its enhanced potency in the present study may similarly arise from such structural features, enabling more effective interaction with partially foldable mutants. This mechanism may explain its ability to restore plasma membrane localization at substantially lower concentrations than conventional derivatives.

Vaping-Induced Injury in Human Lymphatic Endothelial Cells

Ms. Hoda Rahimi[1], Dr. Jiwon Hong[1], Dr. Sam McCullough[2], Mr. Ben Watkin[2], Dr. Justin Rustenhoven[2], Prof. Anthony Phillips[1,3], Assoc. Prof. Kelly Burrowes[4]

[1]School of Biological Sciences, Faculty of Science, University of Auckland, Auckland, Auckland, New Zealand. [2]Department of Pharmacology, Faculty of Medicine and Health Sciences, University of Auckland, Auckland, Auckland, New Zealand. [3]Department of Surgery, Faculty of Medicine and Health Sciences, University of Auckland, Auckland, Auckland, New Zealand. [4]Auckland Bioengineering Institute, University of Auckland, Auckland, Auckland, New Zealand

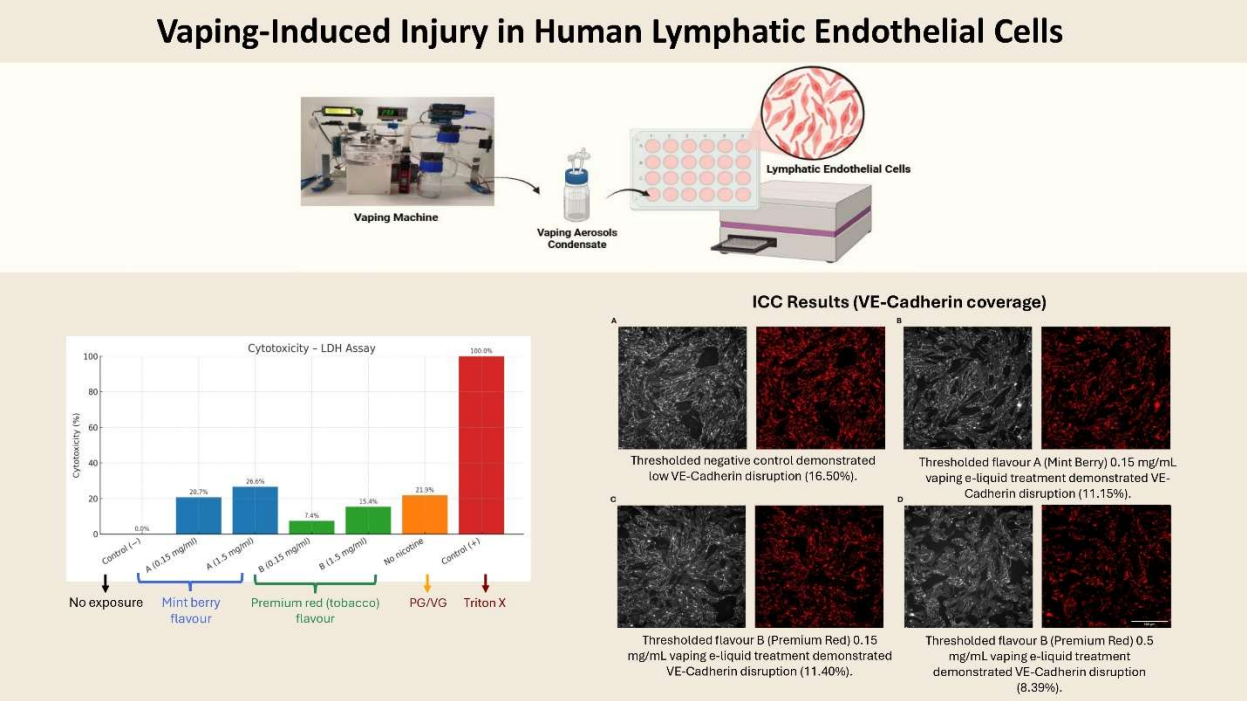
Introduction

Pulmonary lymphatic endothelial cells (LECs) help maintain lung fluid balance and immune surveillance, but their response to e-cigarette aerosols is poorly understood. We developed an induced pluripotent stem cell (iPSC)–derived human LEC (iLEC) model to quantify flavor-specific toxicity and barrier disruption as a first step toward biomechanical and computational models of vaping-exposed lung lymphatics.

Methods

Human iPSCs were differentiated to iLECs using mesoderm/lymphatic induction and CD31-based sorting. iLECs were exposed for 24 h to two flavored e-liquids (Flavor A: mint berry; Flavor B: premium red) at 0.15–1.5 mg/mL nicotine, a nicotine-free PG/VG vehicle, and a negative control (no exposure). Cytotoxicity was assessed by LDH release and normalized to a positive control. Immunocytochemistry quantified VE-Cadherin junctional coverage and Hoechst nuclear counts using a standardized image-analysis threshold. In parallel, we are performing experiments using a programmable vaping machine to generate vaping aerosol condensate, exposing iLECs and measuring inflammatory activation, procoagulant signaling and barrier integrity.

Results



LDH assays showed a flavor-dependent toxicity profile. Mint-berry Flavor A increased cytotoxicity to 20.7% at 0.15 mg/mL and 26.6% at 1.5 mg/mL. Premium-red Flavor B caused lower toxicity (7.4% and 15.4% at 0.15 and 1.5 mg/mL, respectively), whereas the nicotine-free PG/VG vehicle produced 21.9% cytotoxicity, indicating that base components alone can damage LECs. VE-Cadherin coverage fell from 16.5% in controls to 11.15% with Flavor A (0.15 mg/mL), 11.40% with Flavor B (0.15 mg/mL) and 8.39% with Flavor B (0.5 mg/mL), consistent with junctional disruption. Hoechst nuclear counts decreased from

611 nuclei in the negative control to 548 (Flavor A 0.15 mg/mL), 523 (Flavor B 0.15 mg/mL), and 427 (Flavor B 0.5 mg/mL).

Discussion

These preliminary data show that vaping e-liquids, including nicotine-free vehicle, cause measurable, flavor-dependent cytotoxicity and junctional injury when exposed directly to human LECs. Such barrier disruption is expected to alter lymphatic transport and interstitial fluid handling. Ongoing experiments using vaping-machine–generated condensate, combined with inflammatory and coagulation readouts, will extend this platform and provide quantitative inputs for biomechanical and computational models of pulmonary lymphatic system under vaping-induced stress.

How Curvature-Driven Cell Morphology Regulates Nuclear Lamina and Chromatin Architecture

Ms I-CHIA LO, Dr. Pen-hsiu Grace Chao

National Taiwan University, Taipei, Taiwan, Taiwan

Introduction

Geometric cues are key regulators of cell phenotype [1]. Size and alignment are known to influence stem cell fate, but the effects of curvature have only recently been explored [2]. We recently found wavy structures that mimic the native collagen organization increased cell traction forces and collagen expression [3]. These changes correlate with nuclear deformation and point to potential mechanisms of phenotypic regulation. In this study, we investigate the effects of wavy morphology on actin organization and nuclear shape.

Methods

Human mesenchymal stem cells (MSCs) were cultured on micro-molded agarose grooves [4]. The grooves were 15 μm in width and the wavy structures were consisted of connecting arcs with inner radii of 15 or 20 μm. Bottom of the grooves were coverslips coated with fibronectin and MSCs were cultured in these structures for 4 hours before fixation for imaging. Wrinkling Index was calculated by binarized lamin wrinkle area normalized by nuclear area (Fig 1C left).

Results

MSCs conformed to the microgrooves and exhibited elongated and wavy morphology. The straight cells formed long stress fibers with flattened nuclei. The wavy cells had arch-like actin fibers (arrowheads, Fig 1A). Their nuclei also followed the wavy pattern, were pushed against the concave side wall, and had wrinkles that colocalized with actin fibers (Fig 1B). The increase in nuclear wrinkles was accompanied by nuclear volume decrease (Fig 1C).

Discussion

Our work provides a detailed characterization of the internal structures of wavy cells. We previously found actin to be the main regulator of nuclear shape in the wavy cells [5]. The increased traction forces and reduced nuclear volume align with previous findings that elevated forces compress the nucleus and condense chromatin [2]. We are currently employing expansion microscopy to have nanoscale characterization on cytoskeleton, nuclear membrane, and heterochromatin structures to further understand the spatial

organization in the wavy cells. Findings will clarify how curvature-dependent cytoskeletal forces reshape nuclear architecture to modulate chromatin organization and phenotype.

Experimental Characterization and Numerical Modeling of Cell–cell Adhesion in Melanoma Using Dual Micropipette Aspiration.

Presenter Ignacio Quezada-Plaza, Presenter Aldo Abarca-Ortega

Universidad de Santiago de Chile, Santiago, Región Metropolitana, Chile

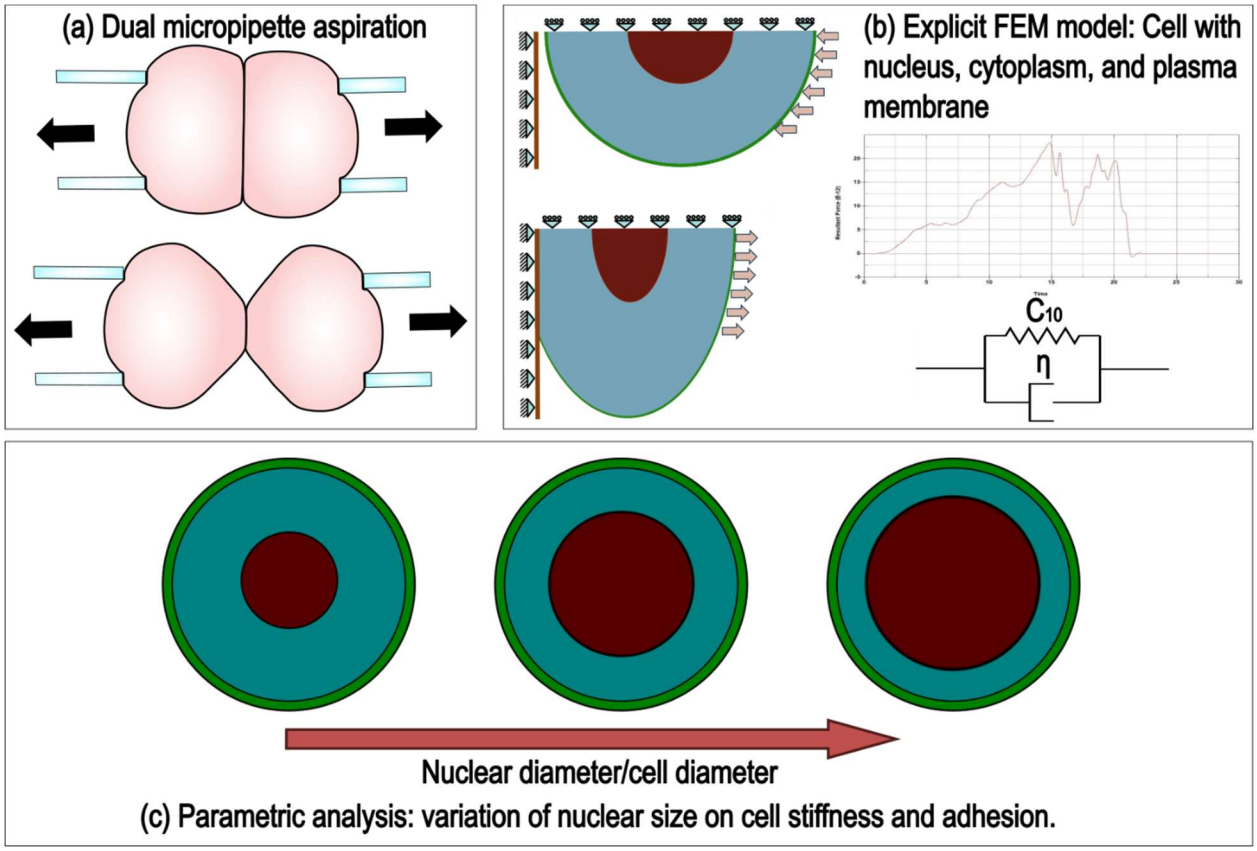
Presenter Ignacio Quezada-Plaza

Introduction

In Chile, cancer is projected to increase by 60% by 2040 [1]. Globally, the International Agency for Research on Cancer reports rising incidence and mortality for melanoma [2], highlighting the need for tools to monitor disease progression. Mechanobiology proposes stiffness and cell–cell adhesion as biomarkers; metastatic cells are softer and less adhesive than healthy cells [3]. This study quantifies cell–cell adhesion forces in melanoma using dual micropipette aspiration and explicit finite element simulations, assuming that cells with higher metastatic potential exhibit lower adhesion.

Methods

Dual micropipette aspiration tests will be performed on melanoma cells. Pairs will be selected, excluding damaged cells or aggregates. Aspiration pressure, aspirated length, deformation and detachment will be recorded to obtain force–deformation curves and cell size, from which effective stiffness, apparent viscosity and adhesion force will be estimated, considering the nuclear-to-cell diameter ratio. In parallel, an explicit quasi-static LS-Dyna model of two spherical cells with three regions (nucleus, cytoplasm, membrane) is implemented, using a Neo-Hookean solid plus Prony-series viscoelasticity. Formulations follow visco-hyperelastic models validated in previous studies [4] and will be calibrated with literature and experimental data.



Results

Preliminary simulations predict adhesion forces comparable to reports for embryonic cells [5] and up to a tenfold reduction when melanoma-type mechanical parameters are used. The model resolves stress and strain in nucleus, cytoplasm and membrane, allowing assessment of nuclear-size effects on mechanical response and adhesion.

Discussion

These preliminary results indicate that dual micropipette aspiration with explicit finite element modeling is a feasible strategy to quantify adhesion in melanoma and relate it to mechanical parameters. Main limitations are the simplified spherical geometry and the initial use of literature-based parameters. Ongoing experiments with the dual micropipette setup will refine the models and help assess stiffness and adhesion as complementary mechanobiological biomarkers in melanoma.

Assessing the Role of Syndecan-4 in Pancreatic Ductal Adenocarcinoma Cell Chemosensitivity

Mr Jan Jethro Baguyo[1,2], Dr Leah Fallon[1,2], Dr Stephen Thorpe[1,2,3]

[1]UCD School of Medicine, University College Dublin, Belfield, Dublin, Ireland. [2]UCD Conway Institute of Biomedical and Biomolecular Research, University College Dublin, Belfield, Dublin, Ireland. [3]Trinity Centre for Biomedical Engineering, Trinity College Dublin, Dublin, Dublin, Ireland

Introduction

Pancreatic ductal adenocarcinoma (PDAC) is characterised by a stiff ECM which promotes cancer cell survival, metastasis and chemoresistance. Syndecan-4 (SDC4) is a transmembrane proteoglycan upregulated in PDAC and associated with poor survival. Syndecan-4 acts as a co-receptor supporting cell adhesion and migration and has mechanosensing capabilities regulating cell contractility. However, the role of syndecan-4 in stiffness mediated chemosensitivity in PDAC is unclear. This study will address the hypothesis that syndecan-4 supports stiffness mediated chemotherapy resistance in PDAC cells in both 2D and 3D culture environments.

Methods

CRISPR gene editing was used to generate SUIT2-007 metastatic PDAC cell lines with either wild-type, knockout or overexpressed SDC4. Additionally, mutated SDC4 protein cell lines were generated to remove extracellular glycosaminoglycan chains (SDC4-ΔGAG), and to block or mimic phosphorylation of the conserved intracellular C1 domain (SDC4-Y180A, SDC4-Y180F). Western blot and immunofluorescent staining were used to confirm SDC4 expression. Cells were cultured on tissue culture plastic or on polyacrylamide gels with stiffnesses mimicking soft and stiff PDAC tissue. Substrates were coated with fibronectin or collagen type I. 3D spheroid cultures were also generated using 100 µg/mL collagen type I. Cells were subjected to gemcitabine, 5-fluoruracil or paclitaxel at IC_{50} concentrations for 48 h. Viability was assessed via metabolic activity and ATP levels.

Results

Western blot and immunofluorescent staining confirmed knockout and overexpression of SDC4 (Fig. 1A). SDC4 knockout cells had similar viability to SDC4 overexpressing cells in untreated and drug treated groups, regardless of ECM, polyacrylamide gel stiffness and drug treatment. In untreated groups, SDC4-ΔGAG exhibited higher viability than all other mutant cells (Fig. 1B). Additionally, C1 domain inhibition had lower viability than C1

domain activation. When treated with chemotherapeutics, all SDC4 mutant cells had lower viability compared to the overexpression control (Fig. 1C).

Discussion

Both SDC4-ΔGAG and phospho-null SDC4-Y180A expressing cells exhibited lower viability than SDC4-HA overexpressing and phospho-mimetic SDC4-Y180F when treated with 5-FU. This indicates that both extracellular glycosaminoglycan chains and intracellular C1 domain phosphorylation can provide therapeutic targets. Work is ongoing to investigate role of the SDC4 specific V-domain.

Macroscopic and Microscopic Biomechanical Analysis of Scaffold-Free Bone Spheroids

Dr Jeonghyun Kim[1], Mr Takashi Inagaki[2], Dr Eijiro Maeda[2], Dr Takeo Matsumoto[2]

[1]Kyushu University, Fukuoka, Fukuoka, Japan. [2]Nagoya University, Nagoya, Aichi, Japan

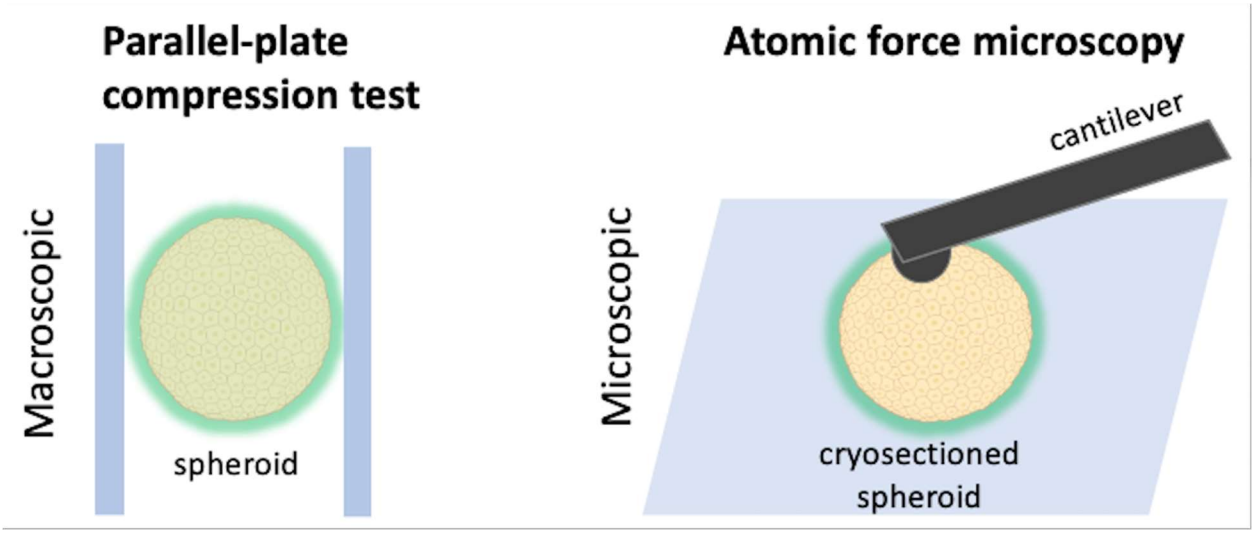
Introduction

Three-dimensional scaffold-free spheroids offer a physiologically relevant model to study bone-like mineralization, yet how long-term culture alters their multiscale mechanical properties remains unclear. This study aimed to evaluate mineralization-dependent mechanical changes in human mesenchymal stem cell (hMSC) spheroids by integrating macroscopic and microscopic biomechanical measurements.

Methods

Spheroids were generated from hMSCs using U-bottom ultra-low attachment plates [1] and cultured for 2 or 35 days under osteogenic conditions in high-glucose DMEM supplemented with ascorbic acid, β-glycerophosphate, and dexamethasone. Mineralization was evaluated by Alizarin Red S staining of cryosectioned samples. Macroscale mechanical properties were measured using a customized uniaxial compression system with a glass plate to determine the apparent Young's modulus and strain-recovery behavior. Microscale stiffness and surface topography were mapped on cryosectioned spheroids using AFM indentation with spherical or conical probes.

Results



Long-term culture induced pronounced and spatially heterogeneous mineralization, primarily in the spheroid interior. Macroscopic Young's modulus increased from 17.8 to 44.4 kPa, and recovery after compression decreased markedly, indicating enhanced plastic deformation. AFM revealed a substantial rise in local stiffness from 0.7 to 15.1 kPa, with some regions exceeding 100 kPa, demonstrating strong microscale heterogeneity. Surface topography also became rougher and more complex, consistent with ECM accumulation and mineral deposition.

Discussion

Spheroids exhibited clear bone-like mechanical maturation after 35 days, characterized by increased stiffness, reduced elasticity, and greater spatial heterogeneity [2]. Agreement

between macroscopic and microscopic trends indicates that mineralization and matrix remodeling reshape tissue mechanics across scales. These findings enhance understanding of the mechanobiology of bone formation in 3D cultures and support future applications in bone tissue engineering.

Adaptive Nuclear Displacement Dynamics Enable Cellular Responses to Small Accelerations

Mr. Jonathan Wadsworth[1], Mrs. Nina Nikitina[1], Dr. Sean Howard[1], Dr. Clinton Rubin[2], Dr. Gant Luxton[3], Dr. Gunes Uzer[1]

[1]Boise State University, Bosie, ID, United States. [2]Stony Brook University, Stony Brook, NY, United States. [3]University of California at Davis, Davis, CA, United States

Introduction

Small mechanical signals such as sound and vibration are ubiquitous across life, yet how unspecialized cells detect them remains unclear. We show that during low-intensity vibration (LIV), the nucleus shifts slightly out of phase with the cytoplasm, generating localized strain at the nucleo-cytoskeletal interface that can be tuned by modifying LINC (Linker of Nucleoskeleton and Cytoskeleton) complexes and cytoskeletal structure. This study therefore explores how small relative nuclear displacements act as intracellular mechanical signals that initiate adaptive responses in both cytoplasm and nucleus.

Methods

To measure nuclear motions, mesenchymal stem cells (MSCs) were labeled with calcein AM and exposed to 45 Hz, 0.2 g LIV for 30 minutes using a custom bioreactor.[1] LIV-induced nuclear and membrane motion were recorded at 1000 fps during LIV as well as after 6- and 12-hours post-LIV using un-paired samples (n=30/grp). LINC connectivity was disrupted via doxycycline-inducible mCherry-KASH[2] and MSCs were transfected with genetically encoded multimeric nanoparticles (GEMs)[3] to probe nucleo-cytoplasmic biophysical properties.

Results

At baseline, the median nucleus–membrane phase difference was 0.12 ms, corresponding to a maximum relative displacement of 0.7 μm. Disrupting the LINC complex doubled the nuclear lag, while increasing F-actin via a RhoA activator (Cytoskeleton, Inc.) suppressed most detectable baseline motion, confirming nucleo-cytoskeletal involvement. Dynamically, the phase difference increased 70% (to 0.21 ms, $p<0.05$) at 6 hours, then decreased to 0.09 ms by 12 hours ($p<0.05$).

Discussion

These findings show that even small-amplitude vibrations produce measurable, transient changes in nuclear motion relative to the cell body. The increased phase lag at 6 hours

suggests short-term cytoskeletal de-polymerization, while the return to baseline by 12 hours indicates re-stabilized nuclear–cytoskeletal coupling. Although detailed biophysical studies are ongoing, preliminary results support the idea that mechanically induced nuclear motion from low-intensity vibrations contributes to mechanosensing and mechanoadaptation independent of extracellular matrix deformation.

[6]University of Liège, Liège, Walloon Region, Belgium

Introduction

Articular cartilage degeneration is a hallmark of post-traumatic osteoarthritis (PTOA), suggested to be triggered by excessive mechanical strains and/or pro-inflammatory cytokines [1]. Since this degeneration process remains difficult to analyze solely by experiments, earlier studies developed computational frameworks to simulate cell-driven cartilage degeneration [2]. However, most models lack intracellular signaling governing degenerative enzymes production [3], which is important for unraveling potential drug-targets. Thus, we developed a virtual framework to analyze spatially varying a disintegrin and metalloproteinase with thrombospondin motifs (ADAMTS) and matrix metalloproteinase (MMP) intracellular activity caused by injurious loading and inflammation.

Methods

We simulated cartilage shear strain (fibril-reinforced poroviscoelastic material) under injurious loading and cytokine diffusion using finite element (FE) models based on earlier experiments (Fig. 1A) [1]. Intracellular behavior was modeled with a gene–protein regulatory network (GPRN), and Monte Carlo analysis revealed two stable states: pro-hypertrophic (PH) and healthy (H) [4]. At each FE node, we determined post-injury cell state ($Z_{0,INJ+IL}$, day 0) as a weighted sum of these states. We converted cytokine concentrations (day 2) from the FE model to a non-dimensional input with a Hill-type function. The input was used to perturb GPRN, and downstream ADAMTS and MMP activity were simulated for 1000 pseudotime steps. We compared the simulated intracellular activity maps to immunohistochemical analysis (IHC) of MMP-1 and digital densitometry (DD) analysis of proteoglycans (optical density).

Results

Injurious loading with inflammation caused high ADAMTS and MMP activity across the sample (bulk avg: 0.94, scale: [0,1]), while inflammation alone limited activity near free surfaces (avg: 0.31, Fig. 1B). IHC confirmed elevated MMP in superficial regions, and DD analysis showed proteoglycan loss in areas of high ADAMTS and MMP activity (Fig. 1C).

Discussion

Our multiscale workflow with cell-tissue interactions in mechanically injured and inflamed cartilage captures experimental findings. Future calibration against gene expression remains essential. Once calibrated, the framework supports development of virtually optimized treatment strategies for PTOA drug therapies.

In Vivo Fatigue Injury Transiently Alters the Capacity of Tenocytes to Interact With Aligned and Unaligned Matrix

Mr. Joseph Denisco, Dr. Nelly Andarawis-Puri

Cornell University, Ithaca, NY, United States

Introduction

Fatigue-induced tendinopathy arises from the accumulation of sub-rupture fatigue damage due to chronic overuse, ultimately impairing quality of life. Exercise post-fatigue tendon injury, akin to physical therapy, exacerbates damage at day 1 (D1) but improves healing at day 14 (D14) [1]. This differential response may reflect intrinsic changes in tenocytes, altered loading conditions created by ECM damage, or a combination of both. Examining tenocyte morphology on organized versus disorganized substrates at D1 and D14 will reveal fatigue-derived cellular responses, informing tendinopathy treatment. We hypothesize that fatigue damage induces tenocyte retraction and reduced contact area, reflecting decreased mechanosensation, with these effects amplified by unorganized ECM at D1 with properties restored by D14.

Methods

Under IACUC approval, the left patellar tendon (PT) of female 11-month old Sprague-Dawley rats (n=2) were fatigue loaded [1]. Tenocytes were harvested from PTs 1 or 14 days post-fatigue, with right PT cells utilized as a naive control. At passage 3, cells were seeded (750 cells/well) onto aligned or disorganized polycaprolactone nanofiber scaffolds (n=6-8), mimicking healthy and injured tendon structure, respectively. Cell nuclei and cytoskeletons were visualized with DAPI and phalloidin, imaged at 25X, and analyzed using ImageJ [2]. Unpaired t-tests compared fatigue-injured and naive tenocytes, and Kruskal-Wallis tests timepoint and substrate effects.

Results

Fatigued tenocytes had significantly reduced areas compared to naive control at D1 regardless of substrate type. On aligned substrates, D14 tenocytes had increased area and circularity compared to D1 tenocytes (Figure 1A,B).

Discussion

Fatigue injury directly impacts D1 tenocytes, which displayed reduced area, consistent with diminished cell–ECM contact and impaired mechanosensation. However, these fatigue-induced alterations in the cells are not sustained: by D14, differences between contralateral and fatigue-injured tenocytes largely resolve on both aligned and unaligned matrices. Results suggest that fatigue injury transiently alters tenocyte mechanosensing, with recovery occurring by approximately two weeks—a timeframe that aligns with when post-injury loading becomes therapeutic in vivo. This supports a model in which early tenocyte dysfunction normalizes as cells recover, guiding future investigation into how ECM organization and injury history jointly shape tenocyte–ECM interactions.

Preliminary Model of Hinge Epithelium Contraction in Palatal Shelf Elevation

Graduate Research Assistant Kayla Whatley BS[1], Postdoctoral Fellow Brittany M. Hufft-Martinez PhD[2], Research Assistant An J. Tran BS[2], Professor Irfan Saadi PhD[2], Professor Kenneth Fischer PhD[1]

[1]University of Kansas, Lawrence, KS, United States. [2]University of Kansas Medical Center, Kansas City, KS, United States

Introduction

Palatal shelves begin as vertical projections from the embryonic maxilla, flanking the tongue. During palatogenesis, they elevate to a horizontal position above the tongue with concurrent tongue flattening. Successful elevation and fusion forms the intact hard palate, whereas failure results in cleft palate. Elevation begins with a bulge in posterior vertical shelf hinge region that extends anteriorly to cause horizontal reorientation [1]. Hinge region contraction is considered one driver of elevation [1]. Finite element modeling can help elucidate the biomechanics and poorly understood “driving forces” of palatal shelf elevation.

Methods

Serial coronal sections (10 mm) were collected from a wildtype embryonic day (E) 13.5 mouse head (3.25 x 2.25 x 2.25 mm), histologically stained, and imaged. Images were realigned in-plane using anatomical landmarks and out-of-plane using midsagittal reference sections from a littermate. Manual image segmentation of the upper and lower jaws, tongue, Meckel’s cartilage, palatal mesenchyme, palatal epithelium, and hinge epithelium was performed in ScanIP (Synopsis), then smoothed and resampled to 10 mm on all planes (Fig 1.C-E). ScanIP generated a linear tetrahedral mesh with element edge lengths ranging between 4.8×10^{-4} mm (epithelium) to 0.28 mm and comprising of 6,881,929 elements with 1,322,124 nodes (Fig 1.A-B). Simulations were conducted in FEBio [2]. Tissues were modeled as neo-Hookean materials with relative moduli estimated from the mechanical measurements of E13.5 palatal epithelium [3]. Tongue descent was modeled using kinematic growth of 0.7. Hinge epithelium contraction was modeled as 0.7 vector kinematic growth approximating epithelial orientation.

Results

The model successfully simulated 30% tongue descent and 30% epithelial hinge contraction which drove medial rotation of the anterior palatal shelves, resulting in tongue contact (Fig 1.E-F).

Discussion

This foundational model enables future studies of the forces driving palatal shelf elevation. We are currently collecting more accurate material property data. Planned mesh convergence studies and model improvements will allow rigorous testing of biological hypotheses.

Morphological characterization of smooth muscle cell phenotypic response to biophysical cues of the extracellular environment

Postdoctoral Researcher Luigi Crimaldi, Prof. Abdul Barakat

École polytechnique, Paris, Île-de-France, France

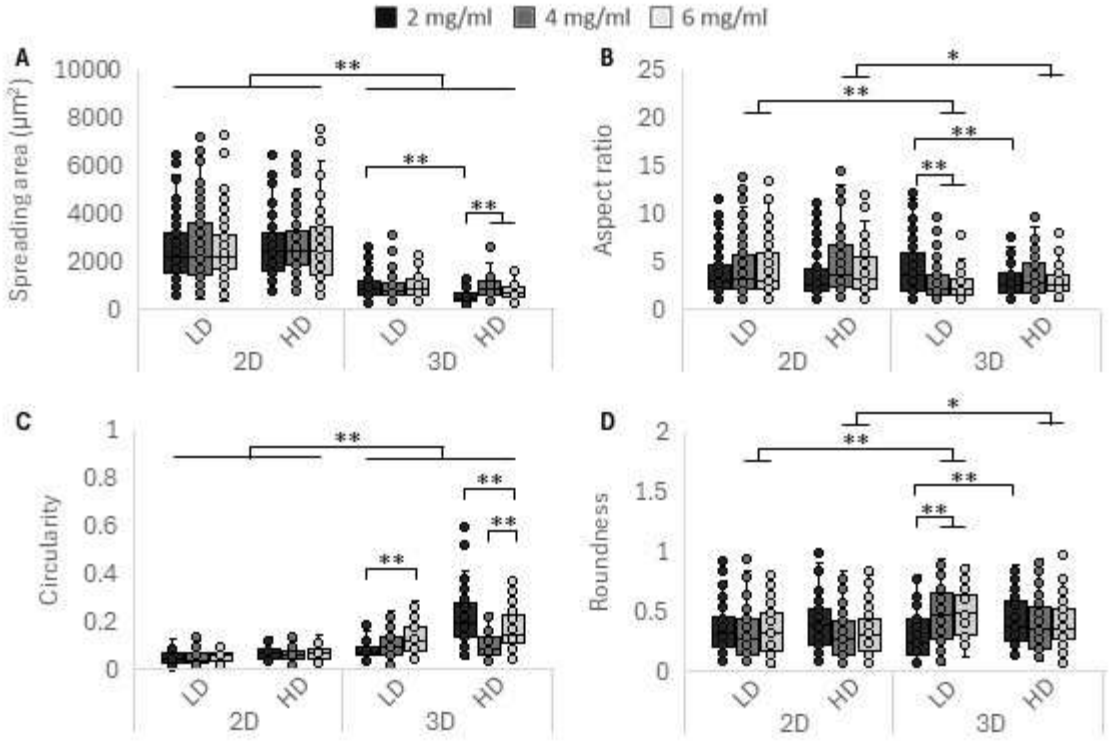
Introduction

In pathological contexts, vascular smooth muscle cells (SMCs) can switch from a contractile phenotype (elongated cell morphology) to a synthetic phenotype (more round shape). Although emerging evidence highlights the key role of extracellular matrix (ECM) biophysical cues in modulating SMC behavior, this relationship remains incompletely understood due to limited and inconsistent studies. This study aims to address this gap by characterizing SMC phenotypic response to ECM stiffness and cell density.

Methods

Bovine SMCs were cultured either on top of (2D) or embedded within (3D) collagen I hydrogels at 2, 4, and 6 mg/mL concentrations, corresponding to different gel stiffnesses. Two seeding densities were used: 100,000 cells/mL (LD) and 200,000 cells/mL (HD) in 3D, with equivalent planar densities in 2D. Cells were fixed at 24 h, stained with phalloidin, and morphological descriptors were extracted from images in Fiji. Approximately 100 cells per condition were analyzed across three independent experiments. Statistical comparisons used Kruskal–Wallis tests ($p < 0.05$*, $p < 0.01$**).

Results



Preliminary results showed that, across all concentrations and cell densities, 2D cells exhibited significantly larger spreading areas (Fig. 1A; $p < 0.01$) and higher elongation (Fig. 1B-D) than 3D cells. While 2D morphology was insensitive to collagen concentration and cell density, cell morphology in 3D depended on both variables. LD–3D cells in 2 mg/mL gels showed significantly greater elongation (Fig. 1B,D; $p < 0.01$) than in 4–6 mg/mL gels. HD–3D cells in 2 mg/mL gels exhibited pronounced gel compaction (data not shown) and markedly reduced spreading (Fig. 1A; $p < 0.01$) than in stiffer gels.

Discussion

Consistent with previous reports, 2D cells showed a contractile-like morphology (larger spreading and higher elongation), likely due to reduced physical constraint. In 3D, LD cells in 2 mg/mL hydrogels displayed higher elongation, in agreement with studies linking lower stiffness to a more contractile phenotype. HD impaired this behavior, possibly due to cell-

mediated gel remodeling that increased local matrix stiffness. Although preliminary, these findings highlight the influence of ECM cues on SMC phenotype. Future studies will correlate morphology with molecular and functional biomarkers and explore broader density and stiffness ranges.

Integrating Mechanical and Inflammatory Cues to Predict Fibrotic Capsule Formation Around Silicone Breast Implants

PhD student Matilde Marradi, Prof. Dr. Martijn van Griensven, Assoc. Prof. Dr. Aurelie Carlier

Dept. cBITE, MERLN Institute for Technology-Inspired Regenerative Medicine, Maastricht University, Limburg, Netherlands

Introduction

The foreign body response (FBR) around silicone breast implants is a chronic reaction, involving persistent macrophage activation and the deposition of an abnormally thick and contractile fibrotic tissue capsule leading to pain and implant failure. We propose that a mechanobiological feedback loop, in which altered mechanical properties drive extracellular matrix (ECM) production and mechanosignaling, sustains the FBR. Our aim is to quantify how peri-implant mechanical conditions and early inflammatory signals influence fibrotic capsule formation around implants.

Methods

We developed a coupled computational framework consisting of a biological and a mechanical module (Figure1). In the mechanical module, an elastic model is used to compute the stress distribution in a simplified 2D breast–implant geometry under static gravity loading. The mechanical simulation is iteratively run to account for changes in tissue mechanical properties arising from ECM deposition, updating the stress field throughout the simulation (28 days, with daily time step). The biological module solves the ODEs for cytokine concentration, myofibroblast density, and normalized collagen content. The cytokine dynamics follows an early peak followed by decay; myofibroblast activation depends on local TGF-β levels and stress following a Michaelis–Menten–type kinetics; collagen deposition increases with myofibroblast density and stress. The collagen density increases the local Young's modulus, closing the mechanobiological feedback loop. Equations and parameters were adapted from [1], and solved in COMSOL-Multiphysics 6.4.

Results

The model reproduces distinct fibrotic responses under different mechanical and inflammatory inputs. Altering the implant material's stiffness generated different stresses at the implant–tissue interface, leading to distinct patterns of myofibroblast and collagen accumulation at 28. Higher initial TGF-β similarly caused an earlier, larger myofibroblast peak, with final collagen levels matching those driven by mechanical cues.

Discussion

These preliminary results indicate that both early inflammatory and interface-driven mechanical cues strongly shape fibrotic tissue development around breast implants. The model's sensitivity to mechanical cues aligns with previous reports [2], supporting the role of local mechanical conditions in the FBR progression. Future work will incorporate spatial cytokine variability and refine parameter calibration to improve the model's quantitative reliability.

Images (Optional)

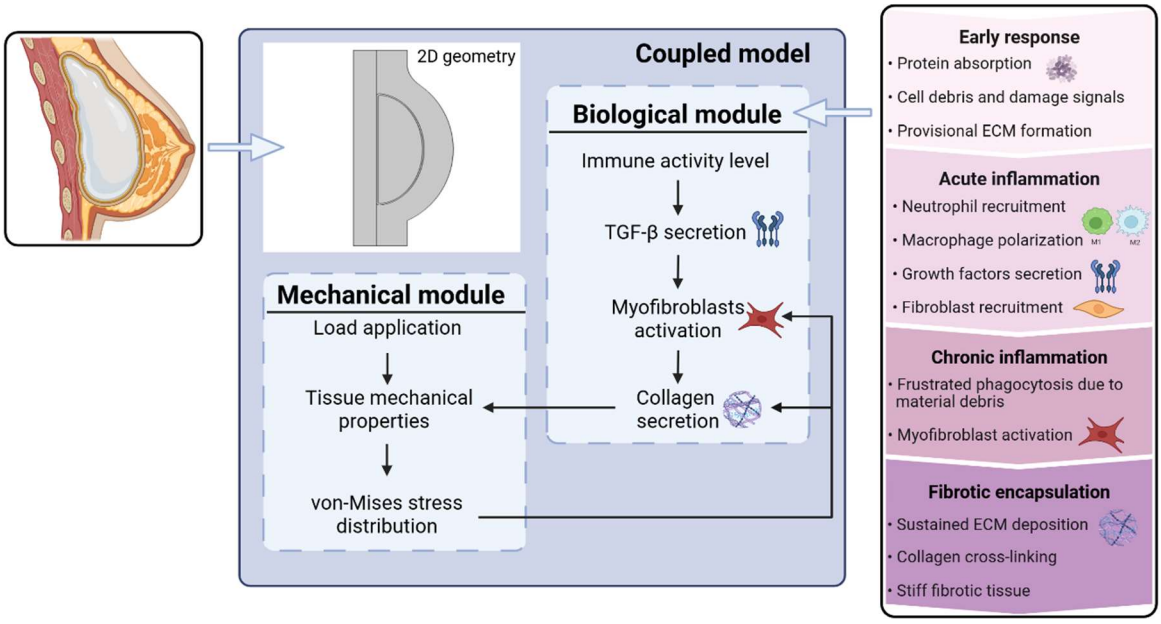

Figure 1. **Flow of infomation between the mechanical and biological module in each iteration of the simulation.** Anatomical breast anatomy is simplified to 2-D computational geometry used in the model. The mechanical module computes the stress field based on loading and material properties, while the biological module tracks four key variables representing the immune response, including collagen, which updates the mechanical properties at each time step.. A schematic of the broader immune processes illustrates how these are condensed into the four-variable biological representation.

Endothelial Dysfunction Caused by Chronic Hydrostatic Pressure: Insights Into Apoptotic Regulation

B.S. Mayuna Abe[1], Ph.D. Satomi Hirose[2], M.S. Norino Uenaka[1], Prof. Kenichi Funamoto[2], Prof. Daisuke Yoshino[1]

[1]Tokyo University of Agriculture and Technology, Koganei, Tokyo, Japan. [2]Tohoku University, Sendai, Miyagi, Japan

Introduction

Research on cellular responses to hydrostatic pressure stimulation and their mechanisms has received considerable attention in recent years. However, numerous aspects of the mechanisms by which vascular endothelial cells respond to hydrostatic pressure stimulation remain to be elucidated. This study examined the mechanism of endothelial dysfunction caused by chronic hydrostatic pressure stimulation.

Methods

Human umbilical vein endothelial cells (HUVECs) were cultured to confluence and subjected to hydrostatic pressures of 0 (control) and 50 mmHg for 24 hours. We then evaluated cell viability under each condition. The expression and localization of proteins associated with endothelial dysfunction were also analyzed based on immunoblotting and immunofluorescence staining after HUVECs were exposed to 0 (control) or 50 mmHg hydrostatic pressure for 3, 6, 12, or 24 hours.

Results

Chronic pressure application increased the proportion of HUVECs undergoing apoptosis. Concurrently, cleaved Caspase-3 expression nearly doubled in HUVECs under pressure conditions 24 hours after loading. Furthermore, GAPDH, a known inducer of apoptotic cell expression, showed substantial upregulation under pressure conditions. Expression of pro-apoptotic protein Bax remained constant regardless of pressure loading. In contrast, the expression of the anti-apoptotic protein Bcl-2 remained constant under pressure conditions, whereas it increased over time during culture in the control. These results suggest that chronic hydrostatic pressure alters pathways that suppress endothelial cell apoptosis, potentially impairing endothelial cell function.

Discussion

This study demonstrates that chronic hydrostatic pressure promotes endothelial apoptosis, as evidenced by increased cleaved Caspase-3 and upregulated GAPDH. The

lack of changes in Bax and Bcl-2 suggests that pressure does not trigger the canonical apoptotic pathway but instead disrupts endogenous anti-apoptotic regulation. Such an imbalance may reduce endothelial resilience and contribute to dysfunction under elevated pressure states, including hypertension or venous congestion. Although limited to HUVECs and apoptosis-related markers, these findings indicate that hydrostatic pressure impairs endothelial homeostasis and underscore the need to explore broader mechanotransduction mechanisms.

Biomechanical Modelling Suggests a Role of Vascular Smooth Muscle Cell Plasticity in Arterial Failure and Maladaptation

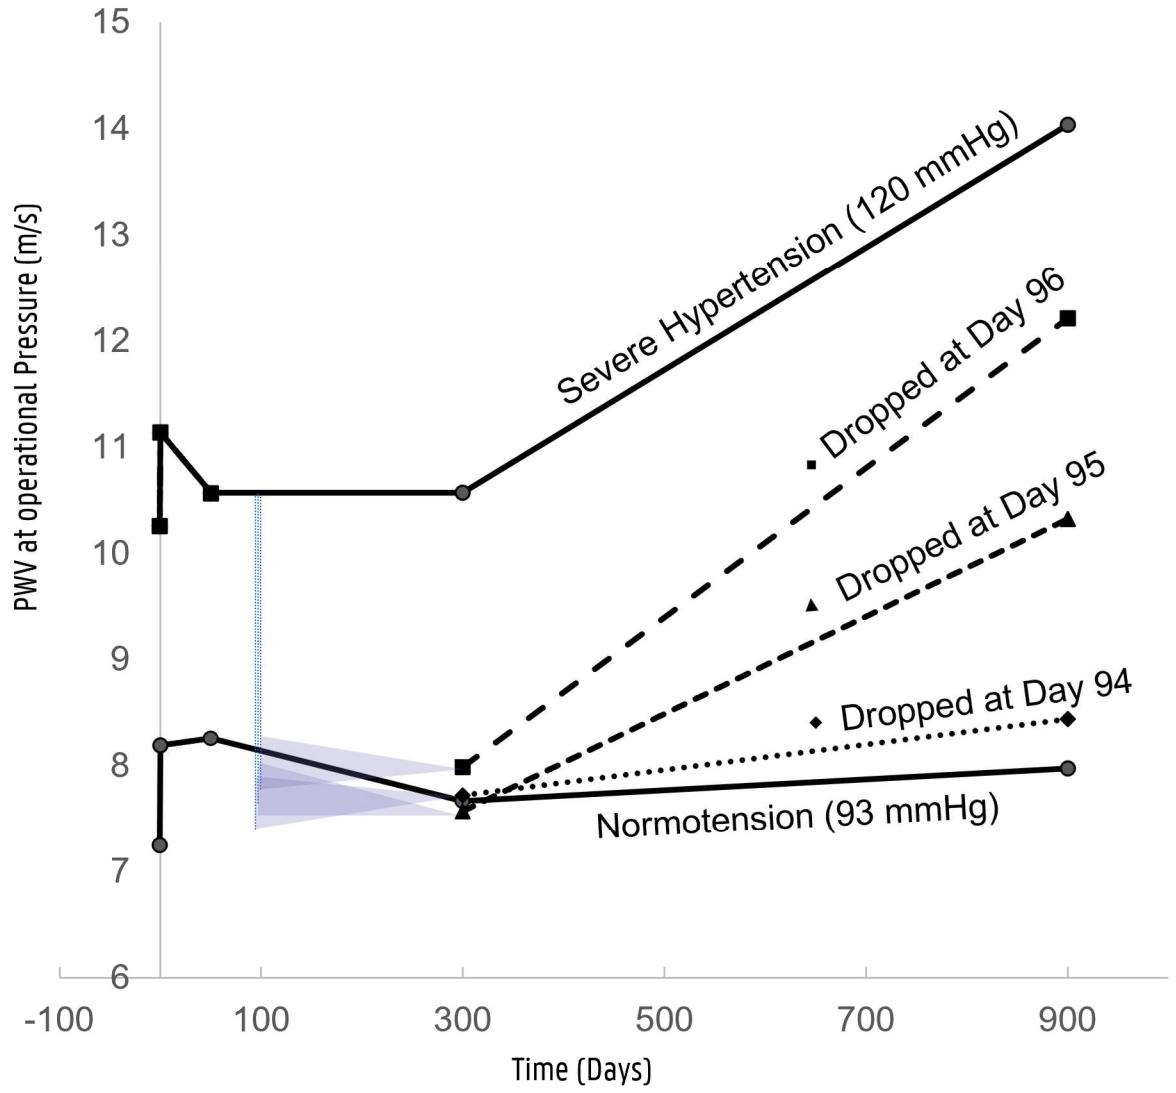
Introduction

Phenotypic plasticity in vascular smooth muscle cells (VSMCs) plays a major role in extracellular matrix (ECM) turnover and the progression of arterial failure. One prevailing hypothesis is that the osteochondrocytic shift seen in synthetic VSMCs drives the accumulation and swelling of glycosaminoglycans (GAGs)—a pattern also noted in ECM disruption associated with connective tissue disorders and in cells experiencing excessive mechanical stress under hypertensive arterial pressures. It remains unclear, however, whether this phenotypic switching under non-homeostatic conditions is a contributing cause of these abnormalities or a downstream consequence of them.

Methods

We implement a cause-effect association between ECM damage, lost cell mechanosensitivity, and cell phenotype modulation using the Constrained Mixture Model [1], to predict the evolution of VSMC population over time. We modelled a cylindrical bi-layer of media and adventitia of a mouse common carotid artery as constrained mixtures *in silico*.

Results



The model demonstrates that under normotensive and mildly hypertensive conditions, ECM disruption is largely corrected through physiological remodeling, which restores mechanical homeostasis to cells with only minor changes to overall mechanical

properties. Under severe hypertension, however, the model predicts complete medial degeneration when ECM damage persists. An initial rise in GAG content temporarily compensates for ECM loss, but prolonged damage triggers a VSMC phenotypic switch that accelerates structural failure. As degeneration progresses, the artery loses nearly all stored elastic energy, resulting in marked stiffening and the elevated pulse wave velocities (PWVs). The model further indicates that reducing blood pressure shortly after the initial insult prevents long-term stiffening, whereas delayed intervention fails to reverse the degenerative changes as shown in Figure 1.

Discussion

Literature suggests clear association between dense transmural GAG aggregation in aneurysmatic and hypertensive arteries [2,3], with the mechanism by which the material properties change being less understood. Our model thus offers a tool to better understand the relationship between ECM damage, arterial failure, and cell response to perturbations in their environments.

Osteoporosis Treatments and Mechanical Loading Restore Osteocyte Mechanosensitivity Measured by Osteocyte Lacunar Morphology in a Mouse Model of Osteoporosis

MSc Sara Lindenmann, Dr. Zihui Li, Dr. Friederike A. Schulte, Dr. Claudia Weigt, Dr. Floor M. Lambers, Dr. Gisela A. Kuhn, Dr. Neashan Mathavan, Prof. Dr. Ralph Müller

Institute for Biomechanics, ETH Zürich, Zürich, Zürich, Switzerland

Introduction

Common treatments for osteoporosis include anti-catabolic agents like bisphosphonates (BIS) or anabolic agents like parathyroid hormone (PTH), and effects may be enhanced by mechanical loading (ML). The lacuna-canalicular network (LCN) morphology can change with disease and may alter mechanosensitivity [1], as shown by higher mechanosensitivity of round versus flat osteocytes [2]. We investigated how ML and BIS or PTH treatment affect trabecular lacunar morphology in a mouse model of osteoporosis as an indicator of osteocyte mechanosensitivity.

Methods

Ex vivo high-resolution (voxelsize: 1.2 µm) micro-computed tomography (micro-CT) images were obtained from a 1.1 mm mid-section of the 6th caudal vertebra of 7 sham-operated and 43 ovariectomized C57BL/6JRcc mice at 24 weeks of age (license: 171/2009). Ovariectomized mice received ML (8N) 3x/week, PTH (80 µg/kg, 20-24 weeks daily) or BIS (100 µg/kg, at 20 weeks). Some animals received combined pharmacological treatment with ML. Newly formed bone from week 22-24 was identified from time-lapsed *in vivo* micro-CT and registered to the *ex vivo* micro-CT. Mean lacunar sphericity (Lc.Sr) and lacunar volume (Lc.V) was evaluated in trabecular bone and in separated formation and quiescent regions using a custom Python script [3] implemented in XamFlow. The statistical analysis is indicated in the figure caption.

Results

Approximately 70000 and 300000 lacunae were analyzed in formation and quiescent regions, respectively. Ovariectomy significantly increased Lc.Sr while ML and BIS restored it to control levels (Fig. 1A). PTH significantly reduced Lc.Sr while significantly increasing Lc.V. Lc.Sr and Lc.V in formation regions correlated with quiescent regions (Fig. 1C and 1D) but was significantly lower in formation regions for Lc.Sr (6/7 groups) and significantly higher for Lc.V (5/7 groups).

Discussion

Higher osteocyte mechanosensitivity after ovariectomy, shown by increased Lc.Sr, likely compensates for bone loss and is reversed by BIS and/or ML. PTH reduces Lc.Sr through a non-uniform increase in Lc.V and decreases variability, suggesting tighter control of its cellular effects. Osteocytes in newly formed bone show lower mechanosensitivity, independent of disease or treatment, potentially limiting excessive bone formation.

Images (Optional)

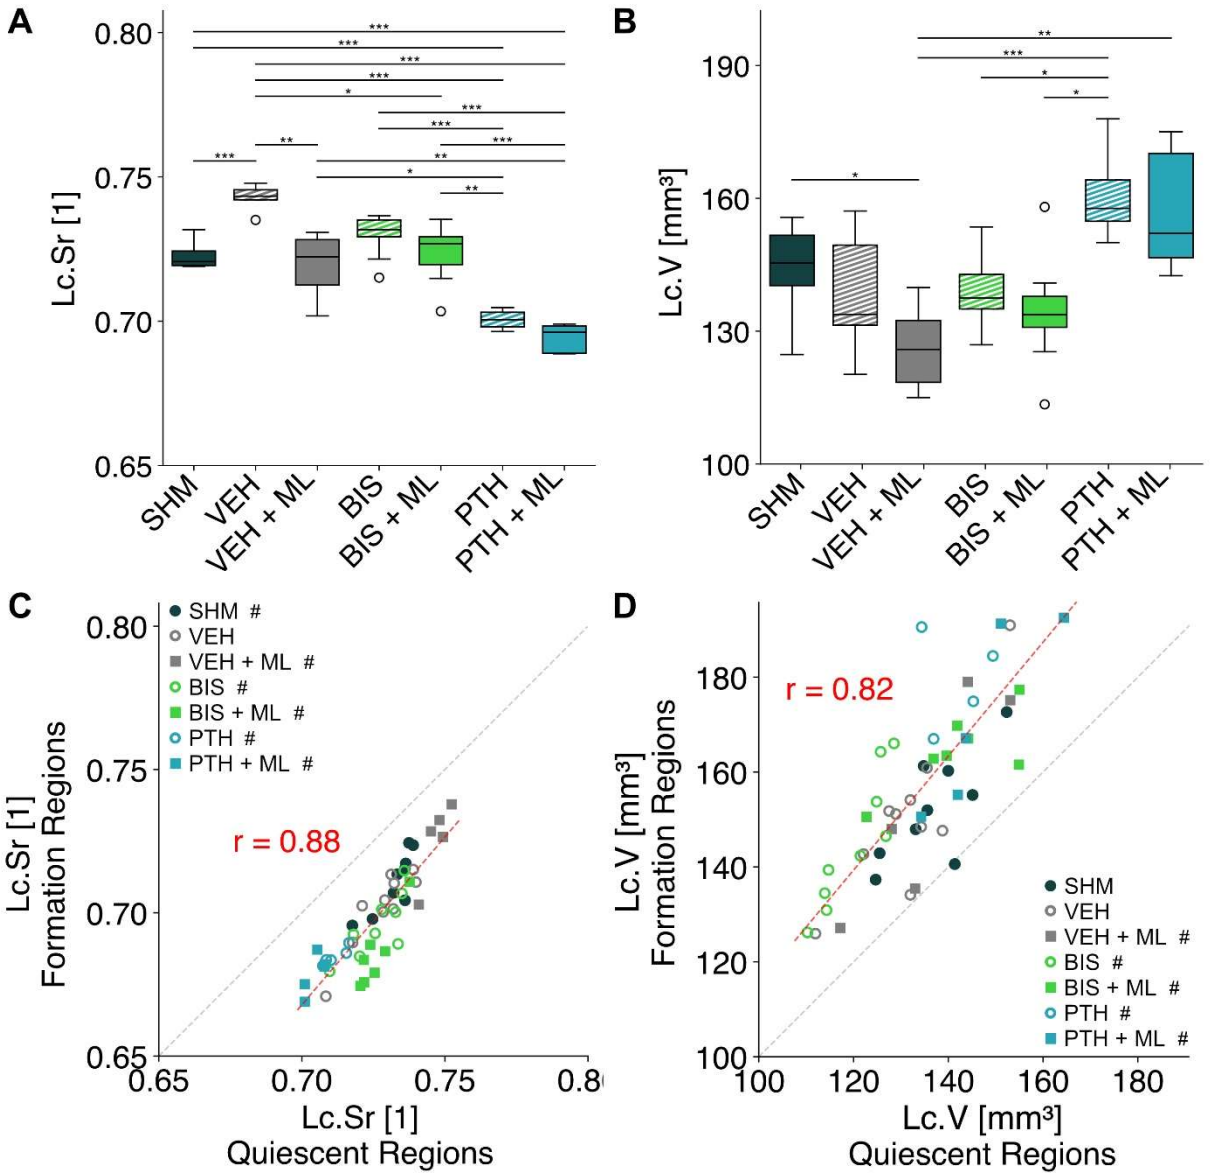

Figure 1: *(A) Mean lacunar sphericity (Lc.Sr) and (B) Mean lacunar volume (Lc.V) in trabecular bone of all groups: sham-operated (SHM), vehicle treatment only (VEH) or with mechanical loading (VEH + ML), bisphosphonate treatment only (BIS) or with mechanical loading (BIS + ML), parathyroid hormone only (PTH) or with mechanical loading (PTH + ML). Differences between groups for were tested using one-way ANOVA followed by a post-hoc analysis using Tukey's test. Significances between groups are indicated with (*) p<0.05, (**) p<0.01, (***) p<0.001. (C) Correlation between mean Lc.Sr of formation and quiescent regions. (D) Correlation between mean Lc.V of formation and quiescent regions. Data in (C) and (D) is shown with a linear fit and overall Pearson. Group-wise significant differences between formation and quiescent regions were tested using paired t-test with Bonferroni correction after confirming normality with the Shapiro-Wilk test. Significances between formation and quiescent regions per group are indicated in the legend with (#) p<0.05.*

Cell Mimic Platform Using Integrin-Targeted Emulsion Reveals Force-Dominated Apoptosis and Frequency-Dependent TRPV4 Activation in PANC-1 Cells

Mr. Sungkil Lee MS, Prof. Ryota Toyohara PhD, Prof. Toshiro Ohashi PhD

Hokkaido University, Sapporo, Hokkaido, Japan

Introduction

Mechanical forces regulate cellular functions through integrin-mediated mechanotransduction [1], yet quantitative thresholds governing fate decisions remain unclear due to limitations in delivering stable, localized mechanical inputs. We present a biofunctionalized oil-in-water cell mimic actuated by a custom hexapole magnetic-tweezer device generating precise low-frequency forces (4–20 pN, 1–6 Hz) [2]. PI control with Kalman and EWMA filtering ensured consistent outputs, while RGDS-conjugated PEG-VS-PVA microrobots [3] selectively engaged β-integrins on PANC-1 cells, enabling targeted activation of the integrin–FAK–TRPV4 pathway.

Methods

Fluorescent antibodies confirmed NHS-ester activation on the cell mimic surface. Stable RGDS–integrin attachment was observed prior to stimulation, and mechanical loading was applied only after sufficient incubation (~12 h) ensured reliable contact. Five stimulated and four control groups were analyzed at 0, 3, and 6 h using Annexin V–PI cytometry and EdU incorporation assays [1]. Ca^{2+} imaging with Fluo-4 AM and TRPV4 inhibition was performed under matched conditions to quantify ion-channel–dependent mechanotransduction.

Results

Apoptosis sharply increased at 3 h, indicating a critical decision window. Logistic regression identified a force-dependent apoptotic threshold of ~10 pN (CV-AUC = 0.833) [2,4], with force as a significant predictor. Frequency showed a positive but non-significant effect, suggesting its contribution cannot be confirmed or excluded. Ca^{2+} imaging revealed frequency-dependent TRPV4 activation: strong influx at 6 Hz suppressed by HC-067047, and negligible activation at 1 Hz. However, this rapid ion-channel response did not directly correspond to apoptosis levels at 3 h.

Discussion

These results distinguish force-dominated apoptotic commitment from frequency-dependent TRPV4 activation. Although TRPV4 gating at 6 Hz may influence early

mechanotransduction, the data do not support a direct link between Ca^{2+} influx and apoptosis under these conditions. This integrin-targeted microrobotic platform provides a quantitative basis for dissecting force- versus frequency-sensitive pathways and offers a scalable tool for precision mechanobiology and therapeutic mechanism design.

Regulating Fibroblast Phenotype in Tissue Engineered Heart Valves

ir. Willem R. Stolk[1,2], ir. Justina Ghebryal[1,2], prof.dr.ir. Frank P.T. Baaijens[1,2], dr.ir. Sandra Loerakker[1,2]

[1]Department of Biomedical Engineering, Eindhoven University of Technology, Eindhoven, Noord-Brabant, Netherlands. [2]Institute for Complex Molecular Systems, Eindhoven, Noord-Brabant, Netherlands

Introduction

Achieving control over the regeneration of in-situ tissue-engineered heart valves (TEHVs) remains challenging, as preclinical studies report unpredictable outcomes and failures from progressive tissue deposition and leaflet retraction [1]. These complications highlight the need to understand fibroblast-driven remodeling, as fibroblasts regulate extracellular matrix production and contractility in response to mechanical and biochemical cues [2,3]. However, the spatial and temporal influence of these stimuli across valve leaflets remains poorly characterized.

Methods

This study introduces a multiscale computational framework combining finite element (FE) modeling of valve mechanics with an ordinary differential equation (ODE)-based model of intracellular signaling to investigate fibroblast phenotype regulation. FE simulations quantified strain in hinge, belly, and tip regions for two TEHV designs: Design 1, linked to leaflet retraction and failure, and Design 2, modified to prevent retraction [3,4]. Strain outputs served as inputs for the ODE model, which predicted contractility activation through intracellular signaling pathways. Knockout analyses identified key molecular targets influencing contractility, filtered for FDA-approved cardiovascular drugs.

Results

Results revealed heterogeneous strain patterns, with Design 1 exhibiting higher strains and markedly greater contractile activation in the hinge and tip region, while the belly region showed minimal activation (see figure). High-strain areas corresponded to elevated contractility, matching αSMA expression in the hinge region for Design 1. In contrast, Design 2 showed low contractility and no αSMA expression in the hinge region. Knockout simulations implicated angiotensin (AT) and endothelin (ET) signaling pathways as major

regulators. Inhibition of AT1, ETA, PI3K, mTOR, and calcium signaling reduced contractility, whereas blocking AT2 and ETB increased it.

Discussion

These findings demonstrate that mechanobiological signaling governs fibroblast phenotype and contractile behavior in TEHVs. The proposed framework provides mechanistic insight into strain-mediated remodeling and identifies pharmacological targets to modulate fibroblast activity during tissue engineering. Such strategies could mitigate leaflet retraction and improve predictability of in-situ TEHV regeneration, informing scaffold design and therapeutic interventions.

Images (Optional)

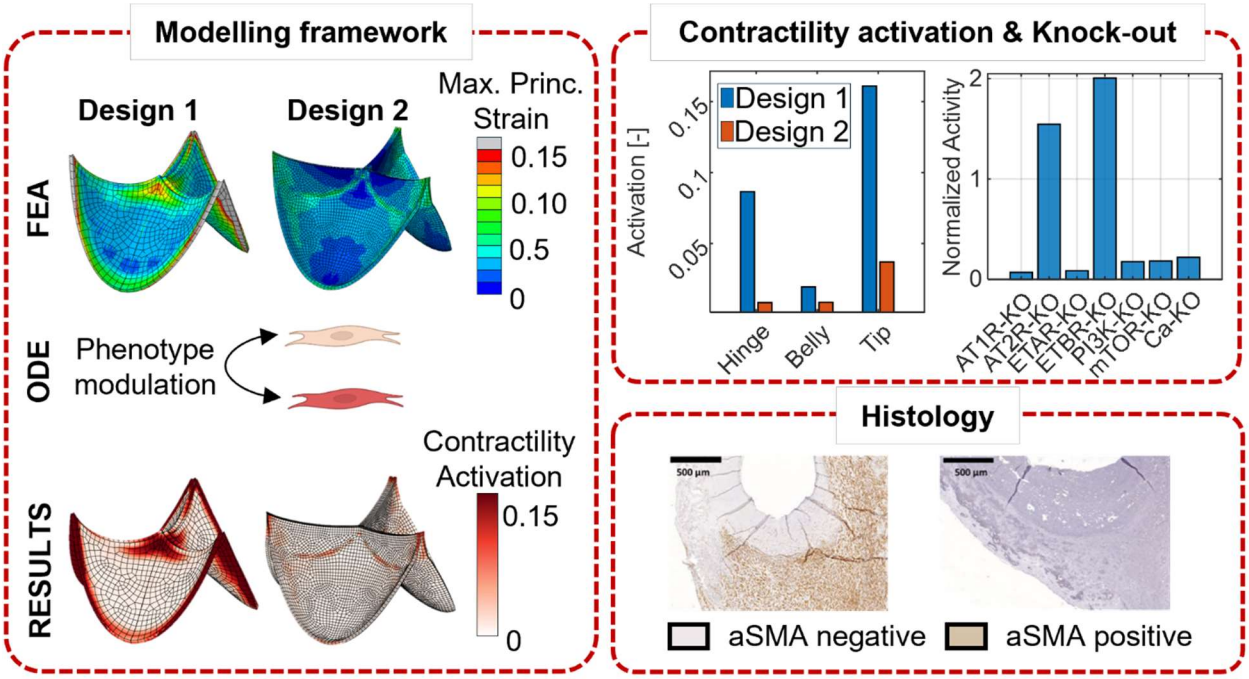

Figure: FE model predicted strain distributions for design 1 and design 2 valves, coupled to an ODE model to estimate regional contractile activation. Bar graphs show contractile activation across leaflet regions and knockout sensitivity. Histology shows αSMA expression in the hinge regions of the for design 1 (left) and design 2 (right) valves adapted from [3].

Mechanical Activation of Piezo1 Drives Osteoarthritis Through Kdm5c-Mediated Epigenetic Silencing

Mr Tianyou Kan, Mr Xuran Li, Professor Zhifeng Yu

Shanghai Jiao Tong University School of Medicine, Shanghai, Shanghai, China

Introduction

Osteoarthritis (OA) remains a leading cause of global joint disability, with no disease-modifying therapy available. While pathological mechanical stress is a key driver of OA, the molecular pathways translating physical forces into persistent gene silencing in chondrocytes are poorly understood.

Methods

A mouse model with chondrocyte-specific conditional knockout of Piezo1 (*Col2a1*^{CreERT}; *Piezo1*$^{flox/flox}$). The mouse chondrocytic cell line ATDC5 was treated with small interfering RNA (siRNA), the Piezo1 agonist Yoda1. OA was surgically induced by the model of post-traumatic OA. Chondrocytes was performed with RNA-sequencing and CUT&Tag sequencing, histology, atomic force microscopy (AFM), and scanning electron microscopy (SEM).

Results

By using Piezo1 conditional knockout (*Col2a1*^{CreERT}*; Piezo1*$^{flox/flox}$) mice, we found Piezo1 activation by excessive mechanical stress caould trigger nuclear pore dilation via cytoskeletal force transmission, enabling nuclear import of the histone demethylase Kdm5c. Kdm5c in turn erases H3K4me3 marks from promoters of cartilage-anabolic genes *Col2a1* and *Runx3*, silencing their expression. Genetic ablation of and Kdm5c rescues mechanical stress induced cartilage degradation. Through drug repurposing, we identify telmisartan as a direct Kdm5c inhibitor that blocks this pathway and demonstrates disease-modifying efficacy in mouse OA models and human cartilage explants. Our results establishe the Piezo1–Kdm5c axis as a fundamental driver of OA and positions telmisartan as a mechano-epigenetic therapy with immediate translational potential.

Discussion

Here, we uncover a **previously uncharacterized mechano-epigenetic pathway** that drives OA progression and demonstrate its therapeutic targeting using a clinically approved drug. Specifically, we demonstrate:

1. **A complete signaling cascade** from the mechanosensor Piezo1 to nuclear pore dilation, facilitating nuclear import of the histone demethylase Kdm5c, which in turn erases the active H3K4me3 mark at promoters of key cartilage-anabolic genes（ *COL2A1* and *RUNX3*）.
2. **Kdm5c as a druggable epigenetic effector**, whose inhibition restores H3K4me3 levels and promotes cartilage matrix homeostasis.
3. **Telmisartan, an FDA-approved antihypertensive drug**, as a direct Kdm5c inhibitor that blocks this pathogenic axis, demonstrating robust disease-modifying efficacy in both a murine OA model and human OA cartilage explants.

Our work not only delineates a novel disease mechanism spanning from mechanosensing to epigenetic silencing, but also provides an immediately translatable therapeutic strategy by repurposing a safe, existing drug.

[4]Department of Computer Engineering and Mathematics, Universitat Rovira i Virgili, Tortosa, Catalonia, Spain. [5]Department of Pathology, Hospital Universitari Joan XXIII, Institut Català de la Salut, Tarragona, Catalonia, Spain

Introduction

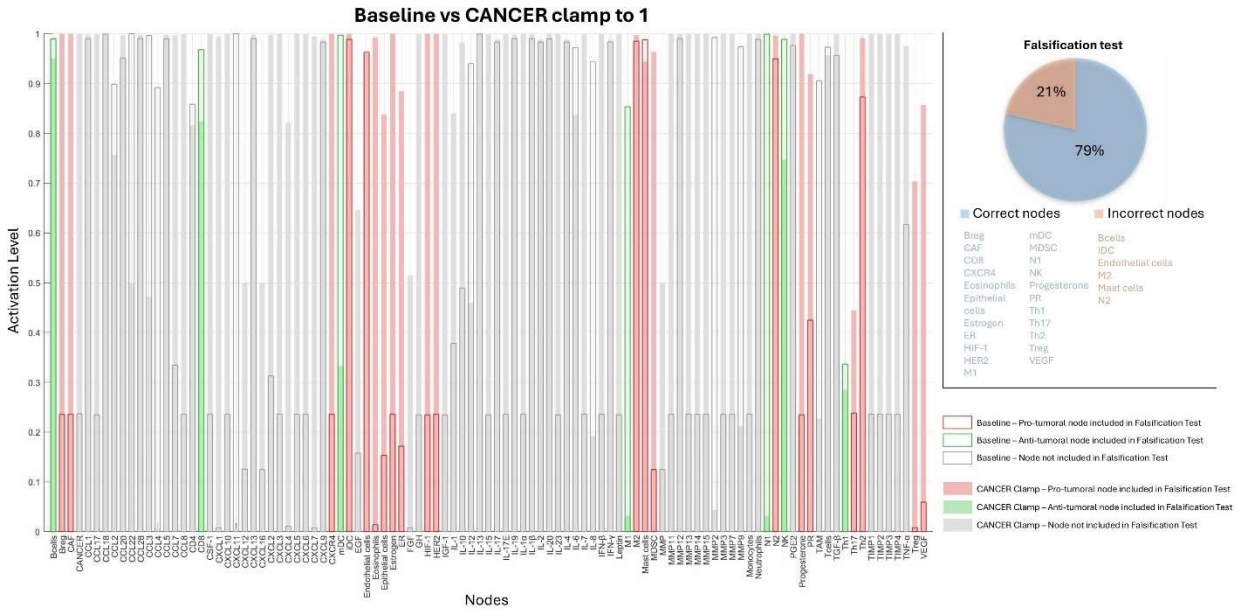
Breast cancer (BC) is the leading cause of cancer-related mortality in women, with risk increasing once tumor cells metastasize to the axillary lymph nodes (ALN) [1,2]. Immune-tumor interactions strongly influence metastatic progression, yet mechanistic understanding remains incomplete. This study develops a regulatory network model (RNM) to examine the molecular and cellular interactions that drive ALN metastasis within the BC tumor microenvironment (TME).

Methods

The RNM was constructed using graph knowledge projection from >200 peer-reviewed publications. Nodes represented immune cells, cytokines, metalloproteinases, proteases, hormones, and tumor cells, interconnected through directional activating or inhibitory links. Node activity was computed on a continuous normalized scale using Boolean-based ordinary differential equations [3]. The model remained high-level, including a Cancer node representing ALN metastasis risk. Baseline behavior was assessed through 100 simulations, each with random node initialization to identify attractors.

Results

The RNM comprised 102 nodes and 1,001 links, being dense and highly interconnected (density 0.092, clustering coefficient 0.307). Centrality analysis identified Cancer as the



dominant hub across all metrics (MCC, EPC, degree, betweenness, closeness), verifying the mater control of this node, to explore cancer-related protein and cell regulations. Excluding Cancer, highly central nodes included endothelial cells, CAFs, CD8, Tcells, Tregs, mDCs, MDSCs, and IL-10, with endothelial cells emerging as the most influential.

Simulations with Cancer node clamped to 0 (no metastasis probability), or 1 (full metastasis probability) revealed the most functionally responsive nodes. Using a 0.05 activity-change threshold, Cancer activation increased several pro-tumoral and immunosuppressive components while decreasing several anti-tumoral nodes (Figure 1). Conversely, Cancer inhibition suppressed pro-tumoral nodes (Breg, CAF, endothelial cells, epithelial cells, hormones, hormone receptors, HIF-1, MDSC, N2, Th17, VEGF) and increased protective immune subsets (Th1, M1).

Discussion

The RNM highlights the central biomechanical drivers of ALN metastasis, reproducing ≈79% of expected early- and late-stage TME dynamics. Initial falsification test confirmed overall validity, though minor deviations suggest the need for further refinement, targeting nodes with incorrect behavior, to ensure the network accurately reflects complex tumor–immune–stromal dynamics.

Myosin-Driven Contraction Enables Controlled Fracture in Actomyosin Networks With Measurable Mechanical Properties.

Mr. Aniket Marne[1], Mr. Octavio Brugo[2], Ms. Sheridyn Campos[3], Dr. José Alvarado[1]

[1]The University of Texas at Austin, Austin, Texas, United States. [2]University of Miami, Coral Gables, Florida, United States. [3]Texas Christian University, Fort Worth, Texas, United States

Introduction

Cells and tissues show fracture in response to mechanical stress due to intrinsic cellular processes or external movements. Fracture can be integral part of development process such as blastocoel formation in mouse or undesired in case of mutations or diseases. Fracture is complex multiscale process and fracture we see is the outcome of molecular and then cellular level ruptures. Fracture can be triggered by passive stress or active stresses where energy consuming molecular motors generate pulling forces and then transmitted across cells through adhesion complexes. Role of active stress in fracture has been observed in multiple natural processes including leg inversion in Drosophila, asexual reproduction in Trichoplax adhaerens, loss of tissue integrity in gastrulation. Collectively, active stresses play important role in giving tissues intrinsic ability to self-rupture. However, understanding has been hindered by inability to quantitatively characterize the process of fracture.

Methods

We addressed these gaps using reconstituted actomyosin network gels composed of actin filaments, fascin crosslinks, and myosin motors. To mimic cellular adhesion, Dirichlet boundary conditions were imposed by anchoring actin filaments to fixed boundaries. A pre-defined crack front was introduced at the gel center, and its propagation was monitored under active stresses generated by myosin motor activity. We quantified crack length over time and measured the energy consumed by myosin motors during rupture. Additionally, we observed contraction both within the cracked region and in areas still attached to the boundary.

Results

Introducing controlled cracks into actomyosin gels enables directed energy relaxation within the network. This approach provides a quantitative framework for characterizing rupture behavior in active gels. We measured the coupled dynamics of crack propagation

and motor-driven contraction in reconstituted actomyosin networks, allowing extraction of key mechanical parameters, including work functions, damage evolution profiles, and effective fracture toughness.

Discussion

By resolving stress-intensity scaling, non-affine strain localization, and active energy partitioning, we present a quantitative framework for fracture mechanics in active soft matter. Our findings demonstrate that stress relaxation pathways can be guided by mimicking cellular adhesion, offering a strategy to control failure dynamics in reconstituted actomyosin networks.

Quantify the 3D Traction Force in Different Germ Layers of Mouse Embryo Organoids

Prof. Fuxiang Wei, Miss Chenyang Ji, Miss Anqi Wang, Miss Xinman Chen, Mr Xinyu Zhang, Mr Wuhuang Liu, Prof. Junwei Chen

Huazhong University of Science and Technology, Wuhan, Hubei, China

Introduction

Mechanical force can direct regulate living cell gene expression and impact cell fate, also plays a key role in embryo development[1]. There are some reports about quantify the traction force in zebrafish embryos[2,3], but it is still elusive how to quantify the traction force during mouse embryo development and how the force impacts the germ layer patterns.

Methods

Here we present a method of quantifying the 3D traction force in mouse embryos and embryo organoids. We injected the elastin round microgels into the mouse embryos, then cultured the embryos in the living cell system compatible with confocal microscopy. The 3D images were performed every hour to record positions of fluorescence beads in the microgel. In the embryonic germ layer organoids, the elastic round microgels were co-cultured with mouse embryonic stem cells in soft 3D fibrin gels. Cytokine combinations were optimized to induce embryonic stem cell differentiation into three germ-layers structures. The microgels will be distributed to different germ layers during this process. 3D images of microgels were taken before and after treating the embryo organoids with Triton X-100.

Results

Comparing microgels deformation between different time points, we can calculate the 3D traction forces generated by the embryos and observe traction force oscillating during mouse embryo developing. The embryo development stopped when the traction force can`t oscillate. Compare the images before and after treating the Triton X-100, we can get the absolute traction force generated by germ layers and find the traction force is significal different in different layers.

Discussion

This study establishes the methods for quantifying 3D traction force in mouse embryos and organoids, reveals germ layer-specific mechanical differences.

Computational Determination of iPSC Stress-Fiber Architecture During Vasculogenesis

Mr. Gabriel Peery[1,2], Dr. Toni West[1,2], Dr. Janet Zoldan[2], Dr. Michael Sacks[1,2]

[1]Oden Institute, Austin, Texas, United States. [2]University of Texas at Austin, Austin, Texas, United States

Introduction

Induced pluripotent stem cell endothelial progenitors (iPSC-EPs) represent a promising avenue for therapeutic tissue constructs owing to vasculogenic capabilities, but achieving sufficient microvascular-network formation requires detailed insights into their biophysical behaviors [1]. We have developed an integrated 3D traction force microscopy inverse modeling pipeline to determine embedded-cell-induced hydrogel remodeling. In the present study, we extend our studies to include analysis of iPSC stress-fiber architecture at different stages of vasculogenesis.

Methods

Human iPSCs were differentiated into EPs, embedded in norbornene-functionalized hyaluronic acid hydrogels with fiducial markers, and then cultured for 4 or 7 days. Cells were stained, specimens of single cells and cell clusters (different stages of vasculogenesis) were imaged *via* 3D microscopy, treated with cytochalasin D to deactivate cellular force generation, and imaged again. Fiducial-marker displacements between states were quantified and cell meshes were generated for subsequent computational analysis.

First, we deployed our inverse finite-element model [2] to reconstruct heterogeneous material behaviors induced by cellular MMP secretion and ECM deposition. Accounting for variations in hydrogel moduli spanning orders of magnitude then allowed accurate estimation of cellular stress-fiber architecture. We adapted our previous inverse model [3] to determine stress-fiber architecture, including orientations and force generation level, to incorporate improvements in numerical stability.

Results

The stress-fiber model was extensively validated to accurately capture prescribed ground-truth fiber architectures in synthetic test cases. Inverse-model analysis revealed spatially-varying fiber orientations and force magnitudes within iPSCs that were significantly different between single and cluster specimens. Cellular protrusions near deposited ECM

exhibited high force generation. Cell-cell junctions produced signature fiber-orientation patterns.

Discussion

Differences in stress-fiber architectures may be attributable to intercellular signaling upon forming adherens junctions between adjacent cells that leads to further stages of vasculogenesis. The biophysical insights into vasculogenesis provided by our inverse modeling techniques may be extended in future work to the lumenized microvascular networks that iPSC-EPs form with longer culture time. Detailed understanding of these processes will be critical to the development of effectively-vascularized therapeutic tissue constructs [1].

Estimation of Cellular Viability Under Cold Storage Using Electrical Impedance Measurement in Cell Monolayers.

Master course of Medical Sciences Hoshito Seno CE[1], Bachelor of Clinical Engineering Kanju Katamine CE[1], Professor Masanobu Ujihira PhD[1], Professor Satoru Nebuya PhD[2], Associate Professor Kazuhiro Yoshida PhD[1], Professor Rina Sakai PhD[1]

[1]Kitasato University, Sagamihara, Kanagawa, Japan. [2]POSH WELLNESS LABORATORY, Tokyo, Tokyo, Japan

Introduction

Cold storage is commonly used for preserving cells and tissues in transplantation and regenerative medicine. However, its clinical utility is limited by short permissible preservation times and the invasive, non-real-time nature of current viability assays that require sampling of the stored material. Electrical impedance measurement has emerged as a non-invasive alternative. The purpose of this study was to examine the possibility of estimation in cellular viability under cold storage of cell monolayers using electrical impedance measurement.

Methods

Cells of rat cardiomyocytes (H9c2) were seeded on a chamber with 64 electrodes (MED probes, Alpha Med Scientific) and cultured with Dulbecco's Modified Eagle Medium (DMEM) for 24 h as a test sample. The sample was stored in DMEM and preservation solutions (ET-Kyoto, UW) at 4°C for 36 h, electrical impedance was measured at 16–200 kHz with impressed current of 10-μA at 3–36 h of storage time, and viability was independently evaluated by WST-8 following rewarming. Impedance ratios were calculated as 16 kHz/200 kHz and converted to corrected ratios (normalization correction) using an exponential fit–derived initial value and a linearly estimated convergence value. After that, estimated viability was obtained using a linear relationship between corrected ratios and actual viability.

Results

Both actual cell viability and electrical impedance ratios exhibited similar decreasing trends with storage time across all preservation conditions. Estimated viability derived from corrected impedance ratios agreed well with actual viability up to the earlier storage periods (< 12 h). Although the difference between the two measures widened slightly as

viability declined at later time points, impedance-based estimation remained applicable throughout the examined duration.

Discussion

It is considered that the slight increase of deviation in longer storage times is resulting from the decrease of change in impedance ratios in low-viability ranges (< 40%). When the temporal slope of the ratio becomes small, differences between conditions are less distinguishable. Because the deviation between estimated viability and actual viability maintained the small value even at lower viability ranges, it is thought that impedance-based estimation is applicable for assessing viability during cold storage up to this duration.

Mechanotransductive Control of Nucleus Pulposus Cells: A Regulatory Network Model Analysis

Dr. Zerihun G. Workineh, Prof. Jérôme Noailly

Universitat Pompeu Fabra, Barcelona, Catalonia, Spain

Introduction

The nucleus pulposus (NP) continuously experiences mechanical forces that are converted into biochemical signals through mechanotransduction (MT). While physiological loading maintains homeostasis, excessive loading induces inflammatory and matrix-degrading responses [1]. Although individual MT pathways are known, their integrated behavior remains incomplete. To address this, we develop an integrated regulatory network model (RNM) capturing NP responses across mechanical regimes.

Methods

A systematic review of 150+ studies was conducted to classify mechanical load conditions relevant to NP cells. Literature, and Reactome and KEGG database, knowledge, was mapped in a 140-node, 353-edge RNM encompassing mechanoreceptors, intracellular mediators, transcription factors, and effectors. The RNM was formulated as a semi-quantitative ODE system consistent with Boolean logic [2], with steady states identified through >100 randomized initializations. Mechanical loading was represented through two regulatory input nodes: NL and HL reflecting normal and hyper-loading, respectively. Load regimes were: Hypo ($NL \leq 0.1$, $HL \leq 0.1$); Normal ($NL > 0.1$, $HL \leq 0.1$); Hyper ($NL \leq 0.1$, $HL > 0.1$).

Results

Hypo-loading produced a globally dampened response, with modest activation of oxidative-stress mediators (Fig. 1). Normal-loading enhanced coordinated anabolic signaling, increasing matrix proteins (ACAN, COL2A1), growth factors (TGFβ, IGF1, GDF5) (Fig. 1), and transcription factors (e.g., SOX9, PPARγ). Hyper-loading redirected the network toward a pro-catabolic–inflammatory state, elevating cytokines, proteases (MMPs, ADAMTS), oxidative-stress/apoptotic nodes (ROS, BAX, CASP3/9), and degeneration-associated transcription factors (NF-κB, AP-1). From 37 RNM falsification tests against independent cell load–response reports, about 92% passed the test.

Discussion

The RNM robustly captured load-dependent NP cell regulation by integrating dispersed MT information into a unified, interpretable framework. The NL/HL switch formulation reproduced established experimental outcomes: Hypo-loading generated slight pro-catabolic drifts, Normal-loading produced a coherent anabolic–homeostatic program, and Hyper-loading activated pro-inflammatory, oxidative, and proteolytic pathways characteristic of degenerative stress, in the modelled NP cells. The high falsification-pass rate further indicated the RNM's ability to reproduce known biological behaviors. The network inputs and outputs remain qualitative, but simulations and interpretability of the resulting node activations are an asset to explore intervention targets in disc degeneration.

MATHEMATICAL MODELLING OF BONE REMODELLING TO SIMULATE $PM_{2.5}$ METAL EFFCTS ON BONE

Ms. Joudi Altaleb, Dr Ulrich Hansen, Dr Richard Abel, Dr Ian Mudway

Imperial College London, London, London, United Kingdom

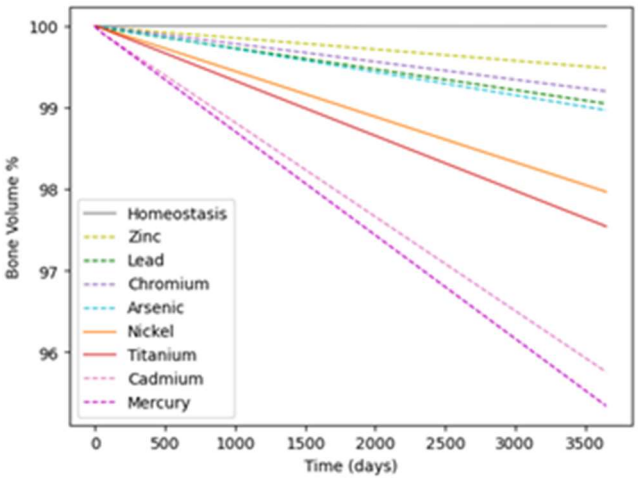
Introduction

Osteoporosis poses a global health challenge. A neglected cause for osteoporosis is $PM_{2.5}$ pollution. Epidemiological evidence shows associations between long-term $PM_{2.5}$ exposure with osteoporosis [1]. One hypothesis suggests that inhaled airborne $PM_{2.5}$ associated metals impact bone cell populations affecting bone remodelling. Therefore, we developed a computational model to simulate the long-term effects of inhaled $PM_{2.5}$ associated metals on bone.

Methods

A biological algorithm of bone remodelling was constructed with a pharmacokinetic–pharmacodynamic framework for $PM_{2.5}$ metals. It includes a bone volume (BV) calculation based on cell population dynamics. Pharmacokinetics follow metals from inhalation $Dose_{metal}$,through the serum compartment $Metal_{CC}$ with both a linear and a nonlinear Michaelis-Menten elimination rate into a bone compartment $Metal_{BC}$. $Metal_{BC}$ is mapped onto functions which modulate the different bone cell types, enabling the BV calculation.

Results



The model predicted the adverse effects of chronic exposure to Zinc, Lead, Chromium, Arsenic, Nickel, Titanium, Cadmium, and Mercury. Ten-year simulations produced bone loss values that are similar to the high levels seen in post menopause. Zn reduces BV by approximately 8.3% of overall BMD loss in post menopause [2]. Pb, As, and Cr resulted in approximately 17% of the BMD loss seen in post menopause [2]. Ni, Ti, Cd, and Hg produced BV decreases equivalent to 33%, 42%, 66%, and 76% of post-menopausal bone loss [2], respectively.

The studies used to get data on metal effects vary widely, so the units of their concentrations also vary. The figure shows the effects of Zn (300 mg/kg), Pb (5.00 μM), Cr (0.5mg/kg), As (10.00M), Ni (0.017 μM), Ti (209 μM), Cd (0.03 μM), and Hg (1.00 μM) on BV percentage over 10 years. The in-vivo and in-vitro data have been grouped for illustrative purposes.

Discussion

Simulations suggest that long-term, low-dose $PM_{2.5}$ metal exposures can meaningfully accelerate bone loss and potentially worsen osteoporosis risk. Even in a healthy baseline model without simulated postmenopausal decline, bone volume decreased by amounts comparable to those observed in menopausal women over a decade.

Basal Body Bending Due to Interactions of Motile Cilia in *Tetrahymena Thermophila*: Computational Modeling Reproduces Observations From Nanoscale 3D Imaging

Dr. Louis Woodhams PhD[1], Professor Phil Bayly PhD[1], Professor Chad Pearson PhD[2], Dr. Anthony Junker PhD[3], Dr. Adam Soh PhD[4]

[1]Washington University in St. Louis, Saint Louis, MO, United States. [2]University of Colorado School of Medicine, Aurora, CO, United States. [3]Emory University, Atlanta, GA, United States. [4]Duke University, Durham, NC, United States

Introduction

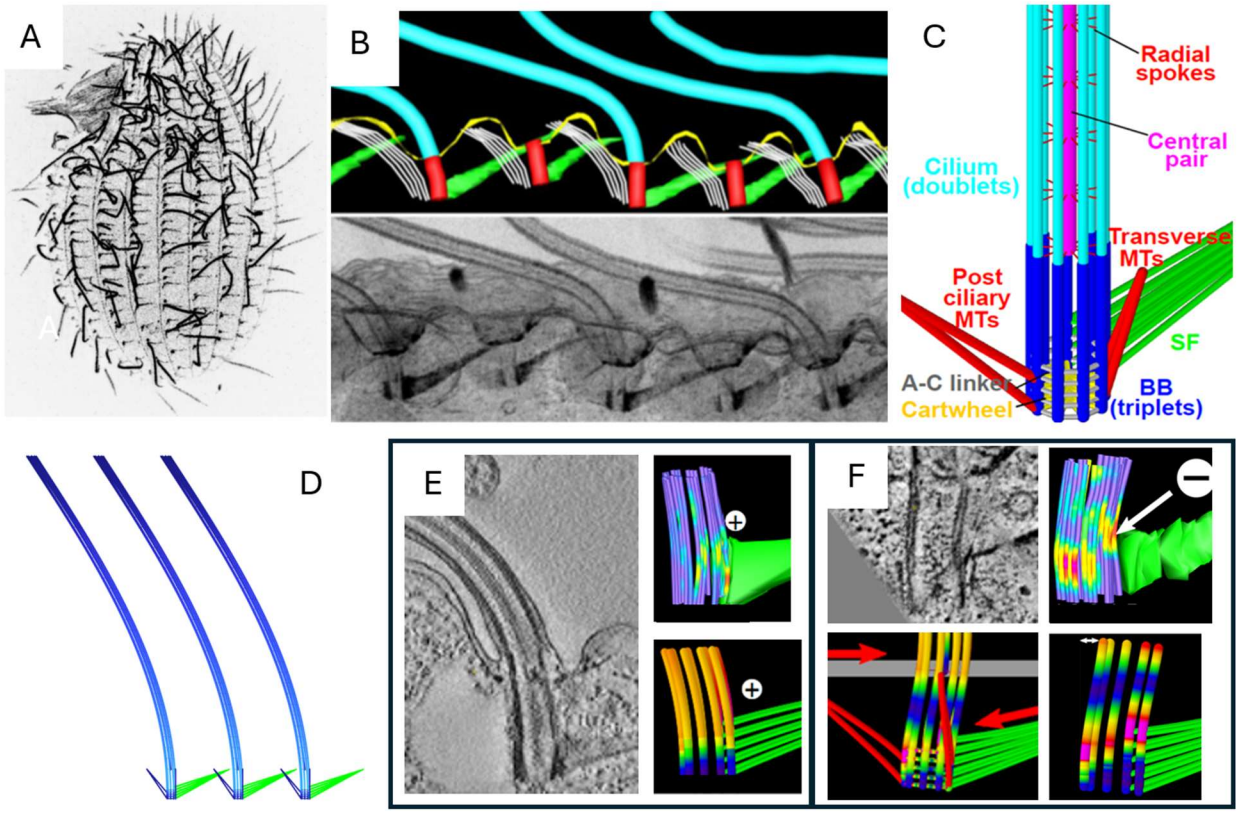
The single-celled organism *Tetrahymena thermophila* is propelled by an array of motile cilia structurally similar to those in human airways, making it an excellent model organism for studying ciliary beating. The approximately 400 cilia covering the surface of a *Tetrahymena* cell in a grid pattern (Fig. 1A) [1] do not beat in perfect synchrony; instead, metachronal waves of ciliary activity sweep across the cell surface much like "the wave" in a crowded baseball stadium.

In the current work, we apply computational modeling to better understand how internal forces transmitted by sub-cortical structures (Fig. 1B) cause deformations observed in *Tetrahymena* basal bodies (BBs). These forces may be responsible for ciliary coordination in a variety of organisms.

Methods

A computational model of the "9+2" ciliary axoneme and BB was built using commercial finite-element software using slender beam elements (Fig. 1C) [2]. Beating was driven by balanced internal forces and moments modeling the effects of dynein motor proteins. Sub-cortical forces between cilia were initially modeled using phase-delayed forces on the BB of a single cilium. In current work we expand this to a model of 3 interconnected cilia (Fig. 1D).

Results



The single-cilium model matched bend patterns observed in BBs at 37 °C (Fig. 1E). Recreating the counter-bends observed at 30 °C required applying a phase-delayed force to BB connections which modeled interactions between out of phase cilia and the structural differences observed in cells grown at lower temperatures (Fig. 1F).

Perturbations to the computational model reproduced deformations observed in mutants with deficiencies in BB interconnections (disA-1) and internal BB structures (Poc1Δ).

Discussion

The current computational model helps us to understand how internal forces create deformations observed in *Tetrahymena* BBs and gives us a way to test hypotheses about the roles of structures within and connected to cilia by perturbing their properties and connections. In ongoing work, we seek to understand how ciliary beating is coordinated by expanding the model to explicitly simulate multiple beating cilia and their interconnections.

A Microscale Thermal Measurement for Evaluating Thermal Transport Properties Induced by Biomacromolecular Structural Transitions

Mr. Rei Nagayama, Prof. Kosei Kawai, Prof. Jeonghyun Kim, Prof. Kosaku Kurata

Kyushu University, Fukuoka, Fukuoka, Japan

Introduction

Recent studies have reported the existence of intracellular hotspots that are locally elevated by 1-2 K relative to the surrounding cytosol. However, calculations of intracellular temperature rise based on heat conduction predict an increase of only 10^{-5} K. As a potential mechanism for these localized intracellular hotspots, we focused on changes in thermal transport properties associated with temperature-responsive structural transitions in biomacromolecules. Therefore, this study aimed to establish an experimental system capable of simultaneously measuring molecular structural changes and thermal transport properties while varying temperature within a microchamber.

Methods

A fine platinum wire was suspended within a microchamber capable of holding liquid samples, allowing localized heating by applying an electric current. First, the relationship between the wire's temperature and electrical resistance was calibrated, confirming that the thin wire can also be used as a temperature sensor. Second, using air, water, and Poly(N-isopropylacrylamide) (PNIPAM) ,which undergoes a hydration-structure transition at approximately 32℃, aqueous solution as samples, the thin wire was heated stepwise under varying heat inputs. The voltage drop and current across the wire were measured using the four-terminal method, and the average temperature rise of the wire was calculated. Finally, based on the heat balance of the thin wire, the average heat transfer coefficient between the wire surface and each sample was determined from the measured temperature rise.

Results

When the thin wire was surrounded by air or water, the average heat transfer coefficient increased in a temperature-dependent manner. Furthermore, the coefficient consistently higher in water than in air. In the PNIPAM aqueous solution, the highest heat transfer coefficient was observed at 35℃, which is above the transition temperature of approximately 32℃.

Discussion

In this experiment, a 100-μm-diameter wire was used. Heat transport from the wire to the surrounding sample is considered to be dominated by thermal conduction rather than convection. Therefore, the obtained average heat transfer coefficient reflects the thermal conductivity of the sample. The increase in the average heat transfer coefficient observed at 35°C in the PNIPAM solution indicates that this experimental system is capable of detecting changes in heat transport properties associated with temperature-responsive structural transitions.

Stress-induced Response of 3D Bioprinted Cell Filaments Under Controlled Strain Rate

Ms. Shanshan Zhang PhD student

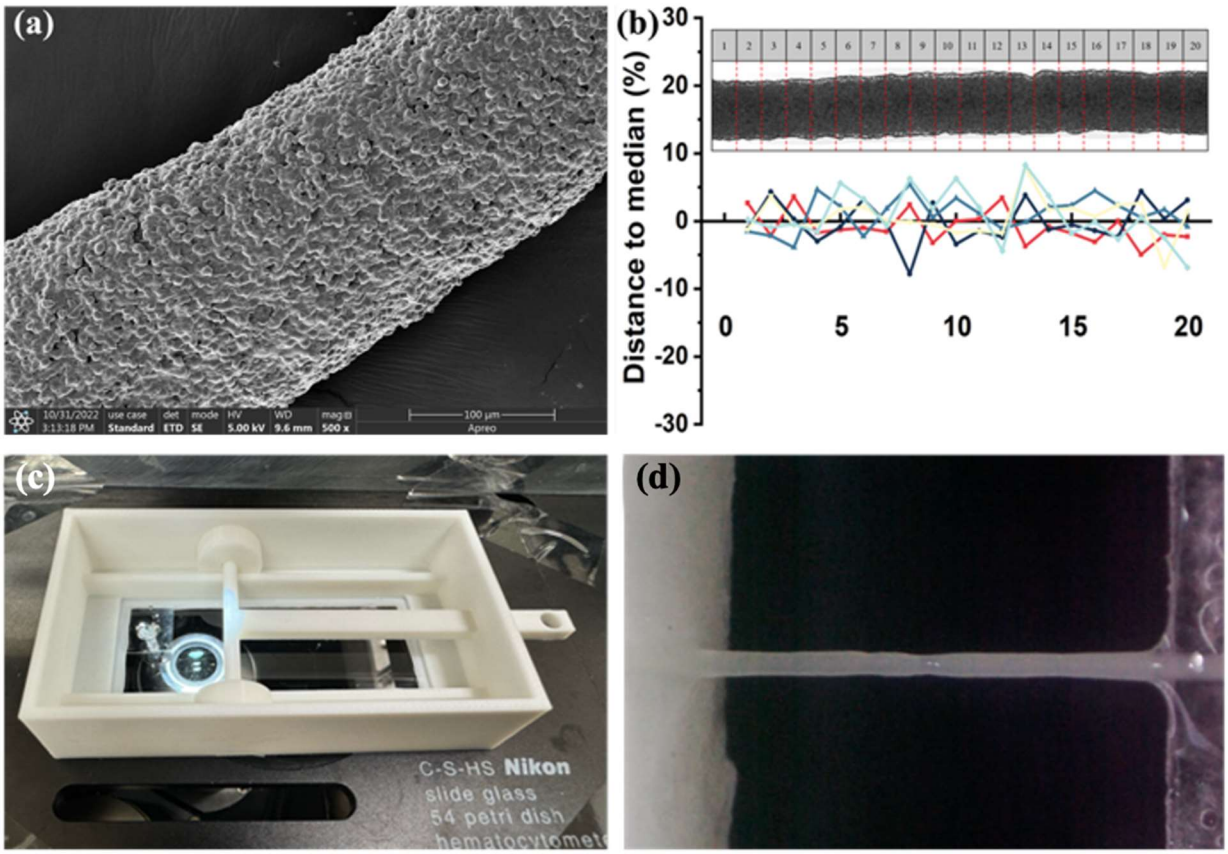
The University of Hong Kong, Hong Kong, Hong Kong, China

Introduction

Mechanical stress not only induces deformation but also triggers morphological remodeling and functional changes within tissues. However, most existing studies have focused on cell spheroids and monolayers, which have a complicated internal stress state and a two-dimensional (2D) nature. This makes it difficult to gain precise insights into how mechanical stress affects the behavior of 3D tissues [1]. In addition, although recent studies have demonstrated that necking and rupture can occur in strip-like heart tissues formed between two micropillars or constraining boundaries, the tensile stress developed there is solely due to active contraction of cells [2]. A method that allows for precise control of external stress on tissues with predefined geometry and composition is still lacking.

Methods

A micro tensile system was fabricated using digital light 3D printing. Force-sensing pillars were created by crosslinking polydimethylsiloxane (PDMS) with a weight ratio of 20:1 for the polymer and curing agent. Different strain rates were applied to the self-organization tissue, and optical images and videos recorded real-time changes in fiber morphology, focusing on necking and fracture processes. The instantaneous force on the fibers was calculated through the displacement of the micropillar, enabling characterization of stress changes over time due to external mechanical stimuli.



Results

The self-assembled cellular filaments have uniform diameters, providing standardized specimens for mechanical testing (Fig. 1a, 1b). The 3D-printed tensile platform delivers controllable, stable uniaxial tension (Fig. 1c), allowing uniform axial loading of the filaments. Optical imaging clearly reveals the morphological evolution of the filaments during tensile testing, including the onset of necking and its failure (Fig. 1d). By measuring the displacement of force-sensing micropillars, we can calculate the loading force on the filaments and compute the tensile stress in real time.

Discussion

Embedded bioprinting enables the systematic production of uniform cellular filaments. The tensile platform provides precise external force, allowing for the systematic investigation of stress-induced responses. This project will deepen our understanding of dynamic fracture of predefined micro-tissue and support the advancement of future theoretical models.

Receptor-Level Modelling of OPG-Modulated RANKL Gradients in a Microscale Chemokine Diffusion Platform

Ms. Mariia Mielkozorova PhD Student, Dr. Alexandra Komrakova Associate Professor, Associate Dean, Dr. Svetlana Komarova Professor, Chair of BME Department

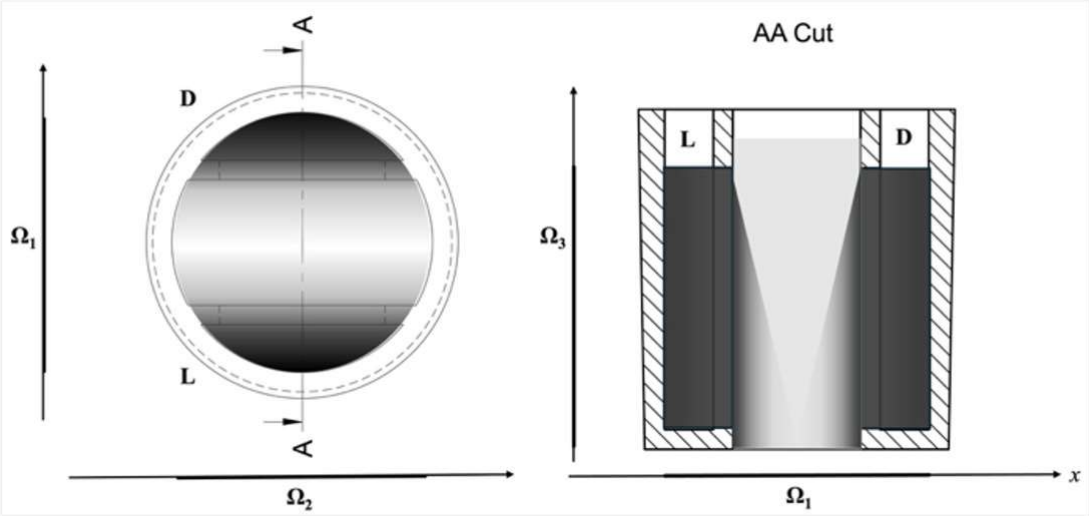
University of Alberta, Edmonton, Alberta, Canada

Introduction

Bone actively adapts to mechanical forces. At the cellular level, bone adaptation is actualized through the action of osteoclasts that resorb bone and osteoblasts that build bone. The key regulator of osteoclast formation and function is RANKL, a cytokine that binds to it cognate osteoclast receptor RANK. OPG is a decoy receptor that binds RANKL and prevents it interaction with RANK. We hypothesize that spatially segregated sources of RANKL and OPG can sculpt chemokine landscapes and mediate precise bone mechanoadaptation. In order to enable future experiments, we aimed to develop a quantitative framework that couples chemokine transport and interactions in experimental environments.

Methods

We engineered a 24-well plate insert with side pockets acting as RANKL and OPG reservoirs, separated from a central chamber by a rectangular window covered by a 70 kDa cut-off porous membrane. RANKL and OPG transport and interactions were simulated using coupled reaction-diffusion equations assuming experimentally suggested RANKL trimer/OPG dimer stoichiometry with Robin boundary conditions. Transport parameters were constrained using published data. Simulations were implemented in MATLAB.



Results

Simulations predicted that when RANKL is the only chemokine present in the system, the RANKL gradient develops across the central chamber within 24 h and is sustained for approximately 72 h, after which RANKL concentration reaches equilibrium across the domain. When only OPG is present in the system, the dynamics of gradient formation was similar, although since OPG dimer is of higher molecular weight, the gradient developed slower and was sustained for longer time. When OPG was placed in the chamber opposite to RANKL, RANKL gradient was steeper, and localized sink behaviour was developed. The position of the sink within the domain depended on initial RANKL/OPG concentrations. Preliminary experiments examined the stability and persistence of RANKL gradients over 3-6 days with and without OPG loaded in the opposite pockets.

Discussion

This study builds the integrated modelling-experimental platform to study live-cell behaviour in defined RANKL/OPG fields. By reframing OPG as an active sculptor of guidance cues, rather than solely a RANKL blocker, our work suggests novel mechanism of RANKL/OPG modulation to achieve precise bone adaptation to mechanical cues.

Directional Control of Cell Division Using Wavy PDMS Substrates for Evaluating Orientation-Dependent Responses to Tumor Treating Fields

Ms. YUEYING WU, Prof. Jeonghyun KIM, Prof. Kosei KAWAI, Prof. Kosaku KURATA

Kyushu University, Fukuoka, Fukuoka, Japan

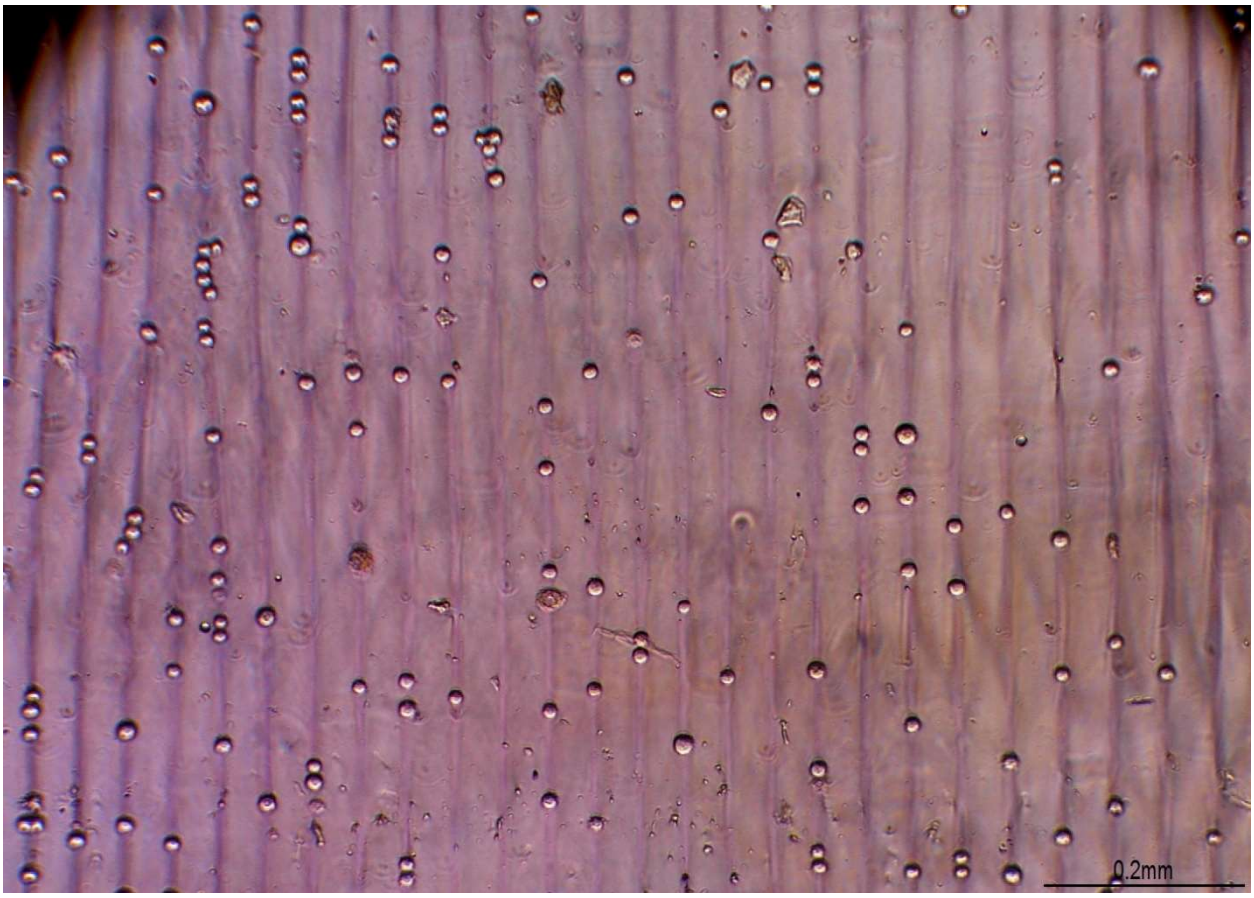
Introduction

Tumor-treating fields (TTF) are a promising cancer therapy that applies alternating electric fields to tumors. Previous studies have shown that TTF generates dielectrophoretic forces that reorient intracellular dipoles and disrupt cell mitosis, as most cells damaged after 72 hours of TTF exposure were found to divide along the electric field direction. To further elucidate the underlying mechanism, we aimed to induce the directional control of cell division and subsequently apply electric fields to cells with predefined orientation.

Methods

To regulate the orientation of cell division, we fabricated wavy wrinkle structures on PDMS substrates. Three-millimeter-thick PDMS films were stretched at ratios of 1.3–1.7 and irradiated with UV light for 20–25 min to induce surface wrinkles. A549 human lung adenocarcinoma epithelial cells were then seeded onto the wavy surfaces, where they preferentially divided along the wrinkle crest. After establishing directional control, electrodes were inserted into the cell culture dish to apply a 3 V, 300 kHz electric field. Time-lapse imaging was performed to evaluate mitosis duration, proliferation, and migration.

Results



Wavy PDMS patterns with wavelengths of 35–50 μm and amplitude of 5–20 μm were successfully fabricated. More than 50% of A549 cells divided along the crest direction, and division-orientation control improved with increasing wrinkle amplitude. No significant effect of wrinkle wavelength was observed.

Discussion

We found that the effectiveness of division-orientation control depends primarily on wrinkle amplitude. It was also influenced by cell attachment and seeding density. Preliminary evidence further indicates that the direction of TTF application may influence the duration of telophase, suggesting a directional dependency in the mitotic response to alternating electric fields. As a next step, we will extend the culture duration or delay imaging onset to enhance orientation stabilization. Once stable directional alignment is

established, TTF stimulation will be applied to these cells to further elucidate how electric-field directionality modulates mitotic progression.

How do the amplitudes of horse's gait affect the three-dimensional kinematics of the trunk and pelvis during riding in typically developing children?

MSc Leandra Aparecida Leal[1], PhD Andréa Gomes Moraes[2], PhD Kate da Costa Barcelos[3], PhD Amanda Piaia Silvatti[4], MSc Aline Dalfito Gava[1], PhD Ana Cristina de David[1]

[1]Universidade de Brasília, Brasília, DF, Brazil. [2]Secretaria de Estado de Educação, Brasília, DF, Brazil. [3]Universidade Federal de Goiás, Goiânia, Goiás, Brazil. [4]Universidade Federal de Viçosa, Viçosa, Minas Gerais, Brazil

MSc Leandra Aparecida Leal

Introduction

Each horse has a natural walking amplitude that generates different postural adjustments for the rider. This is an important factor in planning rehabilitation programs such as equine therapy. This study compares trunk and pelvis kinematics of typically developing (TD) children across different horse walk amplitudes: collected, medium, and extended.

Methods

The study included three TD children experienced in horse riding, aged 6, 11, and 13 years. The horse (*Crioulo* breed) measured 1.39 m at the withers and weighed 380 kg. Riders were equipped with a pad and straps without stirrups. In the collected walk, the hind limb does not overtake the forelimb; in the medium walk, it overlaps; and in the extended walk, it exceeds it. Data were collected in a closed sand arena using eight Vicon Vero v2.2 cameras at 100 Hz, positioned four cameras on each side covering a 10 m distance. The Plug-in Gait full-body protocol with 39 markers was used, and three additional markers were placed on each horse’s hooves. Data were normalized to the horse's gait cycle using forelimb strike as reference, and descriptive analyses were based on the average of three trials.

Results

The speeds (m/s) of the horse´s walk amplitudes were: collected (0.69±0.07), medium (0.97±0.05), and extended (1.54±0.06). It was observed that the pattern of trunk and pelvic

curves in children is similar across the three gait amplitudes of the horse. However, the trunk and pelvis exhibit greater amplitude in the sagittal and frontal planes during the extended equine gait (Figure 1).

Discussion

The results show that the horse's gait amplitude influences trunk and pelvic movements in children, indicating greater postural demands during extended walking. These preliminary findings may assist equine therapy professionals in selecting appropriate strategies based on therapeutic goals. Further studies with a larger number of participants and different horse breeds are needed.

Emergent Behaviors in Human Compensatory Stepping Following Impulsive Torso Perturbation

Mr. Bhavya Giri Goswami MASc Student, Systems Design Engineering, Prof. Arash Arami Associate Professor, Mechanical and Mechatronics Engineering, Prof. John McPhee Professor, Systems Design Engineering

University of Waterloo, Waterloo, Ontario, Canada

Mr. Bhavya Giri Goswami

Prof. Arash Arami

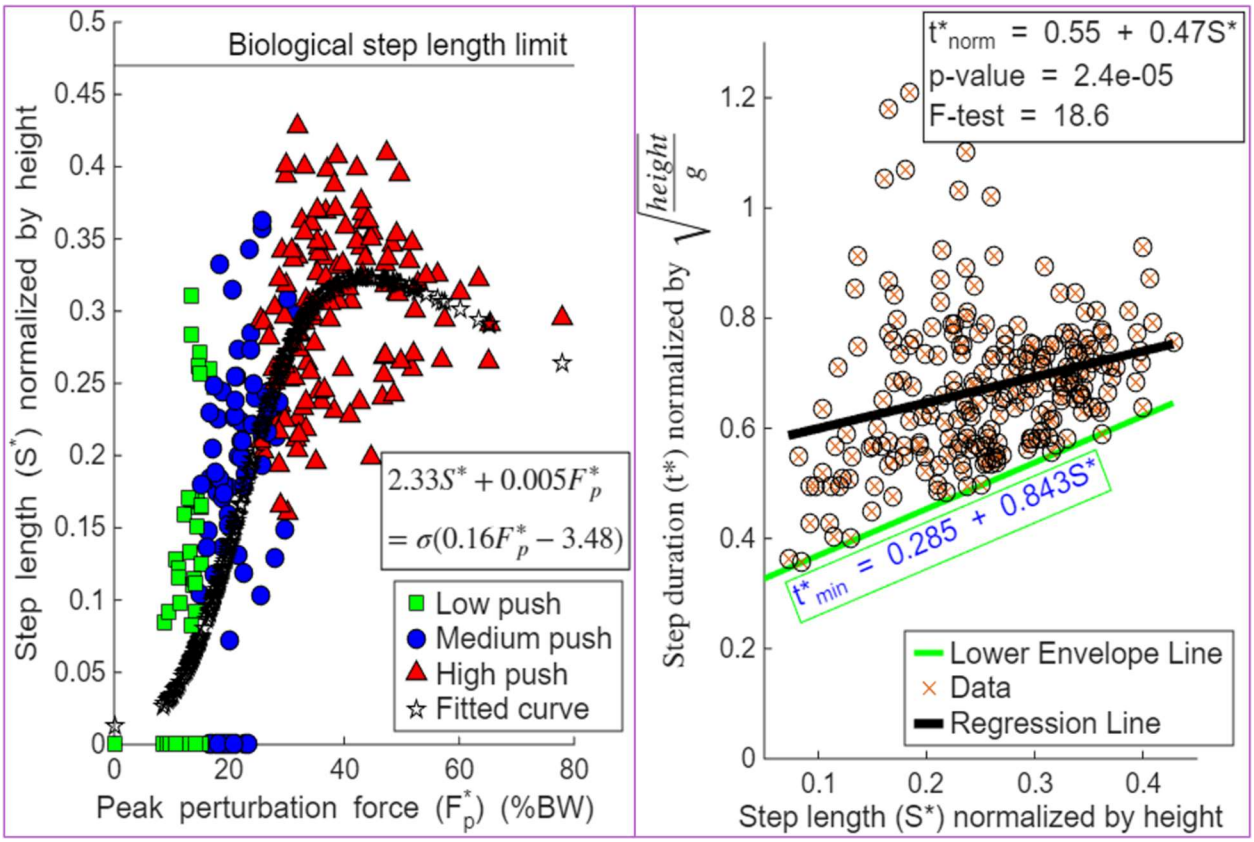
Introduction

Single-step compensatory stepping is a reactive balance strategy used when large, unexpected perturbations push the center of mass (CoM) outside the base-of-support (BoS). While sagittal-plane stepping has been extensively studied[1], our impulsive torso perturbation experiments revealed some new observations.

Methods

Ten able-bodied participants (23.3±2.1yrs; 67.2±13.4kg; 1.73±0.06m; 5M/5F) received anterior–posterior impulsive torso perturbations of three magnitudes (Low <15%BW, Medium <25%BW, High <65%BW). Ten perturbations of each type were applied in random order, above the sacrum using a padded push-stick with an inline 3-axis force sensor. Participants were instructed to “balance naturally”. Whole-body motion capture, force plates, and leg EMG data (Soleus, Tibialis-Anterior, Rectus-Femoris, Bicep-Femoris) were recorded and processed to calculate stepping parameters (S*, t*) and muscle co-contraction.

Results



- Out of 305 trials across all participants, 228 (~75%) involved compensatory stepping; the remainder were stabilized using feet-in-place ankle strategy. Stepping probability increased with perturbation magnitude, reaching 50% at ~16.1%BW and 100% at ~25%BW peak force.

- Step length exhibited a sigmoidal(σ) relationship with peak push force, saturating at larger forces—likely due to biomechanical limits and the need for multiple steps.
- Step duration increased significantly with step length, with high variability for steps shorter than 0.25×height. Moreover, step duration appeared lower-bounded by a linear function of step length, likely reflecting muscle contraction limits.
- The inefficient hip strategy was absent, with negligible pre-toe-off bilateral hip flexion (-0.33±1.50°), minimum Rectus-Femoris activity, and a minor difference in ZMP-CMP trajectories[2] (0.0±2.8mm). This is likely due to perturbation location and induced randomness.
- 76.6% of compensatory steps used toe or mid-foot strike rather than heel strike. This pre-contact plantarflexion shifts the center of pressure anteriorly to enhance CoM deceleration.
- Swing-leg ankle co-contraction before step initiation strongly correlated with the time between CoM projection exiting the BoS and toe-off (r=0.78).

Discussion

This study identifies several new characteristics of sagittal-plane compensatory stepping, including step-force relationships, strategy selection, distinctive foot-strike, and EMG behaviors. These insights can support improved predictive models and control strategies for exoskeletons and prostheses.

Balancing for Two: Inverted Pendulum Model of Pregnancy Reveals Energy/Stability Tradeoff in Adaptation to Added Mass During Standing Balance

Ms. Autumn Routt[1], Dr. Hansol Ryu[1,2], Dr. Kristen Jakubowski[1,2], Dr. Gregory Sawicki[1], Dr. Lena Ting[2,1]

[1]Georgia Institute of Technology, Atlanta, Georgia, United States. [2]Emory University, Atlanta, Georgia, United States

Introduction

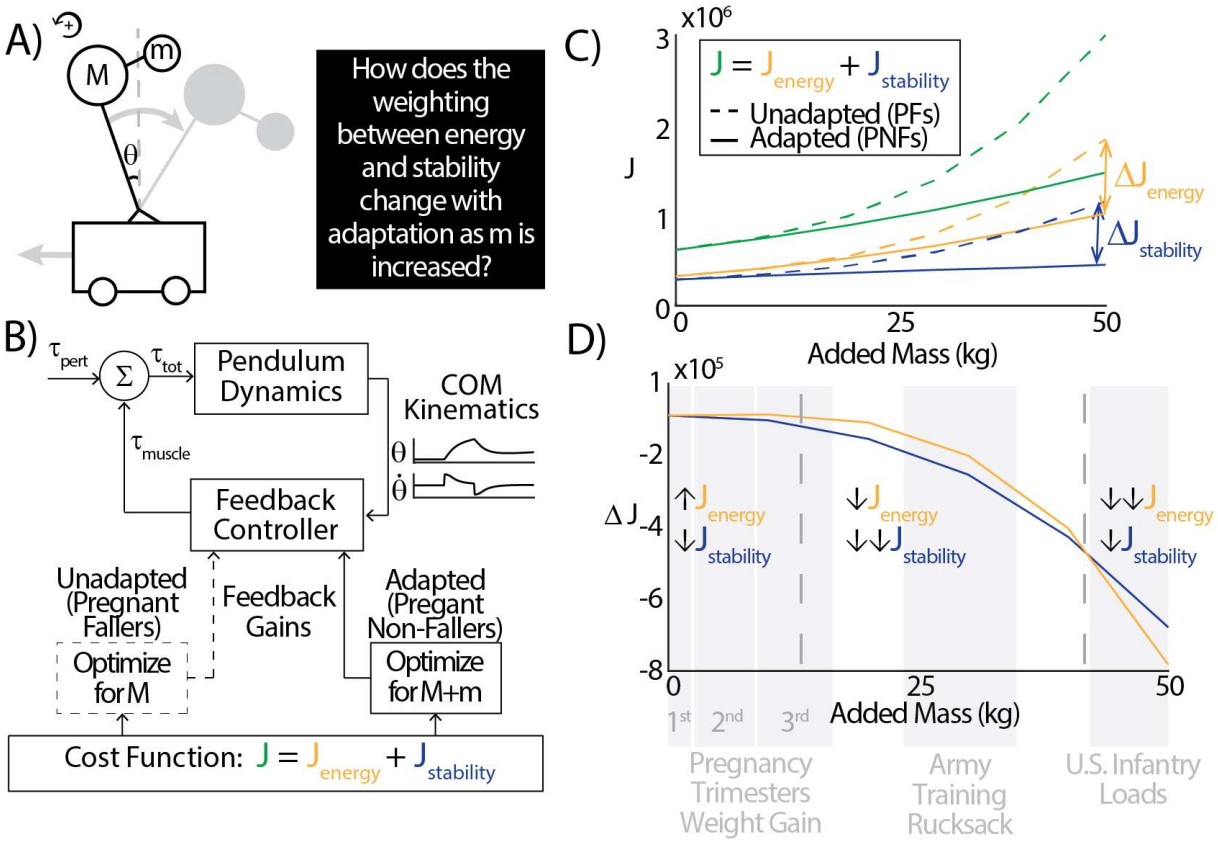
Whether you are carrying a baby or a rucksack, it is important to be able to adapt to added mass. Pregnancy is an extreme example. Falls in pregnancy are common and dangerous, so pregnant people who avoid falling can be considered expert adapters. Prior literature counterintuitively shows that pregnant non-fallers (PNFs) exhibit greater center of mass (COM) displacement during perturbed standing balance compared to pregnant fallers (PFs) [1]. We developed a computational model to test whether increased COM displacement could be attributed to PNFs being better adapted than PFs to added mass. We hypothesized that this difference could be explained by PNFs prioritizing the reduction of energy costs over stability.

Methods

The dynamics-based model simulated an inverted pendulum on a cart with offset added mass (Fig.1A). A feedback controller used angle and angular velocity to create a torque at the pivot point (Fig.1B). We compared outputs from gains optimized for added mass ("adapted") and no added mass ("unadapted") based on a cost function comprised of the sum of squared muscle torques (J_{energy}), and the sum of squared angles and squared angular velocities ($J_{stability}$).

Results

The adapted model reduced stability costs relative to the unadapted model for all conditions (Fig.1C&D). With small added mass, adaptation increased J_{energy}. With larger added mass, both J_{energy} and $J_{stability}$ were reduced, but J_{energy} was reduced more than $J_{stability}$ when added mass >40kg.



Discussion

Our adapted model did not explain increased COM excursion in PNFs. At loads similar to pregnancy, stability costs were always prioritized over energy costs. This might mean that the difference in prior literature is from musculoskeletal remodeling rather than alterations

in neural control strategy. Alternatively, some of the assumptions made in this simulation, particularly that PFs are best represented as being adapted to zero added mass and that cost function weights are fixed over the adaptation period, may be incorrect.

When loads were increased to those of a rucksack, energetic costs were sometimes prioritized over stability costs. This means for very large loads there may be a threshold past which stability is compromised because of heightened energy costs.

Perturbation Recovery Time Detects Age-Related Changes in Balance Control of Running

M.Sc. Carlo von Diecken, M.Sc. Luca Braun, M.Sc. Bastian Anedda, M.Sc. Laila Sikeler, M.Sc. Janina Helwig, M.Sc. Sebastian Rehorst, Prof. Steffen Willwacher

Institute for Advanced Biomechanics and Motion Studies, Offenburg University of Applied Sciences, Offenburg, Baden-Wuerttemberg, Germany

Introduction

Balance control declines with age due to losses in muscle strength and sensory input, with deficits emerging at the fourth decade of life during challenging tasks. Running is a complex motor task requiring continuous and tight regulation of whole-body angular momentum (WBAM), which may be altered by age-related decline. When balance is further challenged by a perturbation (e.g., a slip), the resulting sudden shift in WBAM must be rapidly counteracted to prevent a fall. An accurate method for assessing this balance control during running would enable screening for deficits and facilitate early intervention.

Methods

Twelve young adult (26.8 ± 4.0 years; YR) and nine older adult (51.9 ± 3.8 years; OR) recreational runners completed 8 min treadmill runs at 2.78 m/s under normal running (NR) and restricted arm swing (RA) conditions, while sudden anterior-posterior slip-like perturbations were applied at pseudo-randomized time intervals. Normalized WBAM (nWBAM) in sagittal and frontal planes was computed from full-body kinematics and time-normalized to the gait cycle. Subject-specific 95% prediction bands (PB95) were constructed from unperturbed nWBAM curves (Fig. 1A). Perturbation recovery time (PRT) was defined as the duration from perturbation onset to the final time point at which either nWBAM curve exceeded PB95 bounds (Fig. 1A, B). A linear mixed-effects model assessed main and interaction effects of age group and running condition on PRT.

Results

PRT showed a significant condition–age-group interaction (p=0.004) with RA significantly increasing PRT in older runners (+0.43 s, p<0.001), but not in younger runners (+0.11, p=0.119). Further, no age-group differences were observed during NR (+0.03 s, p=0.821), but older runners exhibited longer PRT than younger runners under RA (+0.34 s, p=0.011; Fig. 1C).

Discussion

PRT increased in older adults only when perturbations were combined with restricted arm swing, indicating that age-related deficits in perturbation recovery emerge under added task constraints. This is supported by previous work showing that arm swing contributes to quick balance recovery and that subtle balance deficits become evident primarily during challenging tasks. Importantly, PRT combined with task manipulation distinguished between age groups, supporting its potential as a sensitive measure of balance control during running.

A Novel Framework for Probing Inter-Limb Control in Standing Balance

Ms. Caroline Aitken M.E.Sc., Mr. Amin Nasrabadi M.E., Dr. Jean-Sébastien Blouin Ph.D., Dr. Lyndia Wu Ph.D., P.Eng.

The University of British Columbia, Vancouver, British Columbia, Canada

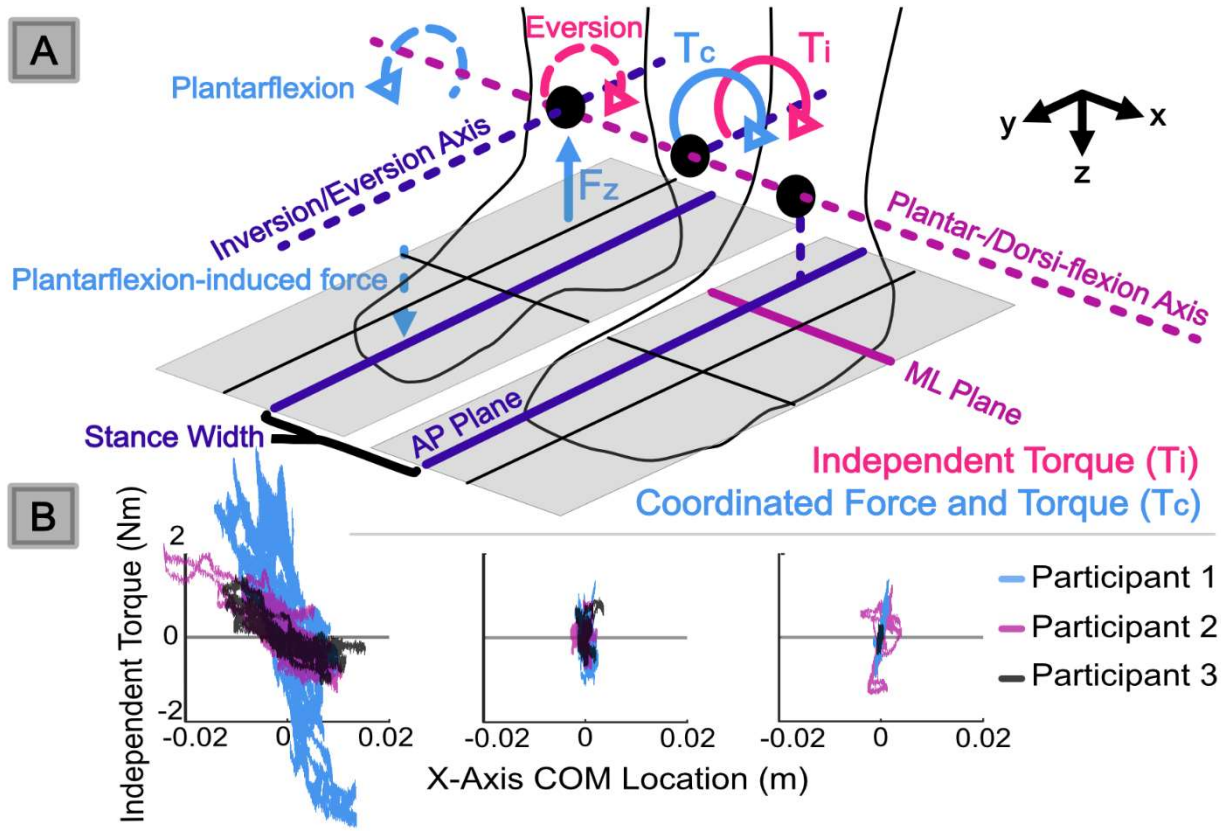
Introduction

Altered mediolateral (ML) balance is a hallmark of some neurodegenerative diseases and neural injury. Most authors quantify the centre of mass (COM) or the centre of pressure to estimate balance control under varied sensory conditions. Although this approach provides global measures of balance, it assumes inter-limb coordination is not an important aspect of balance deficits in clinical populations. To address potential deficits associated with inter-limb coordination, we developed a novel framework using two force plates to estimate bilateral torques required for standing balance control. We hypothesize that inter-limb control strategy preference varies with stance width.

Methods

Data were collected from three healthy participants standing on two force plates for 40 seconds at stance widths of 50%, 100%, and 150% of hip width (inter-hip-joint distance). The plantar/dorsiflexion and inversion/eversion axes of each foot were aligned with the anteroposterior (AP) and ML plane of the corresponding force plate (Fig. 1A). Force plate data were transformed to the ankle, and the COM's gravitational torque component – calculated using double-integration of the ground reaction forces – was removed to isolate the control signal.

Ankle inversion/eversion torques (T_i) contribute to ML motion (Fig. 1A). Plantar- and dorsi-flexion ankle torques also generate vertical forces at the ankle (F_z). When bilateral F_z have the same magnitude, pure AP torque is generated; asymmetric F_z also produces an ML torque (T_c) that increases with wider stance widths. To assess strategy preference, we compared torque variability between stance widths.



Results

T_i at 50% stance width had 8.8- and 11.4-times higher variability than at the 100% or 150% stance width (Fig. 1B). T_c variability was 12- and 8-times greater at 150% compared to 50% and 100% stance width.

Discussion

At narrow stance widths, larger T_i is likely necessary due to the smaller T_c torque arms. At wider stance widths, participants prefer the higher mechanical gain of T_c to enable the maintenance of upright balance. In future analyses, we will explore the coupling of control between the AP/ML planes, with the hope to establish a framework to reveal how neural degeneration and injury impact inter-limb coordination needed for the ML control of balance.

Stable Centre of Pressure Control Is Critical for Balance in the Handstand

Dr. Charlotte Le Mouel

CNRS, Sorbonne Université, Paris, 75005, France

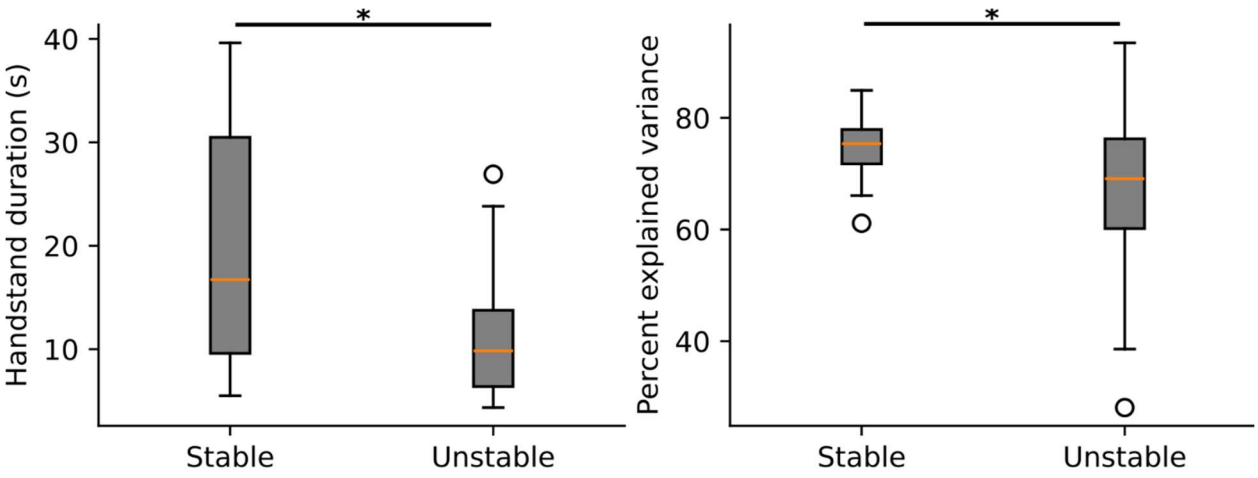
Introduction

During standing balance, participants control their Centre of Pressure (CoP) according to the Centre of Mass (CoM) state. This requires integrating proprioceptive, visual and vestibular information, as there is no physiological sensor of CoM state. Intriguingly, when skilled gymnasts perform the handstand, they also control their CoP according to their CoM state, indicating a novel sensorimotor coordination. We hypothesise that this sensory integration emerges over skill learning, with less accurate CoP control resulting in shorter handstands.

Methods

Sixteen intermediate-level gymnasts (inclusion criterion: being able to perform the handstand for more than 5 seconds) performed handstands during two 3-minute trials. The CoP was recorded using force plates. Full body kinematics were recorded using motion capture, and used to estimate the CoM position. The CoP was reconstructed as a linear sum of the delayed CoM position and velocity in the sagittal plane, yielding the proportional and derivative gains. The stability of the CoP controller on a given trial was determined analytically, depending on whether a controller with these gains can stabilise an inverted pendulum. We thus quantified both the accuracy with which the CoP followed the CoM (percent of CoP variance explained by CoM state) and whether the resulting controller was stable.

Results



Of the 93 recorded handstands, 43 % adopted a stable CoP controller in the sagittal plane. These handstands had a significantly longer duration than those with unstable controllers (16.7 seconds versus 9.8 seconds) and more accurate CoP (75.4 % of CoP variance explained by CoM state for stable and 69.1 % for unstable trials).

Discussion

Contrary to our hypothesis, intermediate-level gymnasts have an accurate control of the CoP both for short and long handstands, suggesting that their skill is not limited by their sensory integration. Instead, their handstand durations are limited by their motor coordination, in particular their ability to adopt stable CoP controller gains. This may be

due to limited wrist flexion strength. This suggests that sensory integration of CoM state in the handstand is learned very early on in the skill acquisition process, and may be critical for achieving handstands lasting more than 5 seconds.

Maintaining Functional Mobility: Effects of Ankle Bracing on Multi-Planar Joint Control During Landing Tasks

Dr. Clark Dickin, Dr. Henry Wang

Ball State University, Muncie, IN, United States

Introduction

Despite the use of Parachute Landing Fall techniques and Parachutist Ankle Braces, ankle injuries remain common during high-impact military landings. Extending support through the metatarsals, this study evaluated the effectiveness of an over-the-shoe External Ankle Brace (EAB) in stabilizing the ankle during landings from height. The goal was to determine whether the EAB could provide frontal and transverse-plane stability while permitting functional sagittal ankle motion without significantly altering knee or hip mechanics. We examined these effects across three landing styles: forward feet-apart, sideways feet-apart, and sideways feet-together.

Methods

Twenty healthy young adults performed landings from 20, 40, and 60 cm under two conditions: standard cross-trainer shoes (SHOD) and EAB worn bilaterally over the shoes. Each participant completed 3–5 trials per landing style and height, totaling 27-45 landings per session across two completely randomized test days (footwear, height, and jump style). A 12-camera Vicon motion capture system and two AMTI force platforms recorded three-dimensional joint kinematics and ground reaction forces, and inverse dynamics estimated joint torques for the two feet-apart landing styles.

Results

The EAB provided significant frontal and transverse plane control, reducing ankle eversion (21-41%) across all landing styles ($p < 0.001$), with the smallest eversion observed in sideways feet-together landings. EAB also reduced ankle abduction (5-16%), significantly for the sideways feet-apart landings ($p = 0.048$). While ankle dorsiflexion was reduced compared to SHOD ($p < 0.001$), sagittal mobility was only reduced by 2-6% across the landing heights and styles. Kinetic analysis for the two feet-apart styles showed a 20% reduction in plantarflexion torque and a 43% reduction in external rotation torque compared to SHOD, while frontal plane torque showed a minimal increase. Knee and hip loading patterns remained largely unchanged, indicating minimal transfer of load proximally.

Discussion

The EAB effectively provided frontal and transverse ankle stability while maintaining functional sagittal motion and not significantly altering knee or hip mechanics. While the landing heights were conservative, the general dose-response effects support the use of an EAB as a viable intervention to reduce ankle injury risk during high-impact landings, particularly in military and tactical contexts.

Eye Drop Instillation Success Is Associated With Eye Drop Bottle Dynamics During Instillation

Mr. Daniel Duque Urrego[1], Dr. Stephen Cain[1], Ms. Ming-Chen Lu[2], Ms. Leslie Niziol[2], Mr. Cameron Haire[2], Dr. David Burke[2], Dr. Susan Brown[2], Dr. Paula Newman-Casey[2], Dr. Alanson Sample[2]

[1]West Virginia University, Morgantown, WV, United States. [2]University of Michigan, Ann Arbor, MI, United States

Introduction

Stability metrics derived from eye drop bottle acceleration in an inertial frame (free-acceleration) are associated with eye drop instillation success, but calculating free-acceleration from a bottle-mounted inertial sensor (IMU) requires gravity removal and frame transformations [1]. The objective of this study was to test whether stability metrics calculated from raw bottle-mounted IMU data, which do not require gravity removal or transformation, are also associated with instillation success. Simpler approaches could reduce the complexity of “smart bottle” implementations to monitor medication adherence events and instillation quality.

Methods

Ninety-nine older adults completed 18 instillation trials (three per eye in standing, sitting, and lying). A bottle-mounted IMU recorded linear acceleration and angular velocity. For each instillation attempt, we identified an instillation period using a velocity-based window. We computed stability metrics like those used for postural analysis from raw IMU data, as well as bottle tilt and instillation duration. Drop success (yes/no) was determined from synchronized video. For each posture and metric, we fitted an univariable logistic generalized estimating equation (GEE) with success as the outcome, the z-scored metric as the predictor, subject as the clustering factor, and an exchangeable working correlation. Odds ratios (ORs) with 95% confidence intervals were estimated, and adjusted p-values using the Holm method.

Results

Larger raw accelerations and angular velocities were associated with lower odds of drop success. In the lying posture, a 1-SD increase in peak planar acceleration was associated with ≈18–19% lower odds of success (ORs 0.81–0.82, adjusted $p \leq 0.002$). Lying angular-

velocity metrics showed smaller but significant effects: 1-SD increases in mean, and RMS angular velocity corresponded to ≈4–11% lower odds of success (ORs 0.89–0.96, adjusted $p<0.01$). Many remaining metrics had odds ratios near 1.0, indicating negligible effects.

Discussion

Even without gravity removal or frame transformations, stability metrics calculated using raw bottle-fixed IMU data captured consistent differences between successful and unsuccessful instillations. Compared with our earlier free-acceleration, multi-frame analysis[1], effect sizes were smaller but directionally consistent, suggesting that streamlined, on-device processing of raw signals may be sufficient for real-time feedback and integration into cloud-connected adherence systems.

Images (Optional)

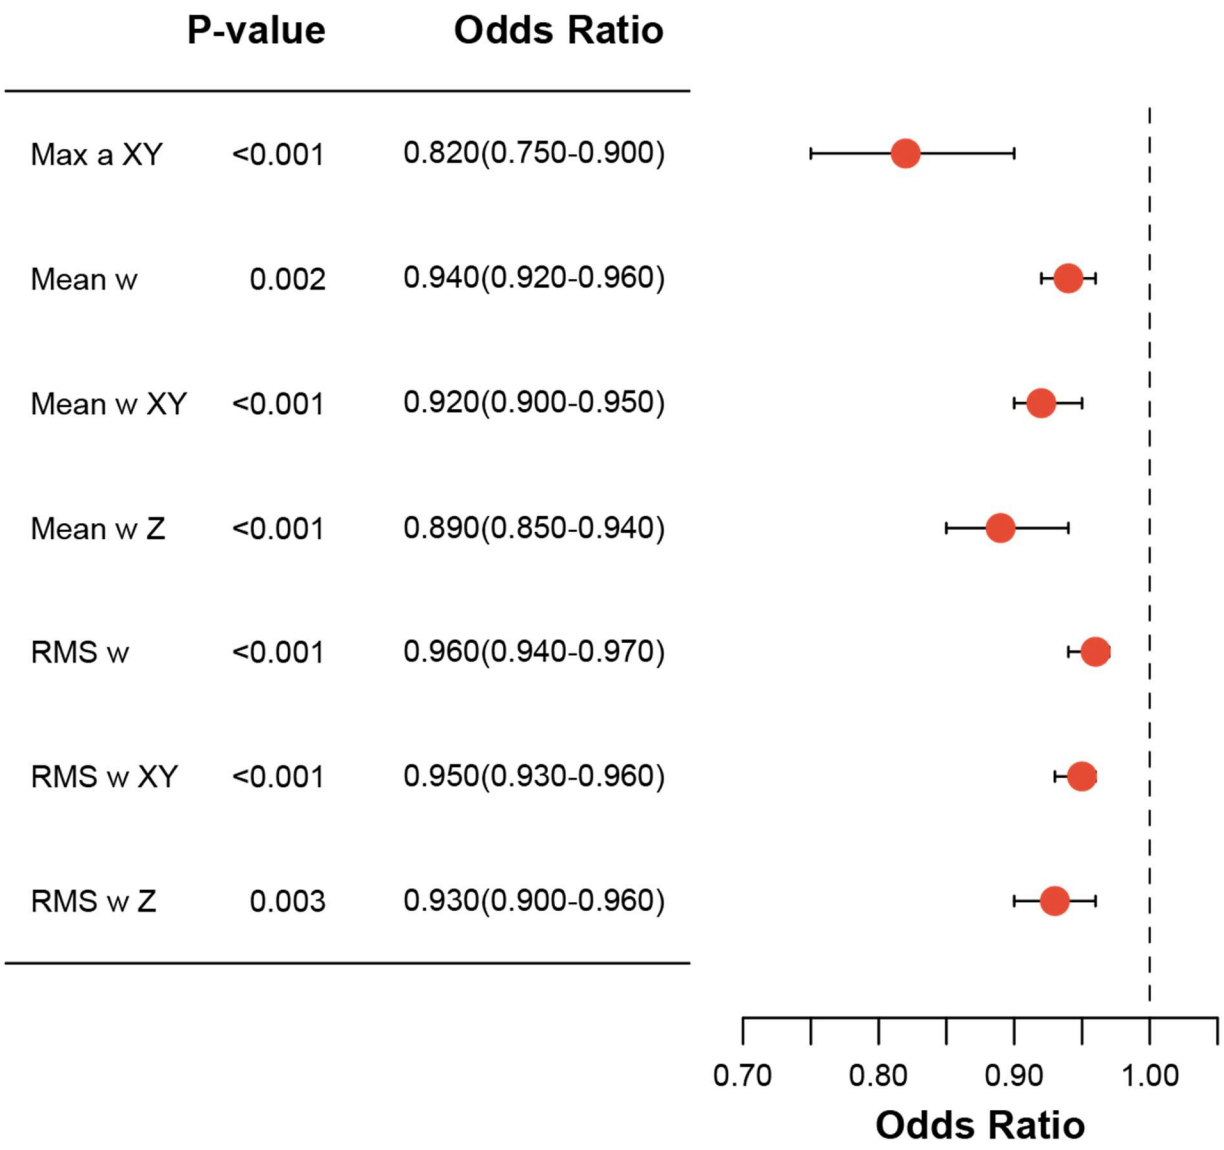

Figure 1. Odds ratios (points) and 95% confidence intervals from univariable logistic GEE models relating standardized bottle-fixed stability metrics to the odds of drop success in the lying posture. Each odds ratio corresponds to a 1-SD increase in the listed metric; the dashed vertical line indicates no association (OR = 1). All metrics shown are significantly associated with lower odds of success (Holm-adjusted p-values shown in the table; a = linear acceleration, w = angular velocity, RMS = root mean square).

Phase-Specific Characterization of Human Bimanual Coordination for Dexterous Robot Hand Manipulation Strategies

Master's student En-Lin Kuo[1], Ph.D Bing-Shiang Yang[1,2]

[1]National Yang Ming Chiao Tung University, Hsinchu, Hsinchu, Taiwan. [2]Industrial Technology Research Institute, Hsinchu, Hsinchu, Taiwan

Introduction

Previous studies have examined bilateral coordination in simple tasks, but few focuses on hand interactions during naturalistic fine manipulation. Also, most existing work treats behaviors as continuous trajectories, without examining how coordination patterns change across task segments.

To address these gaps, this work will provide a data-driven segmentation method with detailed characterization of inter-hand coordination and role allocation. These findings offer a foundation for designing bimanual robotic policies that reflect human coordination patterns, interaction strengths, and role distributions, supporting generalized manipulation strategies applicable to complex, real-world tasks.

Methods

In this study, we use marker-based optical motion capture system (Vicon, 100 Hz) with seven cameras with 29 reflective markers, and four activities of daily living tasks were performed in the experiment.

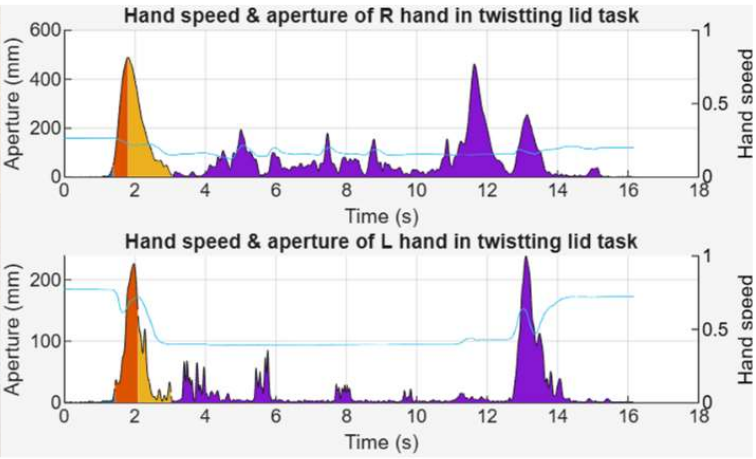
Movement segmentation was performed using finger aperture and hand velocity. For each phase, four kinematic parameters (hand speed, palm speed, finger aperture, and thumb-finger angular velocity) were analyzed using a sliding-window approach to compute regression dependency (RD), Pearson correlation, and phase coupling index (PCI). All metrics were standardized using z-score normalization to allow cross-parameter comparison.

Results

Several consistent patterns were observed in the preliminary data. For symmetric bimanual tasks, all segmentation indicators exhibited a rapid increase at the reach phase. Two hands showed highly similar parameter trajectories throughout the task. During

manipulation phase, correlation and RD values for hand speed and palm speed remained close to 1. These patterns demonstrating strong temporal synchrony and biomechanical similarity between hands.

In asymmetric cooperative tasks, RD and correlation trends diverged depending on the specific object and action during manipulation phase; however, PCI consistently exceeded 0.5, indicating that both hands contributed actively through complementary rather than mirrored roles.



Taken together, these results providing quantitative signatures of how humans coordinate their hands across different forms of daily manipulation.

Discussion

Compared to prior work, our findings extend the understanding of bimanual coordination to more naturalistic, daily life actions. The identification of complementary control strategies expands existing frameworks, emphasizing that effective cooperation does not solely rely on synchronization but also on functional differentiation between hands. Offering a methodological foundation and guiding principles for future investigations and applications in robotic systems.

Frontal Plane Peak Hip Net Joint Moments Vary With Thigh Angle During Walking and Turning

Ms. Erin Kreis, Ms. Zahava Hirsch, Dr. Jun Liu PhD, Dr. Mitchell Tillman PhD, Dr. Antonia Zaferiou PhD

Stevens Institute of Technology, Hoboken, New Jersey, United States

Introduction

Our prior research found significant differences in frontal hip net joint moments (NJM) between straight-line gait (SLG) and turns. Inspection of net joint forces and segment angles indicated the difference could stem from a whole-body strategy of leaning into the turn. The objective of this analysis was to determine whether thigh inclination angle is associated with peak NJMs during SLG and turns, and whether relationships differ by age cohort.

Methods

Healthy young adults (n=7; 20.4 ± 1.13 years) and older adults (n=16; 70.9 ± 5.58 years) completed 12 SLG and 90-degree left turn trials along a T-shaped intersection. Optical motion capture (Optitrack) and force plates at the intersection (Bertec) were used. Internal frontal hip NJM were calculated during the force plate stance phase. Turns were classified as “step” or “spin” turns based on which foot was closest to the intersection center [1]. Trials without acceptable force plate contact were excluded, leaving data from four young and six older adults.

The frontal-plane thigh angle at the time of peak NJM was calculated relative to vertical. Positive angles indicated the hip was medial to the knee. Linear mixed effects models evaluated hip frontal NJM peaks in each direction as a function of thigh angle, with age cohort, task, and foot as grouping variables. Random intercepts were used across subjects.

Results

Peak hip abductor ($p<0.001$) and hip adductor ($p<0.001$) NJM are strongly negatively associated with thigh inclination angle (Fig. 1). There was no evidence of group differences between young and older adults or right and left foot.

Discussion

Frontal plane thigh angle strongly associated with hip NJM peaks during SLG and turning. Whole-body lean into turns changes the thigh angle and its alignment with the knee net joint force, compared to SLG where the leg remains mostly upright. There were no significant differences between the cohorts, suggesting lean strategies during turns and their associated modifications in NJM could be used similarly by both groups. We are currently working on expanding the sample size. Further analysis will deepen our understanding of how turn strategies may impact joint loading and health.

Comparative Functional Trajectory Analysis of Gait Stability Metrics Across Sensory and Mechanical Perturbations

Mr. Francis FASUYI, Dr. Gary Heise, Dr. Abbie Ferris

University of Northern Colorado, Greeley, CO, United States

Introduction

Walking stability requires seamless integration of multiple sensory systems (visual, vestibular, and somatosensory). While stability metrics are traditionally discrete points (e.g., heel strike), full comprehension of sensory and mechanical constraints' influence on stability requires complete functional trajectory analysis of metrics over the entire gait cycle. This study quantified continuous trajectories of ten directional stability metrics (traditional-margin of stability (MOS), center-of-pressure (COP)-normalized MOS, height-normalized MOS, inclination angle (IA), and measured vs. modeled COP misalignment (dCoPmCoP)) across stance phase under seven perturbation conditions compared to normal walking (NW). We hypothesized that all perturbations would functionally alter stability metrics and that the temporal response of these perturbations would be significantly modified by age.

Methods

Fourteen (8 young: 28.9±2.0 years, 6 old: 69.6±2.9 years) healthy adults completed eight NW, including perturbations: NW-on-foam (NWF), narrow-base-walking (NBW), NBW-on-foam (NBWF), head tilt vestibular perturbations in the frontal (NWFHM), sagittal (NWSHM), and transverse (NWTHM) planes, and visual perturbation using stroboscopic glasses (NWVP). Full-body kinematic and kinetic data were recorded and lowpass filtered. Using functional linear mixed models with bootstrap inference to model the trajectory of each metric, we functionally tested (1) condition contrasts against NW with simultaneous confidence bands, (2) sensory system contributions, (3) stance phases (loading: 0-20%, mid-stance: 20-52%, terminal: 52-83%, pre-swing: 83-100%), and (4) age × condition × time interactions.

Results

NBWF caused the strongest disruptions, with the largest changes across all measures. Mediolateral stability was more affected (more significant time-points for NBWF) than anterior–posterior, especially during terminal stance (50–60%), when instability peaked. Visual challenges showed minimal effect, while vestibular challenges produced direction-specific effects, with frontal head movement improving stability, while sagittal movement

reduced it. Age*condition interactions showed older adults exhibited 35% larger responses to NBWF perturbations but attenuated vestibular effects ($p<0.05$ for age*condition functional interaction). NWF and NBW revealed moderate effects, while NBWF produced amplified rather than additive outcomes.

Discussion

Combined sensory–mechanical constraints produced the largest alterations in gait stability, with mediolateral vulnerability during terminal stance. Functional data analysis revealed compensatory temporal patterns beyond discrete-point analyses, offering mechanistic insight into sensory contributions to dynamic stability.

Controlling for Anticipation and Triggering the Glidiator to Elicit Experimental Slips

Doctoral student Gaspard Diotalevi M.Sc.A.[1,2], Scientific professional Chantal Gauvin ing., M.Sc.A.[3], Professor Denis Rancourt ing., Ph.D.[1,4], Professor Cécile Smeesters ing., Ph.D.[1,2]

[1]Université de Sherbrooke, Sherbrooke, Quebec, Canada. [2]Research Centre on Aging, Sherbrooke, Quebec, Canada. [3]Institut de recherche Robert-Sauvé en santé et en sécurité du travail (IRSST), Montreal, Quebec, Canada. [4]Centre for Research in Acoustics-Signal-Human of the Université de Sherbrooke (CRASH-UdeS), Sherbrooke, Quebec, Canada

Introduction

Overground experiments on true slips and falls are usually limited to a single trial per participant to prevent anticipation effects. Could a novel experimental device, the Glidiator [1], eliminate participants' anticipation of an upcoming slip event triggered automatically and thus allow us to elicit repeated unexpected slips? Much larger anticipation-free datasets on true slips could then be acquired within the same testing session, even wearing multiple pairs of shoes.

Methods

Five gait metrics influenced by the anticipation of a slip (cadence, foot angle, step length, step width and double stance time [2,3]) were monitored during repeated slipping trials. They were acquired from force platform and motion capture signals for the last 10 dry steps preceding each novel slip. The slip was induced by introducing a lubricated surface (canola oil on stainless steel) on a treadmill. Note that walking speed is immune to anticipation effects since it is prescribed by the treadmill. Triggering the Glidiator was simulated in post-processing for 20 random acquired steps to explore the feasibility of synchronising it to participant's gait so that their foot lands at the front edge of the lubricated surface, thus allowing for longer slips (Figure 1).

Results

All gait metrics fell within one SD of baseline between repeated slipping trials before participants reached the prescribed walking speed. Randomly triggering the device then blinds both participants and experimenters to the upcoming slip. Triggering simulations showed the foot landing 9.7 ± 4.9 cm from the front edge of the 133.5cm long lubricated surface (Figure 1C), proving the feasibility of targeting random heel strikes.

Discussion

Once the mechanism is made quiet enough to be imperceptible through headphones, the Glidiator will allow us to perform repeated anticipation-free slipping experiments, greatly improving data collection. Upcoming experimental trials should show greater triggering variability, since electro-mechanical delay variability will be added to the human gait variability already included in these simulation results.

Does Self-Motion Perception Predict Compensatory Stepping Responses in Healthy Adults?

Ms. Gracie Zimmer, Mr. Konna Respicio, Dr. Andrew Wagner PT, DPT, PhD, Dr. Corbin Rasmussen PhD

Creighton University, Omaha, Nebraska, United States

Ms. Gracie Zimmer

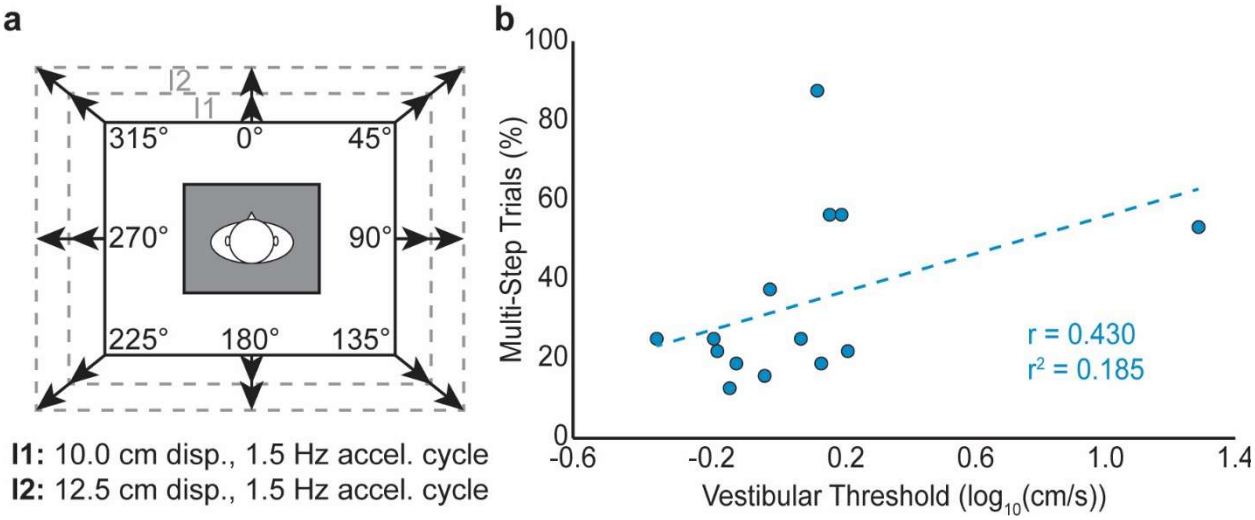
Introduction

Compensatory stepping is crucial for balance recovery following a perturbation, and taking multiple steps is associated with a greater fall risk. Detection of a perturbation relies on the integration of several sensory inputs including the vestibular system; however, it is unclear if the precision of vestibular signals is associated with the quality of compensatory stepping responses employed to regain upright balance. Therefore, our aim was to determine the relationship between vestibular thresholds (an assay of vestibular sensory precision) and the number of steps needed to counteract a slip-like perturbation.

Methods

Fourteen healthy adult participants (31.5±19.4 yrs.) stood with their eyes closed and arms crossed on a platform that randomly translated in one of eight directions and one of two intensities at a frequency of 1.5 Hz (Figure 1a). All participants were instructed to recover their balance without reaching for handrails surrounding the platform. Compensatory stepping reactions were recorded by high-speed cameras positioned in front and to the right of the participants. Vestibular perceptual thresholds were measured using a seated 1.5 Hz interaural translation direction recognition test to determine the smallest translation stimulus that could be accurately perceived. Video recordings were used to determine the number of steps taken to regain balance in each trial. The proportion of multistep trials (i.e., ratio between trials using > 1 step and the total trials performed) was correlated with vestibular thresholds using the Pearson correlation coefficient.

Results



This was a preliminary analysis as data collections were ongoing at the time of submission. Vestibular perceptual thresholds were moderately associated with the frequency of multi-

step responses to balance perturbations (r(12)=0.430, p=0.125; Figure 1b), accounting for 18.5% of the variation in stepping responses.

Discussion

These preliminary analyses show a promising trend between vestibular perceptual thresholds and the number of compensatory steps needed to regain balance after a slip-like perturbation. This supports the idea that imprecision in vestibular sensory feedback contributes to a poorer quality stepping response, even in healthy adults. Future analyses will assess whether perceptual thresholds and directional biases (i.e., right vs. left) influence the specific stepping strategies selected (i.e., lateral sidestep vs. cross-over step).

Stanford Balance Level Evaluation (StaBLE): Using Smartphone Videos to Assess Balance Ability

Ms. Hannah Heigold MS, Mr. Parker Ruth BS, Dr. Scott Delp PhD

Stanford University, Stanford, California, United States

Introduction

With an aging population and rising incidence of falls, objective balance metrics are needed to detect balance deficits and evaluate interventions. Current clinical balance assessments suffer from ceiling effects, lack sensitivity, and rely on subjective evaluation. Recent advances in computer vision have enabled biomechanical analysis in clinical settings using smartphones. We aim to use smartphone video to develop a freely available objective balance assessment that automatically computes balance task performance, removes ceiling effects, and is validated against age and existing balance assessments.

Methods

We designed a balance protocol with 18 tasks, derived from existing clinical scales, that challenges various components of balance. We used OpenCap, an open source platform for motion capture with smartphone video, to collect data from 153 subjects with a wide range of balance abilities from professional ballerinas and acrobats to older adults with high fall risk. We engineered the Stanford Balance Level Evaluation (StaBLE) performance score, which is computed from OpenCap data and quantifies the participant's ability to achieve the goal of each task. We validated the StaBLE performance score against age, the Activities-Specific Balance Confidence (ABC) Scale, and estimated Mini Balance Evaluation Systems Test (Mini-BESTest), 4-Stage Balance Test, and Short Physical Performance Battery (SPPB) scores.

Results

The StaBLE performance score, composed of 18 individual task performance scores, assigned a value between 0 and 1 to each subject (min=0.11, max=0.78, mean = 0.62, std = 0.12). It significantly correlated with age (rho = -0.76, $p<0.001$), Activities Specific Balance Confidence (ABC) Scale (rho = 0.61, $p<0.001$), and estimated clinical functional scores, while demonstrating a spread of StaBLE performance scores within each clinical scale scoring bin.

Discussion

The StaBLE performance score and task scores for balance tasks overcome ceiling effects seen in the ABC Scale and time metrics. It provides increased measurement resolution within each clinical score bin, and differentiates elite balancers that would otherwise be grouped together. The 4-Stage Balance and SPPB may bin high performers in lower scores due to premature stopping rules. Future work will identify a minimal subset of tasks to include in a rapid assessment.

Images (Optional)

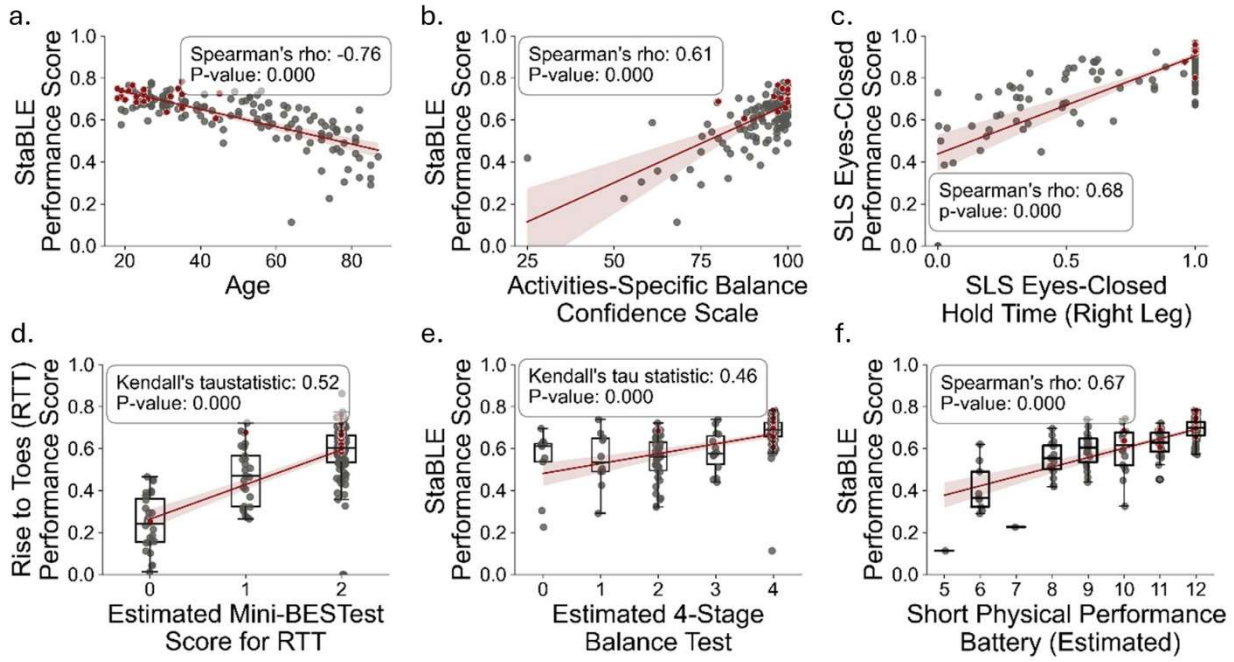

Figure 1: Linear regression and 95% confidence interval for the StaBLE performance score against age (a) and clinical scales (b, e, f); and the StaBLE task-level scores against time metrics (c) and clinical scale scores (d). Elite balancers (competitive and professional gymnasts, dancers, and acrobats) are shown in red.

Footedness has a Limited Relationship With Limb Preferences and Laterality Across Movement Tasks of Varying Stability/Mobility Priorities

Dr. James Tracy PhD[1,2], Dr. Jocelyn Hafer PhD[2], Dr. Thomas Buckley EdD, ATC[2], Dr. Jessica Allen PhD[3], Dr. Hendrik Reimann PhD[2], Dr. Jeremy Crenshaw PhD[2]

[1]University of Arizona, Tucson, Arizona, United States. [2]University of Delaware, Newark, Delaware, United States. [3]University of Florida, Gainesville, Florida, United States

Introduction

Limb laterality hypothesizes that limbs prioritize stability or mobility during movement. The "Waterloo Footedness Questionnaire—Revised" evaluates footedness on a continuum, rather than traditional single-limb dominance. The questionnaire also includes five "stability" and five "mobility" questions allowing for sub-scores to consider footedness within priorities. The purpose of this investigation was to explore footedness, limb preferences, and limb laterality during movement tasks with ranging stability/mobility limb priorities. We hypothesized that footedness would relate (i.e., large effects) to limb preferences and laterality across movement tasks with ranging stability/mobility requirements.

Methods

Thirty participants (15F/15M; 18-40 years; right kicking limb) completed the footedness questionnaire and movement tasks including bilateral standing, unipedal standing, gait initiation, overground walking, and treadmill-perturbation forward reactive stepping. We classified each task's preferred limb as the self-selected unipedal stance limb and the majority stepping limb during six gait initiation and six forward reactive stepping trials. When a preferred limb could not be determined (i.e., bilateral standing and overground walking) we quantified limb laterality with between-limb biomechanical differences: the contribution of each limb to anteroposterior center of pressure control during bilateral standing and the minimum lateral margin of stability (biomechanically proportional to the impulse needed to lose/regain stability) during walking. Footedness sub-scores were compared between preferred limbs (unipedal standing, gait initiation, treadmill perturbations) using Mann-Whitney tests and effect size *r*. Footedness was related to limb laterality (bilateral standing, overground walking) using Spearman-Rank tests with spearman correlation coefficient *r*. Both *r* values were interpreted using small ($r<0.3$), medium ($0.3\leq r<0.5$), and large effects ($r\geq 0.5$).

Results

Unipedal right-limb stance preferences associated with right-footed stability sub-scores (r=0.59;p<0.01;Figure). All other footedness sub-score and limb preference comparisons showed small effects (r≤0.21;p≥0.26;Figure). Footedness sub-scores and limb laterality comparisons also showed small correlations (r≤0.18;p≥0.33;Figure).

Discussion

Footedness stability sub-scores may relate to limb preferences for stability-focused unipedal standing but do not seem related to limb preferences for mobility-focused tasks where required dynamic responses increase. However, the majority of participants showed a limb preference during stepping tasks suggesting that there does exist some underlying factor(s) other than footedness influencing participant preferences to task-specific movements.

Images (Optional)

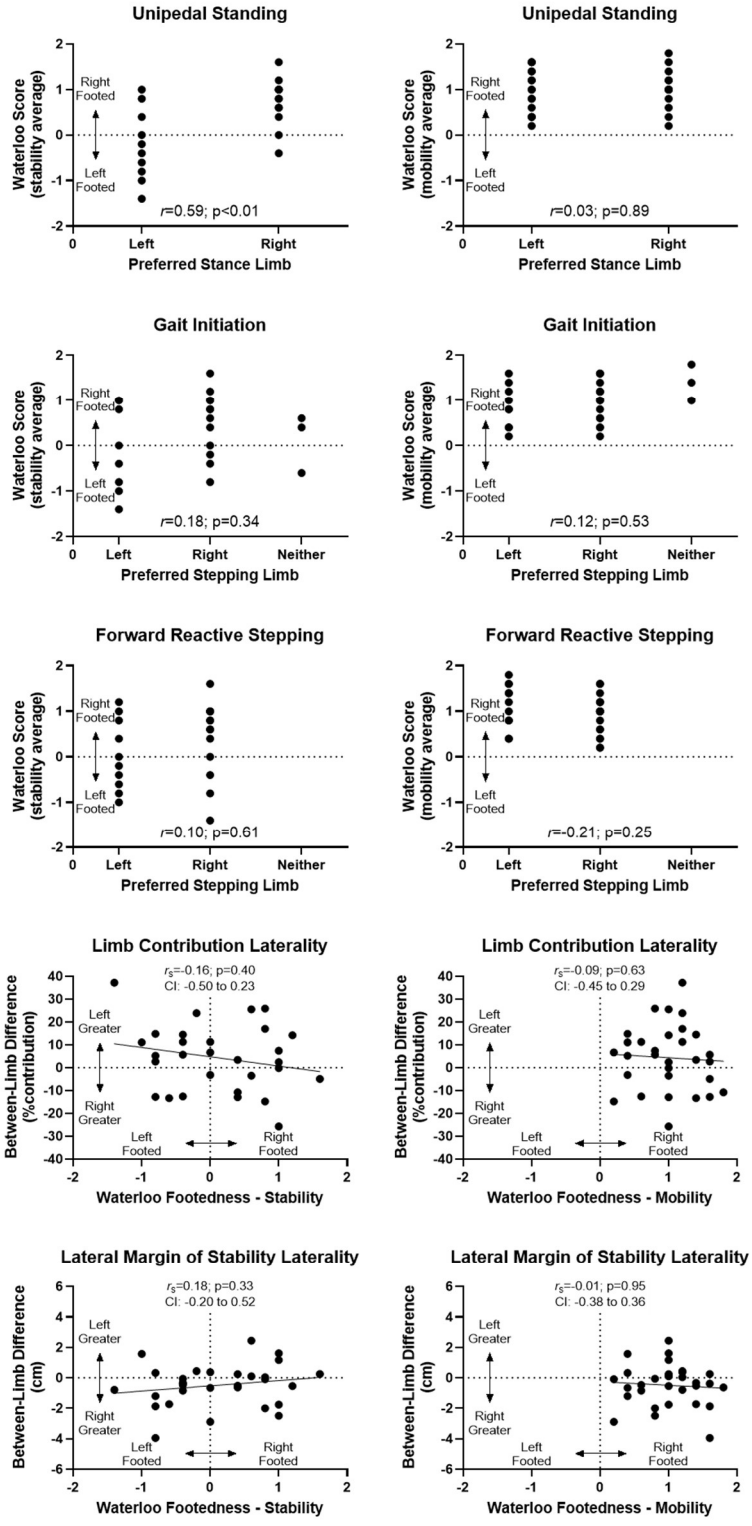

Figure – Relationships of Waterloo Footedness "stability" and "mobility" sub-scores with preferred limbs and between-limb laterality.

The Effects of Hypogravity Exposure on Multisensory Integration in Posture Control

Ms. Joelle Dick M.S., Dr. Chase Rock Ph.D., Ms. Xiaoqiang Dai, Mr. David Liu, Ms. Meira Kane, Dr. Young-Hui Chang Ph.D.

Georgia Institute of Technology, Atlanta, Georgia, United States

Introduction

Posture is regulated by constant integration of sensory inputs (somatosensory, visual, and vestibular) and the selection of suitable motor adjustments within a gravitational field. To accomplish postural control, the central nervous system (CNS) dynamically reweights sensory information in response to perturbations[1]. Building on this foundation, the present study investigates how multisensory integration for postural control adapts after hypogravity exposure: a multisensory challenge to motor control. We hypothesized that updated gravity information from hypogravity jumping will alter the multisensory integration underlying postural control.

Methods

Five healthy individuals (4F/1M) participated in this IRB-approved protocol. Participants completed the modified Clinical Test of Sensory Interaction on Balance (mCTSIB)[2] following targeted jumps in normal-gravity and simulated hypogravity (0.5g)[3]. The assessment involved controlled manipulation of somatosensory (foam vs. firm surface) and visual inputs (eyes open vs. closed). Kinematics data were used to compute center of mass (COM) sway to quantify balance variability. Unimodal sensory (somatosensory, visual, and vestibular) estimates of COM trajectories were created, and resultant variance values were used to derive sensory weights in accordance with the Maximum-Likelihood Estimate Principle[4]. This approach assesses how updated gravity information influences multisensory integration. Initial analyses were performed on two participants.

Results

Our preliminary findings suggest that exposure to simulated hypogravity modified sensory integration for posture control. Following hypogravity jumping, vestibular and somatosensory mean COM variance increased, leading to inputs down-weighting from 35.8±13.0% to 27.9±23.4% and 49.6±27.6% to 44.2±9.2% respectively. Conversely, the visual input was up-weighted from 14.6±14.3% to 27.9±16.6%. This suggests that

multisensory integration for balance control responds to updates in gravitational cues from unrelated tasks.

Discussion

Our preliminary interpretation supports the hypothesis that hypogravity exposure induces multisensory reweighting as reflected by altered balance control. These initial biomechanical findings offer further insights into how the CNS controls posture. The results also highlight gravity's role in multisensory integration for coordinated actions, with relevance to spaceflight and clinical populations with balance deficits.

Load Distribution and Vectorial Margin of Stability in Fundamental Karate-Do Stances: Biomechanical Insights into Postural Control

Msc. Johan Robalino[1,2], Lic. Luiz Pavani[1,2], Dra. Jacielle Ferreira[3], Dr. Márcio Goethel[1,2], Dr. João Paulo Vilas-Boas[1,2]

[1]Centre of Research, Education, Innovation and Intervention in Sport, Faculty of Sport, University of Porto, Porto, Porto, Portugal. [2]Porto Biomechanics Laboratory, Faculty of Sport, University of Porto, Porto, Porto, Portugal. [3]Postgraduate Program in Physical Education, Federal University of Mato Grosso, Cuiabá, Mato Grosso, Brazil

Introduction

Fundamental Karate-Do stances: Forward (*Zenkutsu-dachi*), Horse-riding (*Kiba-dachi*), and Back (*Kokutsu-dachi*) impose distinct patterns of vertical load distribution and center of mass (COM) control, shaping balance and postural strategies. This study evaluates intra-subject and intra-stance postural control using vectorial Margin of Stability (MoS) and vertical load measures to reveal how stance geometry governs functional stability.

Methods

Twelve elite Karate-Do practitioners (24.3 ± 8.2 y; 14.1 ± 6.5 y of training) with a mean height of 164.6 ± 9.5 cm, mass 71.3 ± 15.6 kg and body fat 25.3 ± 10.3 % were recruited. After a 5-min self-paced warm-up, three stances were performed five times each in random order, holding each for 5 s. Kinematic and kinetic data were recorded using two force plates (1000 Hz) synchronized with an eight-camera motion capture system (180 Hz) and processed via markerless reconstruction (Theia System) to generate a six-degrees-of-freedom biomechanical model.

Stability variables were computed, including rear- and front-foot load distribution, base of support area (convex hull and bounding box), COM–centroid and COP–centroid distances, relative stability radius, normalized COP–COM distance and vectorial MOS (Curtze et al., 2024). Linear mixed-effects models assessed the effects of stance and trial (fixed factors) on all variables, with participants as a random intercept to account for intra-subject variability. Post-hoc pairwise comparisons were Bonferroni-adjusted, and effect sizes are reported as partial eta squared ($\eta^2 p$), with significance set at $\alpha = 0.05$.

Results

All outcomes are summarized in Table 1.

Discussion

Karate-Do stance exhibits a distinct biomechanical profile shaping postural control and functional stability. *Kokutsu-dachi* shifted load posteriorly, with the rear foot bearing most body weight, pronounced COM and COP displacement, and the lowest vectorial MoS. *Zenkutsu-dachi* favored the front foot support, had a larger base of support, intermediate COM–COP positions, and moderate COP–COM separation. *Kiba-dachi* maintained near-symmetrical load, minimal COM–COP separation, and the highest relative stability radius and vectorial MoS. Systematic differences ($p < .001$; $\eta^2p = 0.206–0.779$) demonstrate that each stance uniquely modulates base of support, COM–COP dynamics, and neuromechanical demands, aligning with their traditional technical–tactical functions: defensive withdrawal, forward propulsion, and centralized stabilization.

Images (Optional)

Table 1. Load distribution and postural stability parameters across three Karate-Do stances (KIB, KOK, ZEN).

Variable	KIB	KOK	ZEN	LMM (F, p)	η^2p	Pairwise Comparisons
Rear-Foot Load (%BW)	50.98 ± 1.56	71.00 ± 1.56	44.90 ± 1.56	241.24, <.001	0.749	All comparisons significant
Front-Foot Load (%BW)	49.02 ± 1.56	29.00 ± 1.56	55.10 ± 1.56	241.24, <.001	0.749	All comparisons significant
Relative Stability Radius (dimensionless)	0.034 ± 0.002	0.048 ± 0.002	0.030 ± 0.002	42.94, <.001	0.346	KIB-ZEN not significant; others significant
BOS Area – Convex Hull (m^2)	0.093 ± 0.005	0.072 ± 0.005	0.090 ± 0.005	88.48, <.001	0.522	KIB-ZEN not significant; others significant
BOS Area – Bounding Box (m^2)	0.129 ± 0.029	0.244 ± 0.029	0.449 ± 0.029	286.46, <.001	0.779	All comparisons significant
COM–Centroid Distance (% half-diagonal)	4.99 ± 2.02	30.01 ± 2.02	14.30 ± 2.02	129.27, <.001	0.615	All comparisons significant
COP–Centroid Distance (% half-diagonal)	4.22 ± 2.17	31.72 ± 2.17	15.98 ± 2.17	126.52, <.001	0.611	All comparisons significant
COP–COM Distance Normalized to √BOS ($m \cdot m^{-0.5}$)	0.031 ± 0.002	0.028 ± 0.002	0.022 ± 0.002	21.02, <.001	0.206	KIB vs KOK not significant; KIB vs ZEN and KOK vs ZEN significant

Notes: Mean ± SE refers to the mean ± standard error. Linear mixed-effects models (LMMs) were used to evaluate differences, with F representing the F-statistic and p the significance level. η^2p denotes partial eta squared as a measure of effect size. KIB stands for Kiba Dachi (horse-riding stance), KOK for Kokutsu Dachi (back stance), and ZEN for Zenkutsu Dachi (forward stance). BW represents body weight, BOS indicates base of support, COM is center of mass, and COP is center of pressure. Letters (a, b, c) denote significant differences in post-hoc comparisons, with values bearing different letters considered significantly different at $p < .05$.

Dr. Carolline P. Nunes

Introduction

Women experience a disproportionately high burden of patellofemoral pain (PFP) and may be up to twice as likely as men to develop symptoms in sports that involve repetitive loading, cutting, and jumping. These higher rates have been linked to biomechanical patterns commonly observed in women with PFP that increase patellofemoral joint stress. However, most biomechanical studies pool sexes, limiting the ability to identify movement patterns specific to female athletes. Sex-specific analyses are therefore essential to accurately characterize patellofemoral mechanics and guide targeted interventions for women. The objective of this study was to characterize biomechanical patterns in women with PFP during functional jumping tasks and determine whether these patterns differ from asymptomatic controls across different jump types.

Methods

A systematic search of six databases (September 2025) was conducted following PRISMA guidelines. Eligible studies reported kinematic or kinetic outcomes from jump-landing tasks in women with PFP. Studies lacking sex-specific female data, including participants

with prior knee surgery, evaluating only non-jump tasks, or focusing on other diagnoses were excluded. Standardized mean differences were pooled using random-effects models in R.

Results

Thirteen studies met inclusion criteria, including 135 women with PFP and 132 controls. Four jumping tasks were evaluated: single-leg drop jump, double-leg drop jump, single-leg vertical jump, and single-leg horizontal hop. Compared with controls, women with PFP demonstrated greater hip internal rotation (SMD = 0.53; 95% CI, 0.05–1.01; $p = 0.0063$), increased hip adduction (SMD = 1.82; 95% CI, 0.31–3.32; $p < 0.0001$), and larger contralateral pelvic drop (SMD = 1.77; 95% CI, 0.09–3.44; $p < 0.0001$), with heterogeneity ranging from moderate to very high. Other biomechanical variables showed inconsistent findings.

Discussion

Across multiple jumping tasks, women with PFP exhibited a consistent pattern of greater hip internal rotation, increased hip adduction, and larger contralateral pelvic drop relative to asymptomatic controls. These findings emphasize that proximal mechanical factors are central to the biomechanical presentation of PFP during jump-landing tasks in women.

Images (Optional)

An Assessment of the Implications of Menstrual Cycle Phase on Upper Extremity Function, Lifting Risk, and Postural Control

Dr. Kaitlyn Armstrong, Dr. Thomas Andre, Dr. Corbit Franks, Dr. Ruaa Al Juboori, Dr. Chip Wade

University of Mississippi, University, Mississippi, United States

Introduction

Musculoskeletal injuries are the leading cause of time lost from work in the health care. The unique breakdown of female workers in this sector suggests there may be unique factors that need to be accounted for when considering injury prevention. Few studies have assessed sex disparities in healthcare-related occupational injuries, however, when assessing injury risk in other occupational settings studies have suggested consistently higher injury risks for women when compared to men. Understanding the cause behind the discrepancies could be critical to mitigating the injury rate differences. There are a few proposed explanations for the differences in injury rates. These include biomechanical differences such as higher loads that may result from lifting mechanics, ligamentous laxity resulting in lower joint stability, or potentially the strength demands of the tasks. The purpose of this study was to examine the implications of hormonal fluctuations across the menstrual cycle on lifting mechanics and injury risk.

Methods

40 females were recruited and enrolled in the study. The final sample included 26 females. The study consisted of 7 visits over two cycles. Measures included a RightEye Dynamic Vision assessment, a Proteus upper extremity function test, a balance assessment, and the Noraxon Human Factors and Ergonomics assessment. Linear mixed effects models were used to determine the effects of cycle and phase on performance. The threshold for statistical significance was set at $p<0.05$.

Results

The LMM revealed a significant phase effect on composite lifting index and lifting index at the origin for the 35lbs condition when comparing the follicular and luteal phase ($b=-0.171$, $p=0.0029$). The model revealed a significant difference between the cycles in the center of pressure path length for the eyes closed, foam surface condition when comparing the follicular and the luteal phase ($b=130.236$, $p=0.020$).

Discussion

There appear to be variable-specific effects of cycle phase; however, the effects were not consistently observed across cycles, suggesting no clear consensus can be reached on the relationship between cycle phase and performance. Future studies should focus on implementing robust methodological approaches while also considering longitudinal study designs to gain better insight into the variability in parameters across the cycle.

Effects of Object Weight and Availability of Weight Information on Safety Margin Values During Precision Grip

Dr. Kazuki Hokari PhD, Associate Professor, Mr. Satoshi Ota

Nippon Bunri University, Oita, Oita, Japan

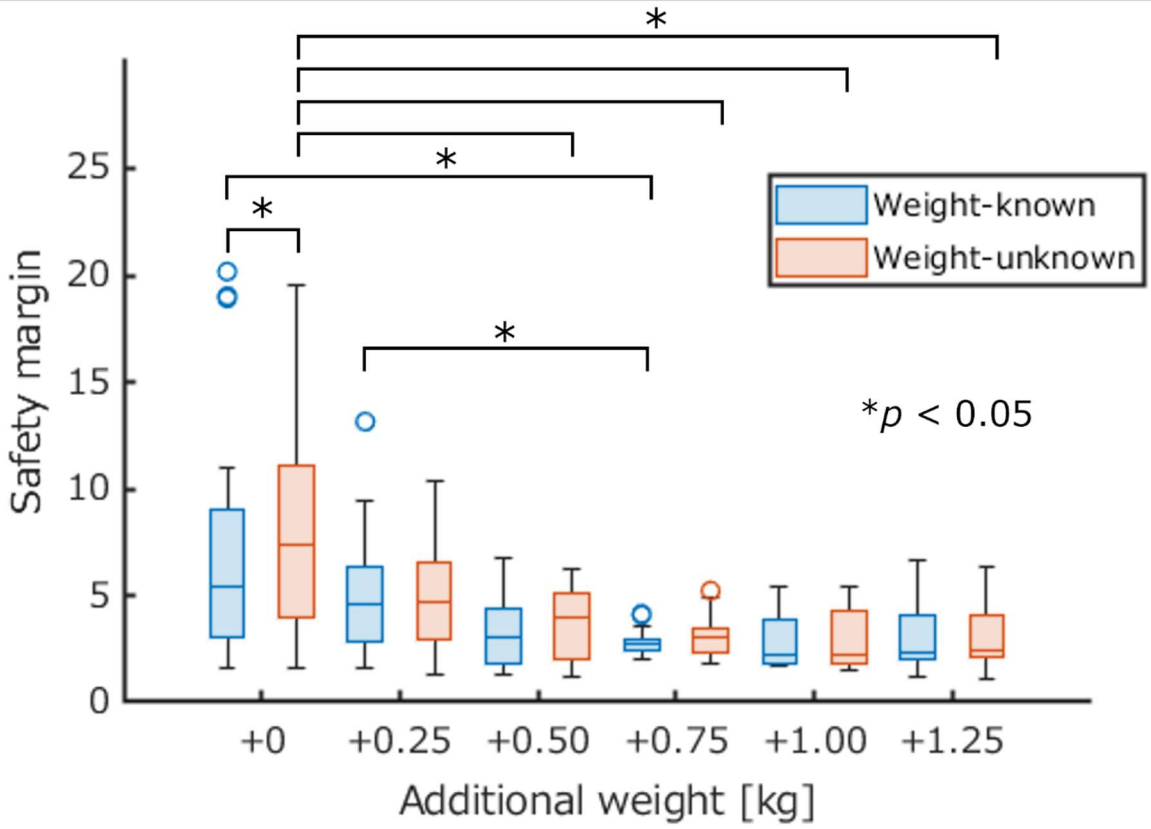
Introduction

Humans modulate grasp force to maintain stable object holding. Although using the minimum necessary force reduces muscle load, people typically apply higher forces to avoid object dropping from unexpected slippage or disturbances. This additional force, known as the safety margin, is thought to be influenced by factors such as object weight and the availability of weight information. This study examines how object weight and weight-known versus weight-unknown conditions affect safety margin values.

Methods

This study investigates grasp forces during precision grip through ongoing experiments. Twenty-three university students will participate, and preliminary results from seven are reported. The object consisted of a 3-axis force sensor fixed between aluminum plates (mass: 0.106 kg), with its weight adjusted by attaching additional masses of 0, 0.25, 0.50, 0.75, 1.00, and 1.25 kg. Two conditions were tested: weight-known and weight-unknown. Safety margins were calculated as the ratio of natural to minimum grasp force, where natural force was the peak force during each trial and minimum force was the force at slip onset.

Results



Preliminary results from seven participants showed the following safety margins under the weight-known condition: 6.9 ± 5.8 (0 kg), 5.1 ± 3.0 (0.25 kg), 3.3 ± 1.6 (0.50 kg), 2.8 ± 0.6 (0.75 kg), 2.9 ± 1.2 (1.00 kg), and 3.1 ± 1.6 (1.25 kg), with significant differences only between 0 and 0.75 kg and between 0.25 and 0.75 kg. Under the weight-unknown condition, significant differences occurred only between 0 kg and weights of 0.5 kg or greater. The safety margin for 0 kg was significantly larger in the weight-unknown than the weight-known condition, with no differences for other weights.

Discussion

The safety margins showed no significant differences under either condition except for a few weight combinations. For objects of 0.50 kg or more, participants adjusted their forces according to the weight. The 0-kg condition yielded larger safety margins than other

weights, indicating the use of force well above the minimum required. Effects of weight information appeared only at 0 kg; without weight information, participants applied much larger forces in anticipation of heavier objects.

P1-064

Effects of Jump Induced Fatigue on Unstable Seated Balance: A Pilot Study

Mrs. Kelly McGhee, Mr. Spencer Goodding, Mrs. Elyssa Bell, Dr. Abbie Ferris

University of Northern Colorado, Greeley, CO, United States

Introduction

Adults spend ~10 hours per day in a seated position [1], including on unstable surfaces (rolling chairs and vehicles). Sports such as cycling, horseback riding, and crew require athletes to maintain seated balance on a moving base of support. Yet most postural control research overlooks seated balance [2]. Further, the effects of lower extremity fatigue may have deleterious effects on seated balance on an unstable surface as fatigue affects coordination and movement control. We hypothesize that, compared to a pre-fatigue state, fatigued participants sitting on an unstable surface will demonstrate an increase in medial-lateral (ML) and anteroposterior (AP) instability and weight support through the seat.

Methods

This pilot study collected seated balance kinematic (VICON, Motion Systems Inc., Denver, CO), and ground reaction forces (AMTI, Watertown, MA) data pre- and post- fatigue protocol. Participants performed maximal countermovement jumps until volitional fatigue of the lower limbs. Participants (n=6, 1.76m$\pm$0.07, 82.11kg$\pm$14.80) sat on a wobbleboard with arms by their side for 30s. The wobbleboard consisted of a circular wooden surface 36.4cm in diameter attached to a plastic hemisphere (20 x 10.3cm) placed on a force plate.

Results

As this is a small pilot study, data are presented qualitatively. Preliminary results suggest a 114.10 $\pm$ 55.77% increase in ML and 62.18 $\pm$ 55.27% increase in AP COP excursion. Two participants demonstrated a post-fatigue increase in maximum weight support though the seat that trended towards pre-fatigue values over time. All participants increased seat reaction force variability post fatigue (Figure 1), with an increase in the coefficient of variation from 0.578$\pm$0.24% to 0.871$\pm$0.22%.

Discussion

These results suggest adaption to lower extremity fatigue includes a more unstable seat. This increased instability may hinder responses to perturbations while seated, such as in rolling chairs or accelerating vehicles. Fatigue may affect an athlete's interaction with their equipment in seated sports or their ability to maintain an effective posture. Seated sport athletes and those requiring assisted mobility devices may benefit from targeted seated balance training under fatigued conditions to counteract these effects.

[6]Division of Rehabilitation Medicine, Children's Hospital of Philadelphia, Philadelphia, PA, United States. [7]Department of Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, United States

Introduction

Clinicians use various tests to evaluate motor abilities and guide intervention programs for individuals with cerebral palsy (CP). The Timed Up-and-Go Test (TUG) is a reliable, cost-effective, easy-to-implement, and safe clinical test for assessing functional mobility and fall risk. Using a single outcome measure of time to complete the TUG limits the ability to identify specific components within the TUG that may contribute to falls. With recent advancements in technology, particularly in body-worn sensors and smartphones, it is now easier to biomechanically analyze components of the TUG, providing clinicians with a broad assessment of mobility and function within a single assessment.

Methods

We evaluated and compared TUG performance of 20 individuals with spastic diplegic CP (GMFCS I-III) and 20 age- and sex-matched typically developing (TD) peers. We divided the TUG into five phases: sit-to-walk, walk-forward, turn, walk-back, and turn-to-sit. The Mann-Whitney U test examined the group differences in the time taken to complete the TUG and its phases. Z-scores were calculated for each individual, standardized to the TD group mean, for all phase-specific parameters, such as center of mass and center of pressure trajectories and spatiotemporal metrics, to explore biomechanical differences between the CP and TD groups through visual analysis.

Results

Individuals with CP took significantly longer to complete the TUG ($p = 0.0001$) and each of its phases compared to the TD group, with medium to large effect sizes. The largest difference was 4.7s for the walk-back period, and 3.6s for the turn phase. All participants with CP showed broader distributions in their z-scores and had at least one phase-time metric more than one standard deviation (SD) from the TD mean, and 11 individuals with CP had at least one metric exceeding 3 SDs (Figure). Those with CP, particularly GMFCS Levels II and III, demonstrated lower, more variable z-scores, showing shorter and wider steps, more steps, and slower COM velocities than the TD group.

Discussion

These results provide preliminary evidence that the TUG may provide useful information about mobility when segmented into its phases in individuals with CP and assist in detecting differences between individuals with mobility concerns and TD individuals.

Images (Optional)

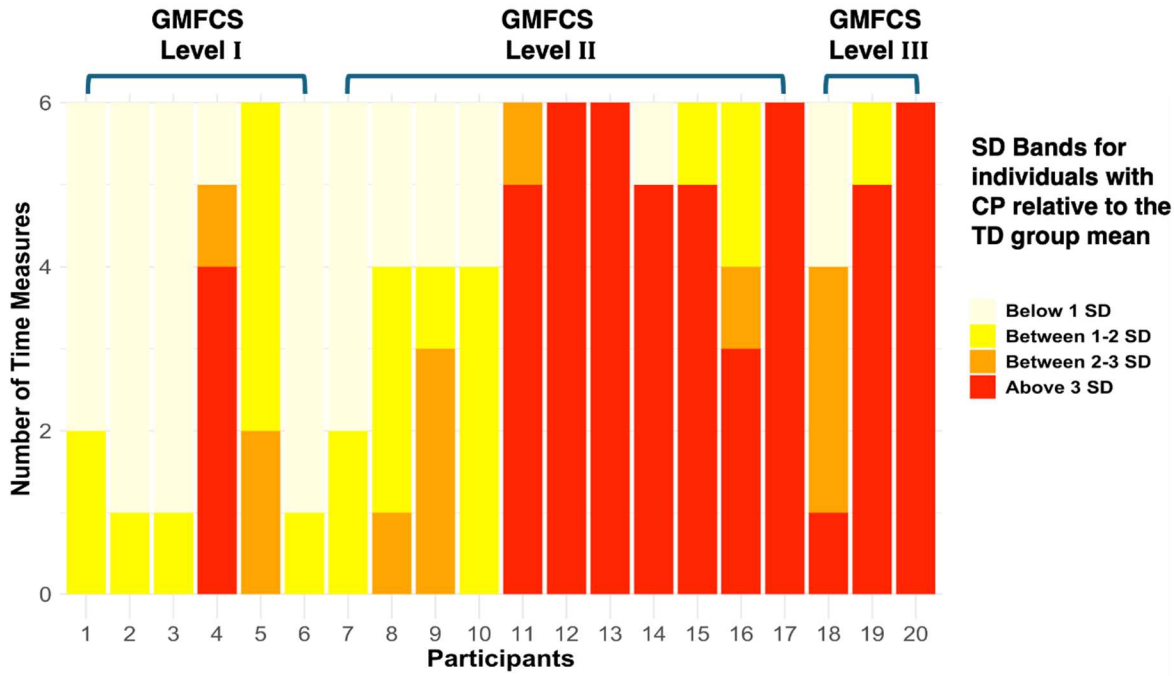

Figure: Z-score standard deviation band distributions of TUG temporal metrics in individuals with CP by Z-score deviation bands relative to the TD group. Each bar represents the proportion of individuals with metrics falling within <1 SD, 1-2 SD, 2-3 SD, or >3 SD.

P1-066

Differential Impacts of Mental Fatigue on Gait and Cognition in Young and Older Adults

Dr. Hang Qu PhD[1], Mr. Jinfeng Li[2], Dr. Li-Shan Chou PhD[3]

[1]University of Florida, Gainesville, FL, United States. [2]Iowa State University, Ames, IA, United States. [3]Purdue University, West Lafayette, IN, United States

Introduction

Mental fatigue can significantly impair both cognitive and motor performance in daily life. Emerging evidence suggests that gait requires substantial cognitive resources and is especially susceptible to mental fatigue [1-3]. This study examined the effects of mental fatigue on cognitive performance and gait characteristics in young and older adults during single- and dual-task walking with cognitive challenges. We hypothesized that mental fatigue would impair cognitive performance in both age groups, with more pronounced effects in older adults, and alter gait characteristics, with older adults exhibiting greater changes particularly under dual-task conditions.

Methods

14 young and 14 old adults completed cognitive and gait assessments before and after a mental fatiguing protocol, which consisted of a 50-minute working memory dual-task paradigm with individualized cognitive loading. Cognitive performance was evaluated using digit span tasks (sequencing: arranging numbers in ascending order; reverse: recalling numbers in reverse order) during seated conditions and while walking. Gait performance was assessed through spatiotemporal parameters and center of mass (CoM) movement during single-task normal walking and dual-task walking with concurrent digit span tasks. A three-way mixed-design ANOVA examined effects of Age, Fatigue, and Task on the dependent variables.

Results

Both young and older adults either maintained or improved their cognitive performance post-fatigue. Young adults increased their walking speed in dual-task conditions post-fatigue (sequencing: $p=.004$; reverse: $p=.031$), while older adults walked at a similar gait velocity across conditions. Following mental fatigue, young adults exhibited significant increases in CoM velocity during normal walking ($p=.001$) and dual-task walking with reverse digit span task ($p<.001$). In contrast, older adults maintained a similar CoM movement, revealing a conservative strategy prioritizing balance control.

Discussion

Our findings revealed that older adults can effectively use compensatory strategies to sustain both cognitive performance and gait balance under mental fatigue. The interplay between mental fatigue and dual-task walking underscores the necessity of multidimensional assessments—including CoM motion control—to fully capture age-specific adaptations and inform evidence-based fall-risk management.

Human Motion and Performance: Balance, Posture and Control

P1-067

Improving Balance Accuracy: Effects of Motivation and Fear on the Base of Support

Ms Liyi Chen

Newcastle University, Newcastle, United Kingdom, United Kingdom

Introduction

Balance can be described in terms of how the body's centre of mass is controlled relative to the base of support formed by the feet. Recently, a 2D model of the functional base of support (fBOS), which can support forces above 40% body weight, has been published, considerably improving the BOS estimate (Millard+Sloot+2025). However, there was a large variation in the fBOS size in young people (9-36% of the foot), which could represent differences in balance ability or task execution. This study examined whether fear, motivation and human variability influence the measured fBOS area.

Methods

Ten young adults (27± 2.6 yrs) were asked to lean as far as they could in all directions in a circular motion while keeping feet in place during five conditions: baseline (repeated within the same day), a safety harness (SH), light fingertip support (PI), visual feedback (VF), and verbal encouragement (VE). Force-plates were used to calculate the fBOS area as the convex hull of the centre-of-pressure data (Figure 1A; Millard+Sloot2025). Conditions were compared using repeated-measures ANOVA; repeatability evaluated using Bland–Altman analysis.

Results

There was a significant overall effect of condition on the fBOS area ($p = 0.0097$). However, post hoc analyses showed no significant differences between Baseline and any other condition (Figure 1B). Baseline within-day repeatability showed task effect: Baseline 2 was 13.9% larger than Baseline 1 (95% LoA: −2.9% to 30.7%; Figure 1C).

Discussion

These findings show that addressing motivation or fear didn't change the fBOS area, although our study is currently limited to young adults. Next step is to compare fBOS area with balance performance. The task effect indicates that the fBOS should be assessed on a

second trial. These results contribute to a better assessment of the fBOS area, thus to a more accurate balance assessment.

Does Arm Posture Influence Wrist Proprioception and Hand Tracking Performance?

Ms. Melanie Altamirano[1], Ms. Meera Sayal[1], Ms. Valentina Massone[2], Ms. Giulia Albanese[2], Mr. Jacopo Zenzeri[2], Dr. Shawn Beaudette[1], Dr. Jae Patterson[1], Dr. Michael Holmes[1]

[1]Brock University, St. Catharines, Ontario, Canada. [2]ReWing, Genoa, Liguria, Italy

Introduction

Proprioception is critical for fine motor control and is essential in occupations requiring high precision such as surgery and dentistry. While previous research has highlighted the influence of fatigue (1) and pain (2) on wrist proprioception, there remains limited understanding of how elbow position impacts wrist proprioception and movement accuracy. The purpose of this study was to investigate how elbow angle and movement direction influences proprioception and tracking accuracy at the wrist.

Methods

Twenty-one right-hand dominant adults (age: 25.5 + 4.1; 9M, 12F) completed two tasks using a 3DoF wrist manipulandum (Edusa PRO-r). Participants completed a joint position matching (JPM) task and a tracking task in three elbow postures (60°, 90° and 120° of flexion). The JPM task involved 4 trials per direction across 6 directions (flexion/extension, radial/ulnar deviation, pronation/supination), with randomized targets. Participants were blindfolded and wore noise cancelling headphones while asked to recreate a previously presented wrist angle. The tracking task required participants to trace a 3:2 Lissajous curve. Participants performed 6 laps; each lap took approximately 20 seconds to complete. JPM outcomes included matching error and error bias, while tracking outcomes included mean tracking error and percent accuracy.

Results

Elbow angle did not significantly affect JPM error, indicating robust wrist proprioception across mid-range elbow postures. Movement direction, however, significantly influenced outcomes, with flexion/extension producing greater variability ($p < .001$) and error ($p = .003$) than radial/ulnar deviation or pronation/supination. Tracking performance had a main effect of elbow angle for both percent accuracy ($p=0.11$) and tracking error ($p = .002$). Percent accuracy was significantly higher at 120° (90 ± 1.1) compared to 60° (85 ± 1.7). Tracking error was significantly higher at 60° (4.2 ± 0.26) compared to both 90° (2.3 ± 0.18) and 120° (3.03 ± 0.32).

Discussion

This study provides novel evidence that wrist proprioception is more direction-dependent than posture-dependent under static conditions, while posture plays a larger role in tracking accuracy. Findings highlight the importance of considering joint configuration and movement direction when designing ergonomic interventions, surgical training protocols, and rehabilitation strategies.

Neuromechanical simulations reveal how feedforward-feedback interactions shape locomotor control

Dr Naomi Chaix-Eichel, Dr Nidhi Seethapathi

MIT, Cambridge, MA, United States

Introduction

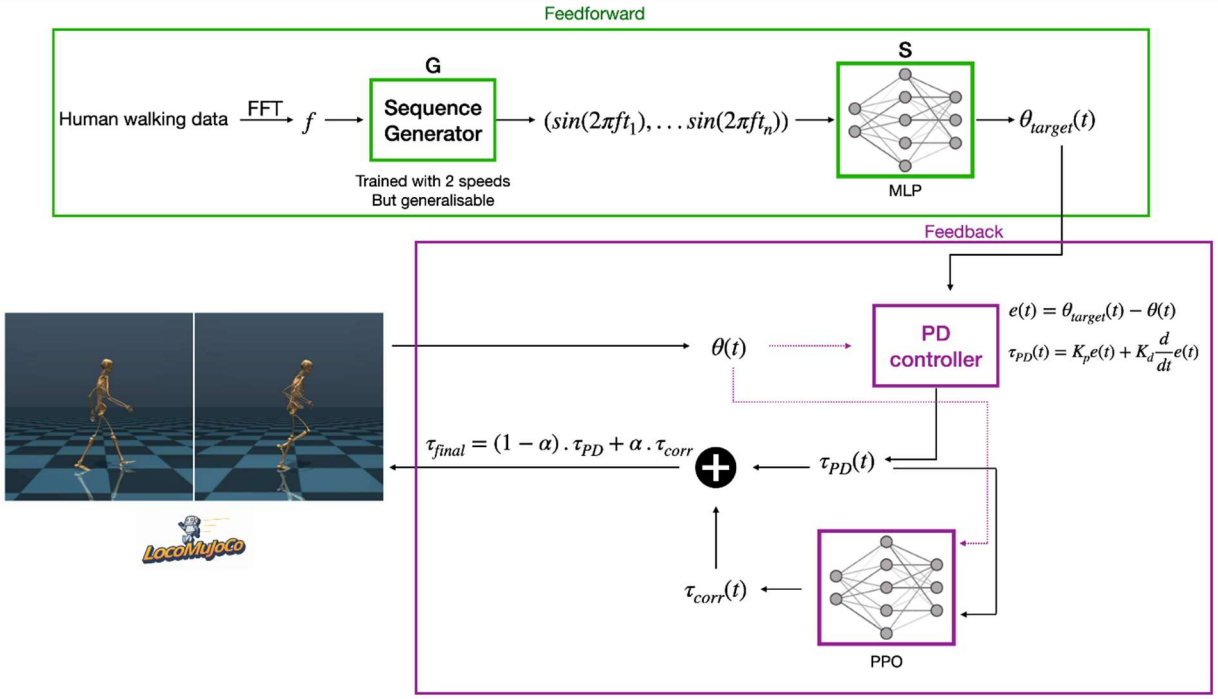
Human locomotion relies on the integration of rhythmic pattern generation and reactive, state dependent corrections. While human locomotion is often studied functionally, a mechanistic simulation-based understanding of the interaction between feedforward (rhythmic, velocity-driven) and feedback (reactive, body state-based) control is lacking. We address this gap by developing a computational framework implementing a dual-module architecture inspired by the AI-CPG architecture (Li et al., 2024) to investigate how feedforward and feedback control interact during locomotion.

Methods

Our framework comprises two modules implemented on a 27-DoF MuJoCo humanoid. The feedforward module generates target joint trajectories from a frequency input using a sequence generator followed by a Multi-Layer Perceptron, providing baseline patterns analogous to spinal central pattern generators. The feedback module employs deep reinforcement learning (PPO) to apply online, state-dependent corrections to PD-controller commands, enabling rapid adaptation to body dynamics. Critically, we parameterized the relative contribution of feedforward versus feedback control, allowing systematic study of how these components shape locomotor control.

Results

Our results demonstrate that the framework can reproduce empirically observed velocity-driven step length and state-dependent foot placement control signatures (De Comite et al., 2025). Initially, increasing feedback contribution amplified lateral foot placement corrections proportional to pelvis state, but revealed an optimal balance beyond which control amplitude decreased, suggesting a trade-off between feedforward and feedback contributions to stability.



Notably, the model is presently unable to replicate the feedforward speed-step frequency relationship observed in humans, suggesting that the CPG module may need to be modified to capture this.

Discussion

These findings provide causal neuromechanical simulation evidence for the common assumption that lateral stability may preferentially utilize state-based feedback, while forward progression may be dominated by feedforward rhythmic generation (Bauby and Kuo, 2000).

This work provides a simulation-based platform for testing causal hypotheses about feedforward-feedback interactions in locomotion. By parameterizing the relative contributions of these two control modes, we can directly examine how different control strategies produce distinct biomechanical signatures. Our framework, built on open-source tools (MuJoCo, JAX), will be released to enable community extensions. Future work will test these control principles across different body morphologies, and validate whether the feedforward-feedback organization observed here reflects known neural underpinnings.

The Effect of Jump Distance and Jump Height Variations on Dynamic Postural Stability

Dr. Nathan Robey Ph.D., ATC[1], Dr. Otto Buchholz Ph.D., ATC[2], Ms. Harnoor Pandher[1], Mr. Sol Dehnert B.S.[1]

[1]Western Washington University, Bellingham, Washington, United States. [2]Eastern Washington University, Cheney, Washington, United States

Introduction

The dynamic postural stability index (DPSI) has commonly been used to assess an individual's dynamic stability. However, a limitation in the previous research is the lack of a consistent testing procedure for establishing jump distance and height. Therefore, the purpose of this study was to investigate the impact of various jump distances and heights on DPSI measures.

Methods

Thirty-nine healthy individuals (F = 20, M = 19, 21.2 ± 1.6 yrs, 1.7 ± 0.1 m, 74.5 ± 15.0 kg) participated in a single testing session. Participants performed a barefoot forward-jumping task using a variety of combinations of testing protocols. Participants jumped from a two-footed starting position set at one of three distances (70 cm, the participant's leg length, or 40% of their body height) and to one of three heights (6 in or 12 in hurdle, or touched an overhead target set at 50% of their maximal vertical jump height) and landed on a force platform (Watertown, MA, USA) in a single-limb position. All combinations of distance and height were tested. Condition order was randomized and counterbalanced using a custom MATLAB script. Participants remained balanced for approximately 15 seconds after landing to collect ground reaction force (GRF) data (2000 Hz). GRF data were filtered with a fourth-order Butterworth low-pass filter with a cutoff frequency of 20 Hz and used to calculate DPSI and its component measures. A doubly multivariate MANOVA ($\alpha = 0.05$) was used to compare jump distance and height conditions.

Results

The multivariate interaction was significant ($p < .001$); however, no significant univariate interactions were observed. Significant main effects for both jump distance ($p < .001$) and height ($p < .001$) were observed. Univariate testing and pairwise comparisons indicated significant differences between DPSI and its components across different protocol variables (Table).

Discussion

Leg length poses the greatest challenge to stability, with worsened dynamic postural stability in both DPSI and MLSI. Dynamic postural stability also worsens, in each directional component, as jump height increases. Interestingly, APSI and MLSI are most affected by jump height, indicating greater difficulty in controlling the GRFs during landing. Researchers should consider both factors when determining the task setup.

Strength, Balance, Cognition: What Works to Prevent Falls in Aging Adults

Ms. Nicole Potter MA[1], Dr. Felipe Gonzalez MD, MSc[1,2], Dr. Matheus Vilela MD, MSc[1,2], Mr. Joshua Samaniego MS[1], Mr. Nurudeen Alli BA[1], Dr. Jonathan Gustafson PhD[1]

[1]Rush University Medical Center, Chicago, IL, United States. [2]Instituto Brasil de Tecnologia da Saúde, Rio de Janeiro, RJ, Brazil

Introduction

INTRODUCTION: Falls remain the leading cause of injury among older adults, affecting one in four Americans aged ≥65 each year. Established prevention strategies (e.g., medical factors and home hazard modification) can reduce fall risk, yet the role of training-based interventions in fall prevention remains underexplored. This systematic review and meta-analysis evaluated the impact of muscle strengthening, balance, and cognitive stimulation interventions on balance and fall reduction among older adults.

Methods

METHODS: A comprehensive database search was conducted with no geographic or language restrictions. Eligible studies were randomized controlled trials (RCTs) evaluating muscle strengthening, balance, and cognitive stimulation interventions with balance as the primary outcome and falls as a secondary outcome. Inclusion criteria required a no-intervention control, participants aged ≥60 years, and no diagnosed cognitive impairment or medical conditions associated with fall risk. Two authors independently screened all studies within Covidence, with disagreements resolved by consensus or a third reviewer. Meta-analyses were performed when outcomes were comparable.

Results

RESULTS: The search identified 6,541studies; 99 of which met the inclusion criteria. The most clinically relevant outcomes – Berg Balance Scale (BBS) and Timed Up and Go (TUG) – are reported here. The pooled analysis showed that muscle strengthening (6 RCTs, 277 participants) significantly improved BBS scores (MD=2.53, 95%-CI 1.69; 3.36, $p<0.0001$, $I^2=0.0\%$). Balance training (9 RCTs, 834 participants) statistically improved BBS scores (MD=2.33, 95%-CI 0.69; 3.98, $p=0.0054$, $I^2=75.9\%$) however, cognitive stimulation (3 RCTs, 124 participants) showed no significant effect (MD=0.89, 95%-CI -0.42; 2.20, $p=0.184$, $I^2=0.0\%$). Muscle strengthening (18 RCTs, 1,702 participants) statistically improved TUG performance (MD=-1.06, 95%-CI -1.56; -0.56, $p<0.000$, $I^2=78.6\%$). Balance training (24

RCTs, 2,439 participants) also statistically improved TUG performance (MD=-0.85, 95%-CI -1.23; -0.46, p<0.000, I^2=83.5%), yet cognitive stimulation (7 RCTs, 554 participants) showed no significant effect (MD=-0.27, 95%-CI -0.80; 0.26, p=0.316, I^2=61.9%; Figure 1).

Discussion

DISCUSSION: This review found that muscle strengthening and balance interventions may reduce falls in healthy older adults, but cognitive stimulation lacks convincing support. Inconsistent outcome reporting, heterogeneous interventions, and limited long-term follow-up diminish definitive conclusions. Future research should investigate whether observed effects persist over time or require continuous intervention.

Postural Responses to Forward and Backward Gait Initiation Tasks in Neurotypical Adults

Mr OLUWAFEMI ADEGBEMIGUN BPT, MSc[1,2,3], Mr Ryland Swearinger MS[3], Dr Christy Conroy[2], Miss Janki Patel MS[2], Dr Arian Vistamehr PhD[2], Dr. Clay Wauneka PhD[4], Dr. Dorian Rose PhD[1,2,3]

[1]Department of Physical Therapy, Gainesville, FL, United States. [2]Brooks Rehabilitation, Jacksonville, FL, United States. [3]Brain Rehabilitation Research Center, Malcolm Randall VA Medical Center, Gainesville, FL, United States. [4]Cook Children's Medical Center, ForthWorth, Texas, United States

Introduction

Gait initiation (GI), the transition from standing to walking, requires precise postural adjustments to maintain stability. Forward Gait Initiation (FGI) is visually guided, whereas Backward Gait Initiation (BGI) is less practiced, with limited visual feedback, and presents a greater challenge to postural control. Center of Pressure (COP) peak displacement and pathlength are two metrics that evaluate the magnitude and sway length of postural adjustment during GI. Most studies examine either peak displacement or pathlength during FGI, leaving it unclear whether one or both metrics are sensitive to gait directions. We examined both COP metrics to offer additional insight into postural control.

Methods

Eleven neurotypical adults (Age: 62.8±12.3 years old; Gender: 6M; Gait speed: 1.3m/s) participated, standing quietly, with each limb on separate force plates, for 10 seconds, and initiated gait with their dominant limb upon a verbal “go” signal. GI was repeated three times in both forward and backward directions. Data was processed in VICON and Visual 3D. Average COP peak displacement in both medial-lateral (ML) and anterior-posterior (AP) directions, and COP pathlength were calculated during the postural phase (PP) of GI. Paired t-test compared COP peak displacement of AP and ML trajectories, and pathlength during FGI and BGI

Results

In the PP, COP peak displacement during FGI and BGI were comparable in the AP (FGI: 38.3 ± 13.4mm; BGI:31.3 ± 6.9); and the ML (FGI: 53.9 ± 16.4mm; 47.6 ± 17.5)

trajectories**.** However, COP pathlength during FGI was significantly longer compared to BGI, *p=0.002* (FGI: 136.7 ± 31.2; BGI: 83.6 ± 43.5)

Discussion

Peak AP and ML COP displacement is similar for forward and backward GI, suggesting that the maximum COP excursion associated with the initial momentum is invariant to task direction, possibly due to constraints in stability margins during both tasks. In contrast, COP pathlength is greater during FGI, indicating that pathlength is direction-sensitive, implying that the initial posterior shift in FGI requires larger corrective sway than the corresponding anterior shift in BGI. Evaluation of both COP peak displacement and pathlength during GI tasks may provide a more comprehensive picture of postural control deficits in those with musculoskeletal or neurologic pathology.

Effects of a Hula-Based Intervention on Balance and Fall Risk in Native Hawaiian and Pacific Islander Older Adults: A Pilot Study

Dr Patricia Young PhD[1], Ms Sheryl Yoshimura MPH, RD[2], Ms Chantelle Matagi MA[3], Dr Christopher Stickley PhD[4], Dr J. Keawe'aimoku Kaholokula PhD[5]

[1]Hawai'i Pacific University, Honolulu, HI, United States. [2]Kōkua Kalihi Valley, Honolulu, HI, United States. [3]Tagata Moana Hui Foundation, Honolulu, HI, United States. [4]University of Hawaii Mānoa, Honolulu, HI, United States. [5]University of Hawai'i, John A. Burns School of Medicine, Honolulu, HI, United States

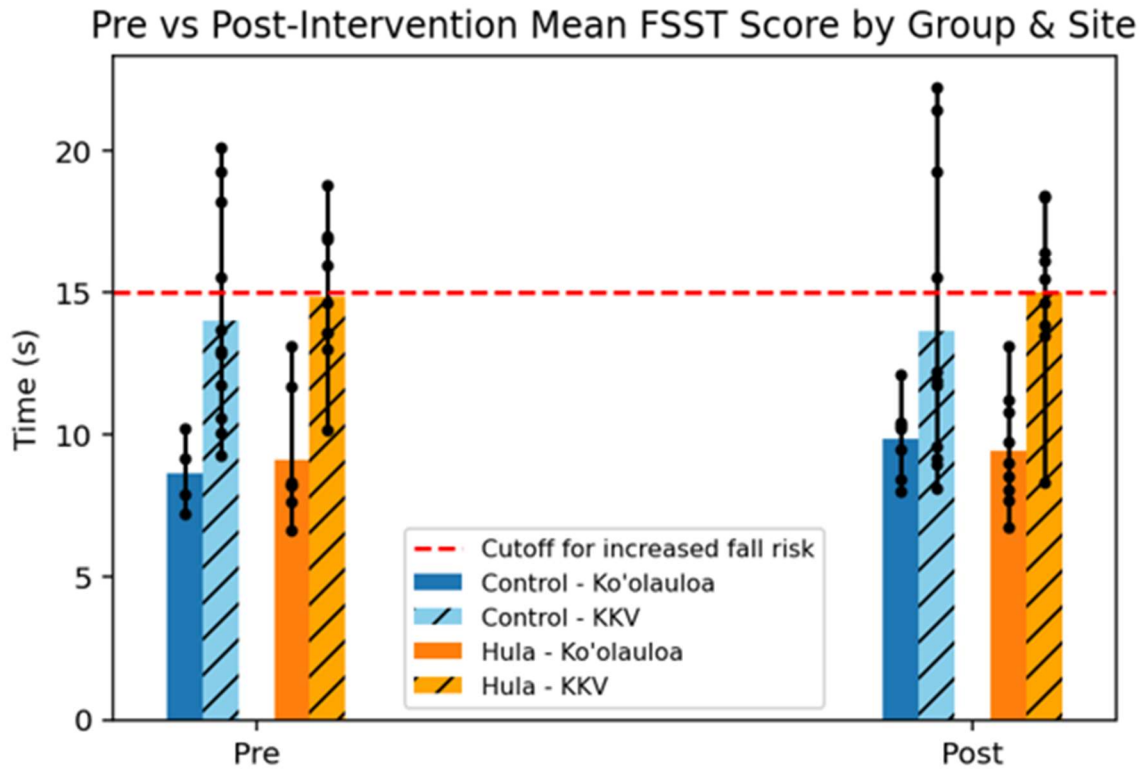
Introduction

Hula, the traditional dance of Hawai‘i, is practiced by Native Hawaiians (NHs) and has been adopted by other Pacific Islanders (PIs), as well as by non-NHPI individuals, of all ages. The motions of Hula include stepping, shifting standing balance, turning the body and head, and upper body positioning that can shift the center of mass, challenging balance. Our goal was to determine whether regular Hula practice could be used as a culturally relevant approach to implementing balance training among NHPI older adults.

Methods

We conducted a substudy of an ongoing Hula-based clinical trial in NHPI adults ages 50-75 years with subjective or mild cognitive impairment. Forty-one participants were enrolled (mean age: 62.5 years) at two community sites: Kōkua Kalihi Valley (KKV) and Ko‘olauloa (KLL). Each site had wait-list control and Hula intervention groups with ~10 people per group. The Hula intervention comprised 2 1-hour sessions per week for 12 weeks. Balance, concern about falling and fall risk were measured pre-post intervention using the Berg Balance Scale (BBS), Falls Efficacy Scale – International (FES-I) and four-square step test (FSST). Fall history was also assessed. We conducted focus groups with the Hula groups post-intervention to determine the intervention’s acceptability.

Results



Participants had fall history rates of 45% and 27% at KKV and KLL, respectively, with an overall rate of ~39%. On the BBS, all KLL participants scored ≥48, with most scoring 56, the maximum score, pre- and posttest. A similar trend was seen on the FSST, with all participant scores <15 s. Approximately 30% of KKV participants scored between 45 and

47, indicating an increased risk of falls. Concern about falling increased pre-post among some participants. Results analyses are ongoing.

Discussion

The rate of individuals with a history of falls was higher than the state average (~22%). The balance measures employed may not have fully captured how balance indicators changed throughout the intervention. However, participants reported improved mobility and confidence in activities of daily living in the focus group followup, indicating promise in using this intervention. Camera and force plate-based measures of balance should be considered in followup studies for their increased sensitivity.

Investigating Stepping Error in Healthy Young Adults Across Task Difficulty and Divided Attention

Investigating Stepping Error in Healthy Young Adults Across Task Difficulty and Divided Attention Payton Reuter Student, Investigating Stepping Error in Healthy Young Adults Across Task Difficulty and Divided Attention Mindie Clark PhD, Professor

University of Minnesota Duluth, Duluth, Minnesota, United States

Introduction

Dual- tasking requires divided attention and can alter gait mechanics, compromising safety [1]. Even healthy young adults show reduced gait performance while texting [2]. The purpose of this study was to evaluate how task difficulty and dual-tasking affects stepping accuracy in healthy young adults using a multi-precision stepping paradigm.

Methods

Twenty young adults completed 40 trials stepping into targets during their first and third dominant footstep. For 20 trials, participants completed a concurrent simple verbal task, and for 20, the second stepping target was rotated 45°. Four combinations of ten trials were performed and participants reported mental effort after each. We calculated stepping accuracy, stepping bias, and variability. We compared within-subjects effects of target orientation and task on stepping performance (mm) and mental effort.

Results

Dual- tasking led to greater mental effort compared to single- task ($p= 0.004$). Target 1 error was not different across task in anteroposterior ($p= 0.747$) or mediolateral ($p= 0.076$) directions. Target orientation affected mediolateral stepping error in Target 2 in which single- pivot conditions were more accurate compared to single- straight conditions ($p= 0.046$), but there was no effect of task ($p= 0.423$). Stepping variability in Target 1 was significantly different across task ($p= 0.013$).

Discussion

Our findings demonstrated that even a simple verbal concurrent task can elicit greater mental effort, although its effect on stepping performance was less clear. The verbal task did not increase stepping error, suggesting that task demands did not exceed available attentional resources. Performance metrics indicate that young adults may expend greater effort to perform on tasks perceived to be more difficult and prioritize distal stepping targets that allows for more planning. Findings may not be generalizable to tasks competing for resources in the same domain (eg. two visually-guided tasks) or to populations that recruit more attentional resources for similar tasks. It is vital to evaluate safe navigation strategies in environments that strain attentional resources.

Force-Plate Calibration for Human Quiet-Standing Studies

Ms. Rika Sugimoto-Dimitrova, Ms. Jiajie Qiu, Professor Neville Hogan

Massachusetts Institute of Technology, Cambridge, Massachusetts, United States

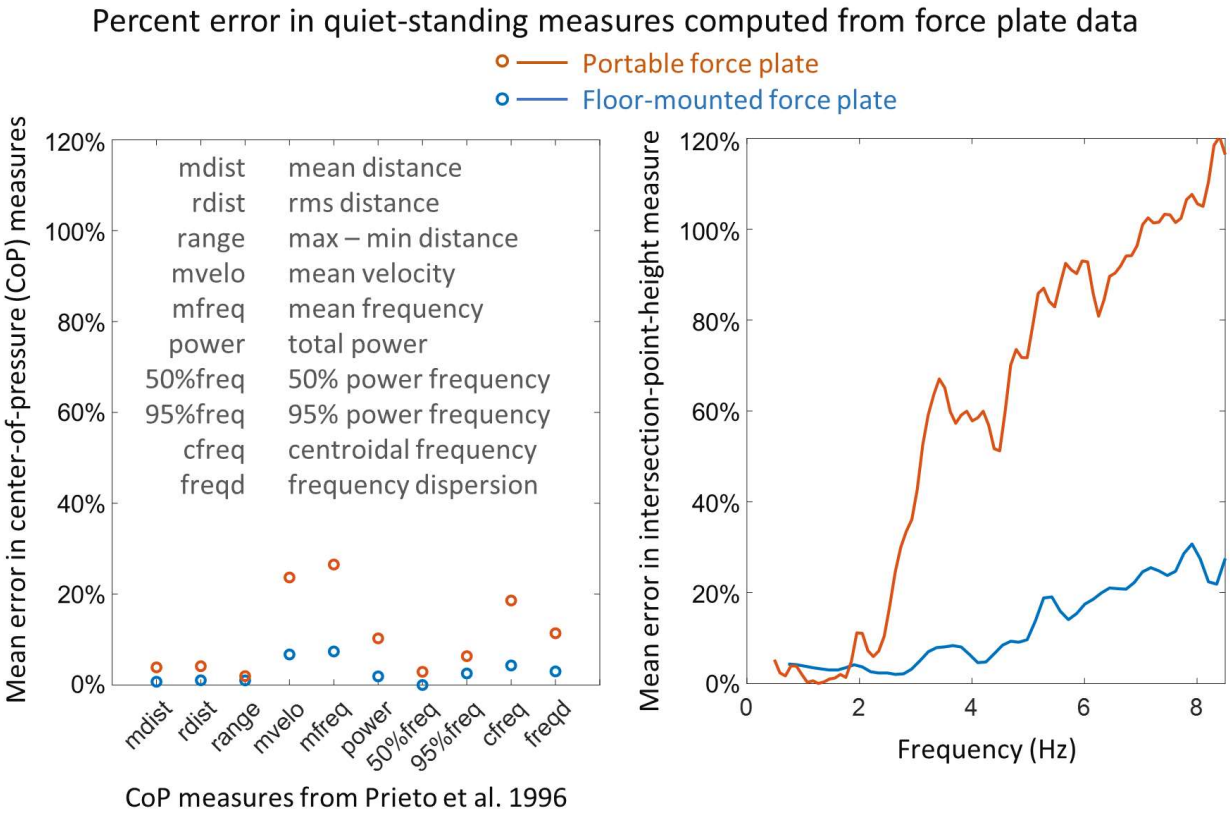
Introduction

Force plates are commonly used to study human quiet standing. Traditionally, statistics of center-of-pressure (CoP) displacement have been used to describe standing behavior. More recently, horizontal foot force has also been incorporated in some balance measures, such as the intersection-point-height measure (Boehm et al. 2019). However, quiet standing involves very small movements, with CoP displacements on the order of millimeters and shear forces less than 1 N. Thus, quantifying measurement uncertainty is essential. In this study, a force-plate-calibration procedure was developed to determine the uncertainties in force-plate-derived quiet-standing measures.

Methods

A testbed was placed on the force plate being tested, and an actuator applied horizontal forces to induce shear forces and CoP displacements. Twelve 30-second trials mimicking quiet-standing data were employed to test two force plates: a portable device (Kistler 9260AA3) and a floor-mounted device (Bertec FP4060-07-1000). The data were low-pass-filtered to 10 Hz, and used to compute 10 CoP-based measures (Prieto et al. 1996) and the intersection-point-height measure. These measures were then compared against ground-truth values from a load cell to estimate error.

Results



CoP data showed a larger signal-to-noise ratio than shear-force data. Measurement error was more pronounced at higher frequencies: CoP measures that depended more on lower-frequency content, such as mean or root-mean-square distance, exhibited low errors (<5%); measures sensitive to higher-frequency signals, like mean velocity, showed larger errors (up to 27%). The intersection-point-height measure showed errors less than 10% below 2 Hz, while error increased for higher frequencies: at 4 Hz, the portable force plate exhibited 60% error. The floor-mounted device generally exhibited lower errors than the portable device.

Discussion

The commonly-used CoP measures could be derived more accurately from force-plate data than the newer intersection-point-height measure that incorporates shear force and

CoP at higher frequencies. Nonetheless, accuracy depends on measurement signal strength and device noise level. Therefore, it is important to investigate data reliability for a given use-case, particularly when analyzing small-magnitude or high-frequency data.

Machine Learning Framework for Optimized Wearable Sensor Detection of Gait Instability

Mr. Roshan Ragu[1], Ms. Jordan Feldman[2], Mr. Constantin Beyer[3], Dr. Jessica Allen[4], Dr. Jason Franz[1]

[1]University of North Carolina at Chapel Hill, Chapel Hill, NC, United States. [2]Harvard University, Cambridge, MA, United States. [3]Digity GmbH, Göttingen, Lower Saxony, Germany. [4]University of Florida, Gainesville, FL, United States

Introduction

Falls represent a major health risk, particularly for older adults. Remote monitoring of locomotor instability is critical for advanced diagnostics, earlier intervention, and real-world assessment of intervention efficacy. We recently discovered that inertial measurement units (IMUs) may have the potential to detect perturbation-induced instability during walking [1]. However, deploying IMUs in real-world settings requires optimization to balance feasibility and accuracy. Here, we developed a machine learning framework based on recorded IMU signals to predict the conscious perception (i.e., “yes” or “no”) of small-amplitude slip perturbations during walking.

Methods

15 healthy young adults walked at their preferred speed on a dual-belt treadmill while wearing IMUs on their posterior sacrum, wrists, anterior shanks, and dorsum of the feet (APDM, 128 Hz). 3D acceleration signals were demeaned, low-pass filtered using a sixth-order Butterworth filter (30 Hz cutoff) and converted to vector magnitudes. While walking, a custom MATLAB treadmill controller rapidly decelerated (6 m/s^2) one foot at initial contact during the stance phase every 12-15 strides at random. Eight perturbation magnitudes delivered in randomized order five times each ranged from 0.02 m/s to 0.3 m/s. Perturbations were labeled according to participant perception (yes/no), producing binary outcomes for supervised learning. A bidirectional long short-term memory (LSTM) network was combined with a Random Forest classifier in a stacked ensemble architecture, with a logistic meta-classifier integrating their predictions. Each possible combination of the seven IMU locations was evaluated to identify the minimal sensor configuration that maximized classification accuracy.

Results

The ensemble model determined that a two-IMU system (i.e., perturbed foot and unperturbed shank) maximized prediction performance (i.e., 85% accuracy); accuracy

peaked for the smallest and largest amplitude perturbations. The perturbed foot IMU appeared in all top 20 sensor combinations (81%-85% accuracy range) (Fig. 1). An important caveat is that models generally had more false negatives than false positives.

Discussion

These results demonstrate that perception of walking balance perturbations can be reliably inferred from wearable IMU data. By identifying feasible, high-performing sensor configurations, this work supports the design of lightweight, unobtrusive systems for real-world instability monitoring and fall-risk prevention.

Assessing the concurrent validity and test-retest reliability of markerless motion capture for static postural control assessment

Mr. Sachitha Wijekoon BScH[1], Dr. Jereme Outerleys BEng, MASc[1], Dr. Benjamin Ritsma BS, MD[1], Dr. Kevin Deluzio BASc, MASc, PhD[1], Dr. Scott Selbie BASc, PhD[2], Dr. Vincent DePaul BHSc, PhD[1], Dr. Stephen Scott BASc, MASc, PhD[1]

[1]Queen's University, Kingston, Ontario, Canada. [2]HAS-Motion Inc, Kingston, Ontario, Canada

Introduction

Accurate assessment of impairment is essential for guiding rehabilitation in patients with postural control deficits [1]. Traditional research-grade tools provide objective precision but face practical barriers to clinical integration. Markerless motion capture systems, like Theia3D, offer a promising alternative, although their utility for measuring postural control remains unclear. To address this gap, this study evaluated the concurrent validity and test-retest reliability of Theia3D for measuring static postural control, in both laboratory and clinically relevant contexts.

Methods

Fifty-three healthy adult participants (16♂, 37♀; age=24 [18-50] years) without neurological or musculoskeletal disorders performed three quiet standing tasks across two sessions, spaced ~one week apart. Tasks were performed under two conditions: standing alone (unaccompanied), and with an individual standing nearby simulating clinical supervision (accompanied) (Figure 1). Eight synchronized cameras and a force plate recorded data simultaneously. The pelvis Centre of Mass (COM) was estimated from video using Theia3D and the Gravity Line Projection (GLP) was computed from ground reaction forces. Concurrent validity was assessed using cross-correlations and root mean square differences (RMSD) between the COM and GLP. Test-retest reliability was evaluated for common COM parameters using Intraclass Correlation Coefficients (ICCs). Spearman's correlations compared parameters across conditions.

Results

Across all tasks/conditions, COM and GLP signals showed good to excellent mean zero time-lag cross-correlations ($r=0.88$-0.99) and RMSD <0.12cm. ICCs were stronger in the unaccompanied condition across tasks, particularly for the 95% confidence ellipse area

(ICC=0.75-0.89) and mediolateral mean velocity (ICC=0.63-0.84). Significant positive correlations (r=0.37-0.81) were observed between conditions for most COM parameters.

Discussion

The COM and GLP showed strong agreement, consistent with prior work [2,3]. Several COM parameters also demonstrated good reliability. Reliability fell in the accompanied condition, likely due to occlusions and subtle behavioural changes. Nonetheless, strong validity and correlations across conditions suggest Theia3D can support comparisons between healthy and pathological postural control. Study limitations include lack of clothing standardization and using the pelvis COM as a surrogate for whole-body COM. Future work will evaluate performance in clinical populations and extend validation to dynamic tasks.

Dr. Ana Filipa Durão

M.S. Jacopo Epifanio

Introduction

Knee osteoarthritis (KOA) is a prevalent degenerative disease that compromises joint stability and postural control [1]. Although these are common biomechanical alterations associated with KOA, patients often exhibit heterogeneous clinical trajectories, highlighting the need for stratified analyses. Emotional and psychological factors have been shown to influence postural stability [2], yet their relationship with objectively quantified postural control parameters in KOA remains unclear. This study investigated the association between emotional factors and postural stability using advanced postural control metrics, accounting for sex and treatment type.

Methods

Eighty-three adults with KOA (Kellgren Lawrence grades 2–3; 50 women, 33 men) performed quiet standing on a force platform. Participants were stratified by sex and treatment: conservative management or total knee replacement (TKR) waiting list. Emotional factors were assessed using the Pain Catastrophizing Scale (PCS). Postural control was characterized using traditional center-of-pressure parameters, a Synchronization Index [3], and Rambling and Trembling decomposition to distinguish supraspinal (rambling) and peripheral/reflexive (trembling) contributions [4,5] in anterior–posterior (AP) and medial–lateral (ML) directions. All stability data were normalized by

height. Associations were explored using correlation-based variable selection and second-order surface fitting (adjusted R^2).

Results

Significant associations between emotional and postural stability metrics were observed exclusively in men. In conservative men, PCS was associated with the mean trembling frequency in the ML direction and peak distance (adjusted $R^2 = 0.83$), yielding a saddle-shaped response surface (Figure 1a). In men awaiting TKR, PCS was associated with AP rambling root mean square and global spectral peak maximum frequency (adjusted $R^2 = 0.83$), characterized by a surface with a maximum (Figure 1b).

Discussion

These findings strongly suggest that emotional and physical factors are interconnected in KOA through sex- and treatment-specific postural mechanisms, involving distinct peripheral and supraspinal control components. Integrating pain management strategies and a gender perspective could improve the evaluation of postural instability in KOA.

Images (Optional)

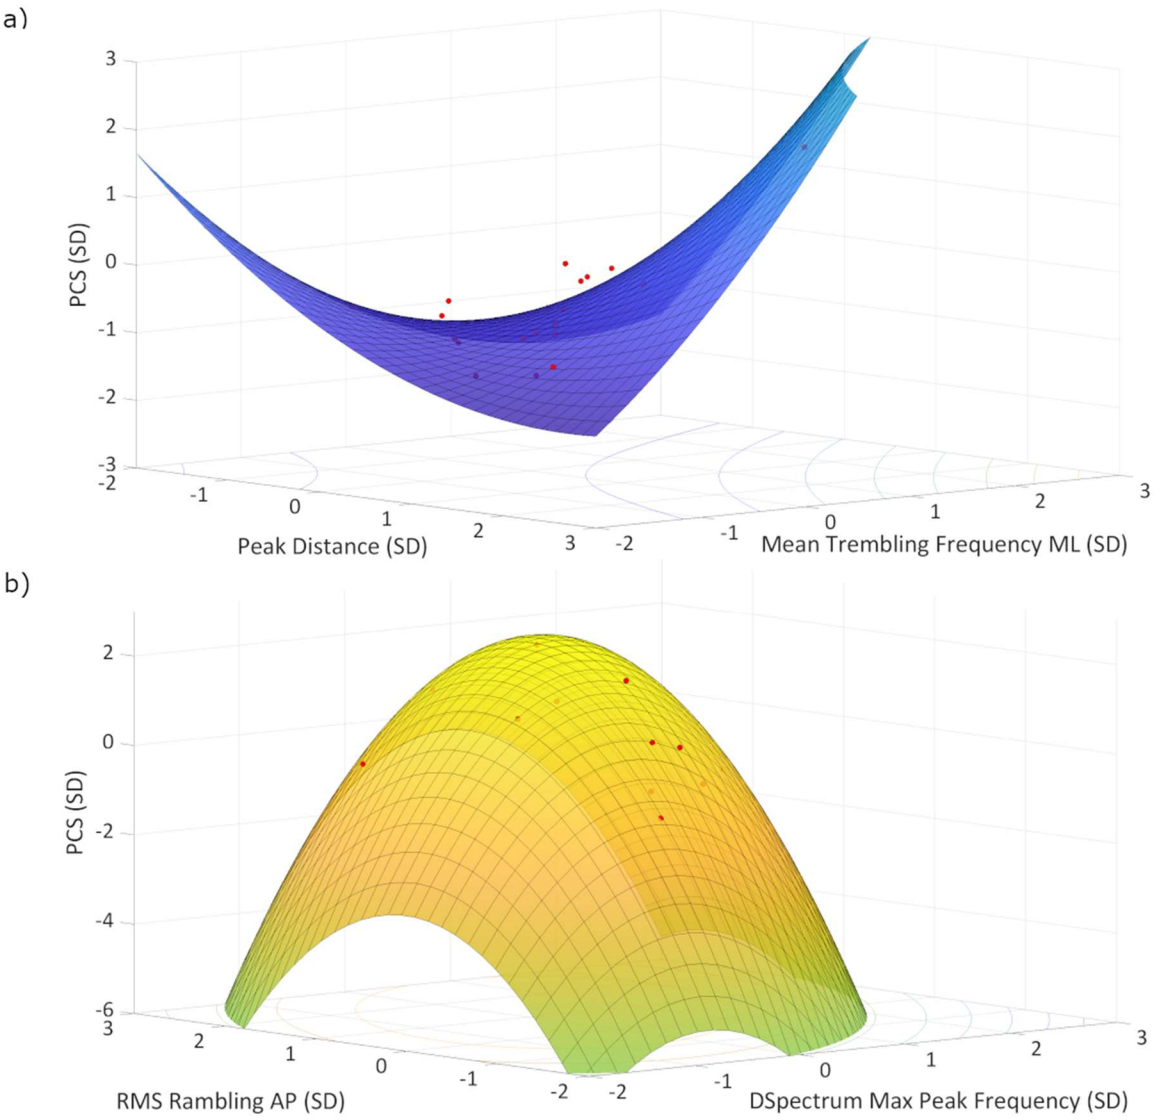

Figure 1. Second-order bivariate surface fits showing the relationship between PCS and postural stability parameters, for conservative men (a: adjusted $R^2 = 0.83$) and men awaiting TKR (b: adjusted $R^2 = 0.83$). All parameters normalized by standard deviations.

Comparing Effects of Control Parameters on Stability and Energy in Powered Knee Prosthesis Users During Perturbed Walking

Mr. Sixu Zhou[1], Mr. Hanjun Kim[1], Mr. John Shim[1], Mr. Atli Örn Sverrisson[2], Mr. David Langlois[2], Mrs. Kinsey Herrin[1], Dr. Aaron Young[1]

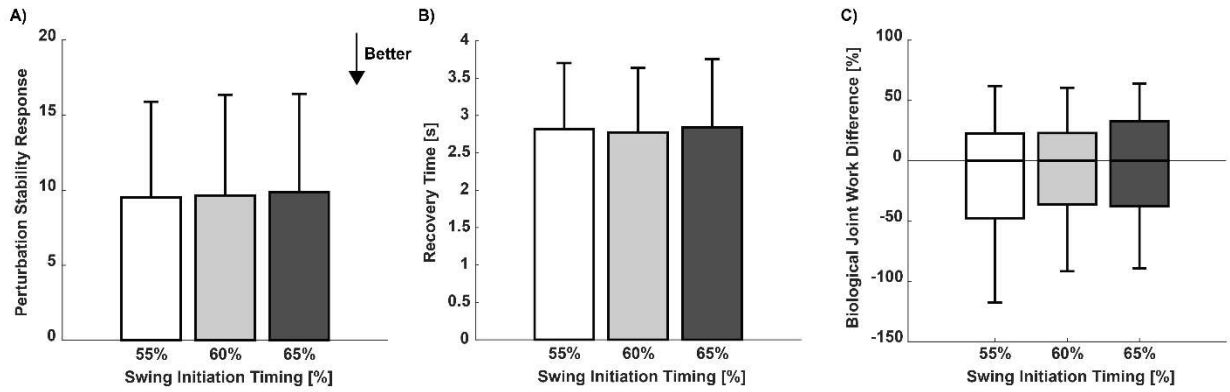
[1]Georgia Institute of Technology, Atlanta, Georgia, United States. [2]Össur, Reykjavík, Reykjavík, Iceland

Introduction

Powered lower-limb prostheses restore mobility to individuals with transfemoral amputation (TFA) and reduce mechanical energy cost during walking. However, slips and falls remain a major problem for individuals with TFA [1]. While previous studies examined powered knee control parameters on energy efficiencies during steady-state walking, the impact of control parameters on stability during perturbations remains largely unexplored [2]. Thus, we evaluated the biomechanical response of individuals with TFA using the Össur PowerKnee during perturbed walking. We tested the hypotheses that an earlier swing initiation timing would 1) improve post-perturbation stability and 2) reduce biological joint work compared to a later swing initiation timing.

Methods

Nine participants with unilateral TFA consented to an IRB-approved protocol and were fit and trained on the PowerKnee. After acclimation, motion capture and force plate data were collected while participants walked on the CAREN at a self-selected speed. During each trial, perturbations were applied through the CAREN platform that included two magnitudes, four directions, and four timings, while sweeping swing initiation from 55–65% of the gait cycle with a minimum of two repetitions per perturbation condition. The biomechanical results were generated using OpenSim and the joint work is determined by the trapezium integration of the joint power. The stability is quantified using the maximum Mahalanobis distance and the recovery time of the center of mass (CoM) relative to the center of pressure (CoP) trajectory in the limit cycle.



Results

As shown in Fig 1A-C, on average, an earlier swing initiation did not show a significance difference compared to a later swing initiation in both stability and energy efficiency, therefore allowing us to reject the Hypothesis 1 and 2.

Discussion

On average, an earlier swing initiation timing slightly improved stability and energy, but it was not sufficiently sensitive to detect differences in both stability and energy. However, the high subject variability emphasizes the importance of control parameter personalization. Future work should examine how biomechanical responses vary across perturbation types, magnitudes, and timings.

The Characterization of a Step Up, Stand Still, and Step Off Balance Assessment

Miss Sophia Chirumbole, Dr. Jessica Krok-Schoen, Dr. Shawanee' Patrick, Dr. Daniel Merfeld, Dr. Ajit Chaudhari

The Ohio State University, Columbus, OH, United States

Introduction

Falling is a concern, especially with increasing age. Falls can cause significant morbidities, such as bone fracture, traumatic brain injury, spinal cord injury [1], as well as fear of falling and self-isolation [2], so preventing falls is critically important. While quiet standing balance metrics are well-correlated to fall risk [3,4,5], dynamic balance (i.e. during stepping tasks) may be better than standing balance for predicting falls since most falls occur when someone is moving [6]. This study developed a novel step up, stand still, and step off (SUSO) task and associated analysis approach for further exploration into balance ability.

Methods

For each SUSO trial, participants were asked to step onto the force plate, stand still with their arms at their sides for approximately 3-5 seconds, then step off of the force plate. Ground reaction forces (GRF) were measured at 1000 Hz. Time to stabilization (TTSz) was calculated using the moving standard deviation (0.5 second window), with the minimum representing the most stable time window in the SUSO balance trial. The first timepoint with a standard deviation of less than five times the minimum was considered the TTSz in seconds (Figure 1).

Results

41 healthy adults participated after providing IRB-approved informed consent (36 ± 13 years old, 17M 24F). The mean (standard deviation, min-max) of TTSz was 1.44 (0.25, 1.03-2.21) seconds across all participants for the SUSO task.

Discussion

Gaining detailed information on stepping tasks could improve understanding of dynamic postural control and stabilization. The addition of force plate data and quantitative metrics like TTSz could allow for increased sensitivity and predicting balance performance. The proposed SUSO task could be easily implemented due to its familiarity for people who regularly use a weight scale. This exploratory work sets a foundation to better inform

studies of what movements contribute to falls and to design the most effective screening tools.

Impact of Walking Speed, Perturbation Direction, and Arm Constraints on Perceived Balance Capacity and Fall Risk

Dr. Sriram Muralidhar Postdoctoral scholar, Ms. Nkumbu Kamfwa Research Coordinator, Prof. James Finley Associate Professor

University of Southern California, Los Angeles, California, United States

Introduction

People's perceptions of their balance capacities and the risk associated with walking in different environments guide everyday walking choices. Because misjudging the relationship between one's capacity and balance-threatening features of the environment can lead to falls, it is essential to understand how task-specific estimates of perceived capacity and fall risk are influenced by factors known to modulate the risk of falls. Here, we present an experimental paradigm to quantify perceived balance capacity and fall risk, examining how they vary in response to task features known to impact actual fall risk during walking.

Methods

Participants walked on a split-belt treadmill and experienced random perturbations caused by unexpected changes in the speed of the left or right belt. In each trial, we progressively increased the change in speed until participants reported that a stronger perturbation would cause them to fall; we defined this highest tolerated perturbation as their perceived balance capacity. In addition, participants rated the riskiness of each perturbation on a 0–10 scale, with 0 corresponding to the perceived riskiness of quiet standing and 10 to a fall. They completed 28 trials each, walking at seven speeds (25–175% of self-selected speed) while experiencing forward or backward perturbations with their arms either tied or free. We fit linear mixed-effects models to determine how walking speed, perturbation direction, and arm constraint influenced perceived capacity and risk.

Results

Linear models explained trends in perceived capacity (R^2 = 44%) and risk (R^2 = 44%). Perceived capacity (Fig. 1 a-b) was higher for forward perturbations and the arms free condition ($p<0.05$). Perceived risk (Fig. 1 c-d) increased with walking speed, and was higher for backward perturbations and the tied condition ($p<0.05$).

Discussion

Our results suggest that perceived balance capacity and perceived fall risk depend on walking speed, perturbation direction, and arm constraint. This implies that fall-prevention interventions, such as perturbation training, should incorporate non–self-selected speeds, backward perturbations, and possibly physical constraints to limit the range of feasible balance recovery strategies. These perceived capacity measures may also help characterize how disease, injury, aging, or fatigue affect balance.

Energy Cost for Force Changes Is Nonlinear and This Nonlinearity Predicts Human Forces in Legs, Arms, Fingers, and Muscles

Dr. Sriram Muralidhar Postdoctoral scholar[1,2], Ms. Nadja Marin[3], Mr. Colin Melick[2], Dr. Hansol Ryu[4], Dr. Aya Alwan[2], Mr. Zhengcan Wang[5], Mr. Ross Baldwin[2], Prof. Kristen Heitman[2], Prof. Sam Walcott[6], Prof. Manoj Srinivasan[2]

[5]University of Wisconsin–Madison, Madison, Wisconsin, United States. [6]Worcester Polytechnic Institute, Worcester, Massachusetts, United States

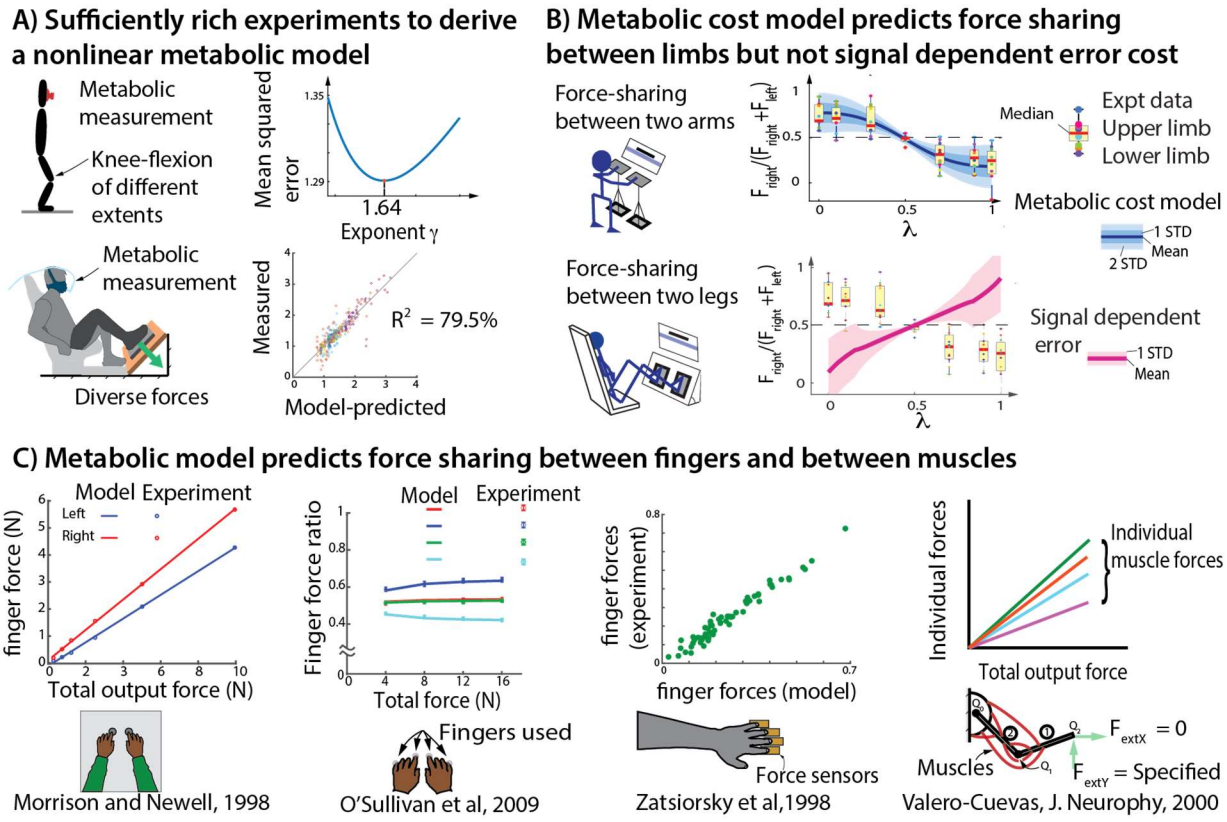
Introduction

A central challenge in motor control is the 'redundancy problem': how the CNS selects a specific solution from infinite possibilities. Two dominant theories propose that humans minimize either metabolic cost [1] or motor variability arising from signal-dependent noise [2]. Distinguishing these theories is difficult because they often yield correlated predictions. Here, we resolve this conflict by deriving an accurate metabolic cost function and employing novel experiments designed to disambiguate these objectives. We show that our metabolic model accurately predicts force distribution across arms, legs, fingers, and muscles.

Methods

Our study had multiple experiments, combining metabolic measurements with behavioral experiments. First, metabolic cost was modelled via two experiments: one where 19 participants tracked diverse, time-varying leg-force profiles and another involving isometric knee-flexed standing. Second, we conducted two experiments where 23 participants produced a total goal force using both arms or both legs, a redundant task allowing infinite limb-force combinations. We compared the right-left force sharing strategies predicted by minimizing our metabolic cost model with those predicted by minimizing signal-dependent error. We also applied our metabolic model to predict force sharing across fingers (unimanual and bimanual) and muscles using data from previous literature [3,4].

Results



The two metabolic experiments revealed that metabolic energy scales superlinearly with force (F^{γ} with exponent $\gamma \sim 1.6$, Fig. 1a). In the force-sharing experiments, human behavior matched predictions from minimizing this nonlinear metabolic cost (Fig 1b). In contrast,

the alternative theory of minimizing signal-dependent noise predicted forces anti-correlated with the empirical data. The metabolic model also predicted force-sharing patterns between fingers and the linear scaling of individual muscle forces observed in prior literature (Fig 1c).

Discussion

Our findings demonstrate how metabolic energy scales superlinearly with force, contrasting with the common linear and quadratic models. We show that the nervous system accounts for these nonlinearities, as our model predicts force-sharing patterns across limbs, fingers, and muscles. Our findings rule out signal-dependent noise minimization, establishing metabolic energy minimization as a central driver of force sharing.

Does Balancing a Ball on the Back Change Spinal Movements During the Bird-Dog Exercise?

Dr Cathrine Feier PhD, Dr Stephen Brown PhD

University of Guelph, Guelph, Ontario, Canada

Introduction

The “bird-dog” is a commonly prescribed rehabilitation exercise for low back pain that attempts to activate spine stabilizing muscles while minimizing compressive forces. The exercise involves contralateral arm and leg extension while maintaining a neutral spine; ideally avoiding excessive rotation and flexion/extension movements. This study aimed to investigate if balancing a rubber ball on the lower back during bird-dog exercises could immediately decrease spine flexion/extension and axial rotation range of motion (RoM) in a healthy population.

Methods

Fifteen participants (mean ± standard deviation: age: 21 ± 1 years, mass: 65.4 ± 11.4 kg, height: 166.6 ± 6.9 cm) volunteered to participate in the study. Marker-based motion capture (120 Hz) was utilized to collect kinematic data for the trunk and pelvis during three trials (Pre, Ball, Post), each of 20 bird-dog repetitions. The second trial included a small rubber ball on the lower back and instructions to attempt not to drop the ball (Figure 1). A flexion-extension, lateral bend, axial rotation Cardan sequence was used to calculate the three-dimensional angles between the trunk and pelvis segments.

Results

Repeated measures ANOVAs demonstrated significant differences between trials (Pre, Ball, Post) for spine flexion/extension ($p < .001$, partial $\eta^2 = .556$) and axial rotation ($p < .001$, partial $\eta^2 = .565$) RoM. Post-hoc tests with Bonferroni adjustments revealed significantly decreased flexion/extension RoM during the Ball trial (mean ± standard error: 16.0° ± 1.0°) compared to the Pre (23.7° ± 1.8°; $p = .002$) and Post (23.2° ± 1.7°; $p = .001$) trials. Similarly, axial rotation RoM was significantly lower during the Ball trial (8.7° ± 0.9°) compared to the Pre (15.7° ± 1.6°; $p = .002$) and Post (15.0° ± 1.5°; $p = .001$) trials.

Discussion

The results indicate that attempting to balance a small ball on the lower back during bird-dog exercises can significantly decrease spine flexion/extension and axial rotation RoM. A ball could therefore be a simple facilitator for maintaining a neutral spine during bird-dog exercises. However, there was no immediate retention effect, indicating a likely need for repeated interventions to induce long term changes.

Participant Instructions During Research Studies: Open to Interpretation? a Case Study

Dr Cathrine Feier PhD[1], Ms Samantha Tsioros BSc[1], Ms Victoria Lippitt BSc[1], Dr Shawn Beaudette PhD[2], Dr Stephen Brown PhD[1]

[1]University of Guelph, Guelph, Ontario, Canada. [2]Brock University, St. Catherines, Ontario, Canada

Introduction

Clear communication is essential when providing instructions to human participants in biomechanics research studies. Underlying beliefs or experience can affect people's interpretation of instructions and lead to variable outcomes despite identical instructions. This case study explored the kinematic changes observed when clarifying instructions between movement blocks in a spine flexion study.

Methods

The participant (P12) volunteered for a study asking participants to "bend forward" with a tucked chin and arms hanging. All participants performed three blocks of 10 forward bending movements. It was deemed necessary to explain to P12 that spine flexion was preferred over hip hinging after they had completed the first block. Kinematic data were captured with marker-based motion capture (120 Hz). Flexion-extension angles and range of motion (RoM) were calculated for the lumbar (S1-T12), thoracic (T12-C7), and total spine (S1-C7). Intersegmental angles for each repetition were used in a principal components analysis and subsequent single component reconstruction (SCR) of the first principal component.

Results

P12 was the most variable participant in the study and more than doubled their mean lumbar and total spine RoM from the first to the second block (Figure 1). This can be compared to P10 who demonstrated similar values in all three blocks. The SCR plots revealed more variability in intersegmental RoM magnitude, seen as a larger separation between the 5^{th} (red line) and 95^{th} (blue line) percentiles for P12 compared to P10 (Figure 1). P12 also demonstrated different thoracic spine movement strategies between repetitions, indicated by the red and blue lines moving in opposite directions at the same point of the movement cycle.

Discussion

The change from hip hinging in the first block to spine flexion in the other blocks led to large changes in RoM and intersegmental movement strategies. The changes can be visualized by comparing the RoM for separate blocks and through SCR plots. Researchers need to be mindful of potential underlying beliefs that can affect how people move (e.g. “spine flexion should be avoided”) and previous work/exercise/injury experience.

Strategies for Successful Balance Recovery Following Trips and Slips While Walking: A Systematic Review

Mr. Sungmin Chun PT, Mr. Junwoo Park PT, MSc, Dr. Kitaek Lim PT, PhD, Prof. Woochol Joseph Choi PT, PhD

Injury Prevention and Biomechanics Laboratory, Yonsei University, Wonju, Gangwon-do, Korea, Republic of

Introduction

One quarter of falls among older adults occur during walking, with tripping and slipping identified as primary causes [1]. Although studies have shown that individuals who successfully recover their balance following a trip or slip utilize distinct balance-recovery strategies [2–4], no comprehensive synthesis has yet outlined the most effective strategies for preventing a fall during gait [5]. This review identifies the strategies associated with successful balance recovery while walking.

Methods

Following PRISMA 2020 guidelines, PubMed, Scopus, and EMBASE were searched (1984–2025) using terms related to walking, trip, slip, and balance recovery. The search identified 1,981 records; 972 remained after deduplication. After screening and full-text review, 15 studies met inclusion criteria involving humans exposed to externally triggered, unexpected trip/slip perturbations during walking and reported strategies distinguishing successful from unsuccessful recoveries. The final dataset included sixteen studies. Data on perturbation type, strategy classification, protocols, and outcome measures were extracted.

Results

Among the six trip-related studies, elevating strategies—lifting the obstructed limb to clear the obstacle—were observed in successful recoveries in five studies (Figure 1a), whereas lowering strategies—rapidly placing the foot on the ground—were reported more frequently in three unsuccessful cases (Figure 1b). Arm movements—asymmetric retroflexion–anteflexion with abduction—appeared in two studies as secondary trunk stabilizers (Figure 1c). In the ten slip-related studies, eight identified compensatory stepping—initiating a rapid step to expand the base of support—as the primary successful strategy (Figure 1d).

Arm strategies—contralateral arm abduction—were noted in two studies but were insufficient without effective stepping (Figure 1e).

Discussion

Our results suggest that successful balance recovery following a trip-related loss of balance is primarily supported by elevating responses, whereas recovery during slip-induced falls relies on rapid compensatory stepping. Arm strategies, observed in both trip and slip scenarios, aided trunk stabilization but functioned as supplementary rather than primary recovery mechanisms. These insights can inform cause-specific, perturbation-based balance training programs to enhance fall-prevention outcomes.

Joint contributions to whole-body centre of mass work and muscle coordination patterns during single leg squats

Ms. Sylvia Masse BSc, Dr. Jordan Cannon PhD

University of Waterloo, Waterloo, Ontario, Canada

Ms. Sylvia Masse

Introduction

During single leg squats (SLS), changing the non-stance (NS) limb position alters kinematics and kinetics across the trunk-lower limb linkage as well as discrete activation measures for select hip muscles [1, 2]. The impact of NS limb position on relative joint contributions to whole-body centre of mass (WB-COM) dynamics and associated muscle coordination strategies is unknown. The purpose of this study was to investigate multi-joint control strategies and muscle function with relation to varying NS limb positions during SLS tasks.

Methods

3D kinematics, ground reaction forces (GRFs), and EMG of trunk and lower limb muscles were collected from 18 females during SLS tasks with NS limb positions: front, lateral, and rear. An inverse dynamics approach calculated joint power. WB-COM power was estimated as the dot product of the GRF and WB-COM velocity. Joint and WB-COM powers were integrated over time to yield work. Muscle synergy analysis is currently in progress to quantify muscle coordination and associations with joint work contributions to WB-COM work. Linear mixed effect models compared joint contributions and WB-COM work under varying NS limb positions.

Results

Results did not differ between descent and ascent phases of SLS. The hip and knee were the greatest contributors to WB-COM work, with the knee contributing significantly more than the hip (Figure 1). Despite joint contribution variability, WB-COM work was well estimated by the sum of joint work of the stance limb and lumbar joints, adding arm and NS limb joints worsened estimates.

Discussion

SLS tasks are not equal. While WB-COM work was consistent across NS limb positions, joint work contributions vary. The joint work of the NS limb and arms have opposing polarity to stance limb and lumbar spine joint work, reflecting internal work to move the segments about the WB-COM, not move the WB-COM itself. Muscle coordination is expected to change with altered magnitude and timing of muscle subsets to meet the specific demands incurred due to the NS limb position, opposed to the primary motion demands of the squat task to lower and raise WB-COM.

Accuracy of DeepLabCut Pose Estimation Software in Extracting Whole-Body Kinematics During Falls

Ms Kylie Shlecker BSc[1], Dr Nataliya Shishov PhD[2], Teah Cribbie[2], Dr Yaejin Moon PhD[3], Dr Stephen Robinovitch PhD[2]

[1]Simon Fraser University, Burnaby, British Columbia, Canada. [2]Simon Fraser University, Burnby, British Columbia, Canada. [3]Syracuse University, Syracuse, New York, United States

Introduction

Falls are the number-one cause of injury, and a top-ten cause of death for adults over age 65. Quantifying the movements of the body during falls can provide clues on why falls occur, and how they can be prevented. In this project, our objective was to determine the accuracy of DeepLabCut (DLC), a neural network software package for markerless pose estimation, in estimating the time-varying positions of body segments during falls, when compared to manual digitization by Kinovea.

Methods

We analyzed 30 videos of sideways falls, from fall initiation to landing. Each video had a resolution of 640x480 pixels, a frame rate of 30Hz, and a duration of at least 42 frames (1.4 s). We focused on the time-varying positions of eight body parts (ankle, knee, ASIS, wrist, elbow, sternum, head, and shoulder). For DLC, 80% of the data (24 falls) were used for model training, and 20% were used for model testing (6 falls). During model training, 20 frames per video were manually annotated. Results are reported in terms of raw values of root mean square error (RMSE) in cm, and normalized values of RMSE (NRMSE), calculated as a percent of the movement amplitude for the given body part, in each of the horizontal and vertical directions.

Results

Raw errors averaged 4.1±0.2 (SE) cm, and normalized errors averaged 9.9±0.6 percent (Table 1). Overall, there was no significant difference in the accuracy of vertical versus horizontal position estimates, but this varied with body part. There was a significant effect of body part on DLC accuracy, with the wrist, ankle, and ASIS showing higher NRMSE values than other body parts ($p>0.003$). NRMSE values were affected minimally by use of a 2D (grid) versus a 1D (height) calibration.

Discussion

We found that DLC was accurate, in general, to within 4 cm in estimating the time-varying positions of the body segments during lab-based falls. This is similar to the errors reported previously for pose estimation in extracting gait kinematics. Future research should extend the analysis to real-life falls, where complex issues like occlusions of body parts may create challenges, and from 2D to 3D.

Thoracolumbar Spinal Posture in Classical Ballet Dancers During Standing and Walking: The Flatter Lumbar Spine Does Not Persist Under Dynamic Conditions

Mr. Tempei Tominaga[1], Ms. Haruka Okuyama[2], Ms. Ayaka Hobo[1,3], Ms. Yoshino Shinabe[1], Dr. Natsuki Sado[4,3]

[1]Graduate School of Comprehensive Human Sciences, University of Tsukuba, Tsukuba, Ibaraki, Japan. [2]Graduate School of Human Sciences, Waseda University, Tokorozawa, Saitama, Japan. [3]Advanced Research Initiative for Human High Performance, University of Tsukuba, Tsukuba, Ibaraki, Japan. [4]Institute of Health and Sport Sciences, University of Tsukuba, Tsukuba, Ibaraki, Japan

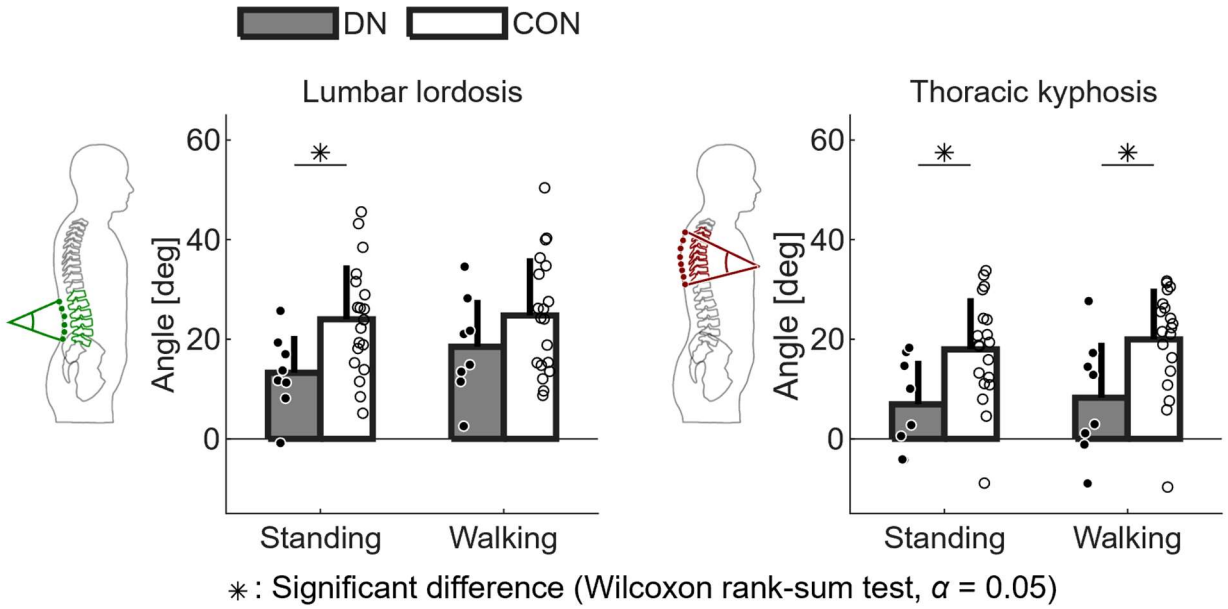
Introduction

The spinal curve has been targeted in postural interventions because excessive curvature can lead to musculoskeletal pathologies [1]. Exercise programmes lasting up to 30 weeks are effective in reducing thoracic kyphosis (TK) but are less effective in reducing lumbar lordosis (LL) [1]. Ballet dancers, who have undergone years of ballet-specific postural training focusing on the spine, exhibit a flatter lumbar spine when standing [2]; thus, more prolonged postural training may alter LL. However, it remains unclear whether this flatter lumbar spine persists in dynamic conditions as well. Therefore, we investigated the thoracic and lumbar curves in ballet dancers under both static and dynamic conditions.

Methods

Eight female ballet dancers (DN: 16.1 ± 4.6 years of experience) and 19 female non-dancers (CON) performed 3-second quiet standing and preferred speed walking. Kinematic and ground reaction force data were collected using a motion capture system with three force platforms. TK and LL were quantified using Cobb-angle–like metrics [3] derived from markers on the T3–T10 and T12–L5 spinous processes, respectively.

Results



During standing, DN exhibited a flatter spine than CON, showing lower TK (DN vs. CON: 6.9 ± 8.7° vs. 18.0 ± 10.3°, $p = 0.016$) and lower LL (13.3 ± 7.4° vs. 24.0 ± 10.8°, $p = 0.028$). During walking, stride-averaged TK was lower in DN (8.3 ± 11.0° vs. 20.0 ± 10.2°, $p = 0.021$), whereas LL showed no significant difference (18.5 ± 9.4° vs. 24.8 ± 11.5°, $p = 0.232$).

Discussion

Although LL is difficult to change through exercise programmes [1], ballet dancers exhibited flatter thoracic and lumbar spines in standing. This implies that long-term training

may be effective in reducing not only thoracic, but also lumbar spinal curvature. However, the between-group difference in LL was obscured during walking, despite the consistent between-group differences in TK. These results suggest that reducing dynamic lumbar curvature may be difficult, even with long-term intervention, and this finding should be taken into account when designing postural interventions.

Age-Related Changes in Lower Limb Joint Contributions During Jump Landing in Children

Mr Thibaut Toussaint[1], Dr. Clément Gambelli[1,2], Pr. Bénédicte Schepens[1]

[1]UCLouvain, Louvain-la-Neuve, ., Belgium. [2]North-West University, Potchefstroom, ., South Africa

Introduction

Landing from a jump requires coordinated control of the body segments to dissipate the mechanical energy accumulated during the aerial phase. Throughout motor development, children progressively adapt their landing strategy by increasing the mechanical contribution of their lower limb joints, while the contribution of the upper limbs remains relatively unchanged [1]. The joint-specific mechanisms underlying this increased reliance on lower limb joints remain unclear. This study aimed to quantify the contributions of the ankle, knee, and hip joints during landing across childhood.

Methods

Sixty-eight children (3–12 years) and twenty-one adults performed double-leg landings by hopping off a 30-cm box. Ground reaction forces and full-body three-dimensional kinematics were recorded. Using a bottom-up inverse dynamics approach, mechanical work performed at the ankle, knee, and hip joints was computed from touchdown to the lowest vertical position of the center of mass. A linear mixed model was used to assess the effect of age.

Results

The mass-specific amount of negative mechanical work performed by the ankle and knee increased with age (p<0.001), whereas the work performed by the hip was higher in young children and decreased throughout childhood (p=0.046; Figure). During the first instants of landing (in red), the amount of negative work performed by the lower limb joints was lower in young children and increased with age, and the ankle was the main contributor. After the force peak (in blue) the amount of negative work performed by the lower limb joints was higher in young children and decreased with age, and the knee and hip were the main contributors.

Discussion

The age-related increase of lower limb joint contribution results from modifications during the initial instants of landing, when the ankle joint dominates mechanical energy absorption. Although negative work after the force peak was higher in young children, primarily due to greater hip involvement, it did not compensate for the lower amount of work produced during the initial instants. This pattern may reflect a proximo-distal maturation of lower limb joint control.

Biarticular muscle energy transfer across childhood during jump landing

Mr Thibaut Toussaint[1], Pr Bénédicte Schepens[1], Dr Clément Gambelli[1,2]

[1]UCLouvain, Louvain-la-Neuve, ., Belgium. [2]North-West University, Potchefstroom, ., South Africa

Introduction

Landing from a jump requires coordinated control of the body segments to dissipate the mechanical energy accumulated during the aerial phase. Throughout motor development, children progressively adapt their landing strategy by increasing the mechanical contribution of their lower limb joints, while the contribution of the upper limbs remains relatively unchanged [1]. From our unpublished data analysis, we found that this increased contribution of lower-limb joints with age is driven by greater mechanical work produced at the ankle and knee. Through biarticular muscles, proximal muscles can generate work that contributes to more distal joints; for example, knee extensors can contribute to the mechanical work observed at the ankle. In the present study, we aimed to investigate the potential for energy transfer through biarticular muscles to better understand the lower mechanical work performed at the ankle and knee in young children.

Methods

Sixty-eight children (3–12 years) and twenty-one adults performed double-leg landings by hopping off a 30-cm box. Ground reaction forces and full-body three-dimensional kinematics were recorded. Using ankle, knee and hip joint angles, we quantified the potential for energy transfer as the percentage of time during which adjacent joints moved in-phase (see [2] for more details). A linear mixed model was used to assess the effects of age.

Results

The potential for energy transfer between the ankle and knee, and between the knee and hip increased with age ($p < 0.001$, Figure). The percentage of time during which the ankle and knee moved in-phase ranged from 50% to 75%, whereas the percentage for the knee and hip was around 75%.

Discussion

The age-related changes in the potential for energy transfer appear to reflect adjustments in joint coordination. Throughout childhood, the increasing contribution of the ankle and knee joints, may result from a growing ability to use biarticular muscles to transfer energy. Consequently, the contribution of proximal muscles to the mechanical work observed at the ankle and knee would improve with age.

[4]Department of Health and Human Physiological Sciences, Skidmore College, Saratoga Springs, NY, United States

Introduction

Lateral ankle sprains are the most common injury in physical activities, with a high reinjury risk. Individuals with ankle instability are associated with poor postural control performance. Therefore, this study aimed to evaluate limb differences in postural control during an eyes-closed single-leg stance task in patients with torn lateral ankle ligaments prior to surgical reconstruction.

Methods

Seven patients (5 females and 2 males, 29.1 ± 8.7 yrs, 70.9 ± 10.3 kg) performed an eyes-closed single-leg stance task on a force plate (Bertec, Columbus, OH, USA; sampling frequency=1000Hz) for both the injured and uninjured limbs. They were instructed to fold their arms across their chest and maintain a single-leg stance for up to 30 seconds. If patients were unable to continue, they were allowed to place the foot down, and the actual stance time was recorded. Center of pressure (CoP) data were collected to quantify postural control. CoP range, standard deviation, and peak velocity in the anterior-posterior and medial-lateral directions were calculated during the stance duration. The stance duration and CoP sway area were also included as dependent variables. The Wilcoxon signed-rank test was applied to identify the limb differences (p-value<0.05).

Results

Uninjured limbs showed significantly longer stance duration than injured limbs (Table 1). No significant differences were observed in the rest of the variables (Table 1).

Discussion

Although participants aimed to maintain a single-leg stance for 30 seconds, they were able to stand only about 12 seconds on the uninjured limb and approximately 6 seconds on the injured limb. The lack of statistically significant limb differences in CoP outcomes may be related to a small sample size and the data reduction. At this stage, only seven patients completed testing before their lateral ankle ligament reconstruction. In addition, the CoP outcomes were calculated based on each limb's actual stance duration. Because stance time on the uninjured limb was roughly twice that of the injured limb, the CoP metrics captured different lengths of postural control performance. Therefore, the findings suggest that the injured limb demonstrated postural control similar to the uninjured limb, but for approximately half the stance duration.

Images (Optional)

Table 1 Mean ± standard deviation and p-values of Wilcoxon signed-rank test for dependent variables during the eye-closed single-leg stance task.

	Injured leg	Uninjured leg	P-values
Stance duration (s)	5.90 ± 6.29 *	11.13 ± 8.30 *	**0.018**
Range of CoP in medial-lateral direction (cm)	6.91 ± 7.01	5.16 ± 2.69	0.499
Range of CoP in anterior-posterior direction (cm)	10.98 ± 8.65	9.58 ± 3.23	0.866
Standard deviation of CoP in medial-lateral direction (cm)	1.51 ± 1.13	1.25 ± 0.59	0.612
Standard deviation of CoP in anterior-posterior direction (cm)	2.04 ± 1.02	1.86 ± 0.52	0.499
Sway area of CoP (cm^2)	88.10 ± 154.53	37.84 ± 40.46	0.310
Peak CoP velocity in medial direction (cm/s)	70.49 ± 77.36	72.30 ± 56.69	0.866
Peak CoP velocity in lateral (-) direction (cm/s)	-82.71 ± 111.44	-51.74 ± 50.18	0.866
Peak CoP velocity in anterior direction (cm/s)	97.64 ± 95.89	77.48 ± 56.17	0.499
Peak CoP velocity in posterior (-) direction (cm/s)	-130.40 ± 113.39	-92.22 ± 79.69	0.176

Quantifying Sex-Specific Coordination Variability of the Inter-Segmental Center of Mass Velocity During Sidestepping

Dr. Xiaoyi Yang[1], A.P. Qichang Mei[2], Dr. Vickie Shim[1], Prof. Justin Fernandez[1]

[1]Auckland Bioengineering Institute,The University of Auckland, Auckland, North Island, New Zealand. [2]Faculty of Sports Science, Ningbo University, Ningbo, Zhejiang, China

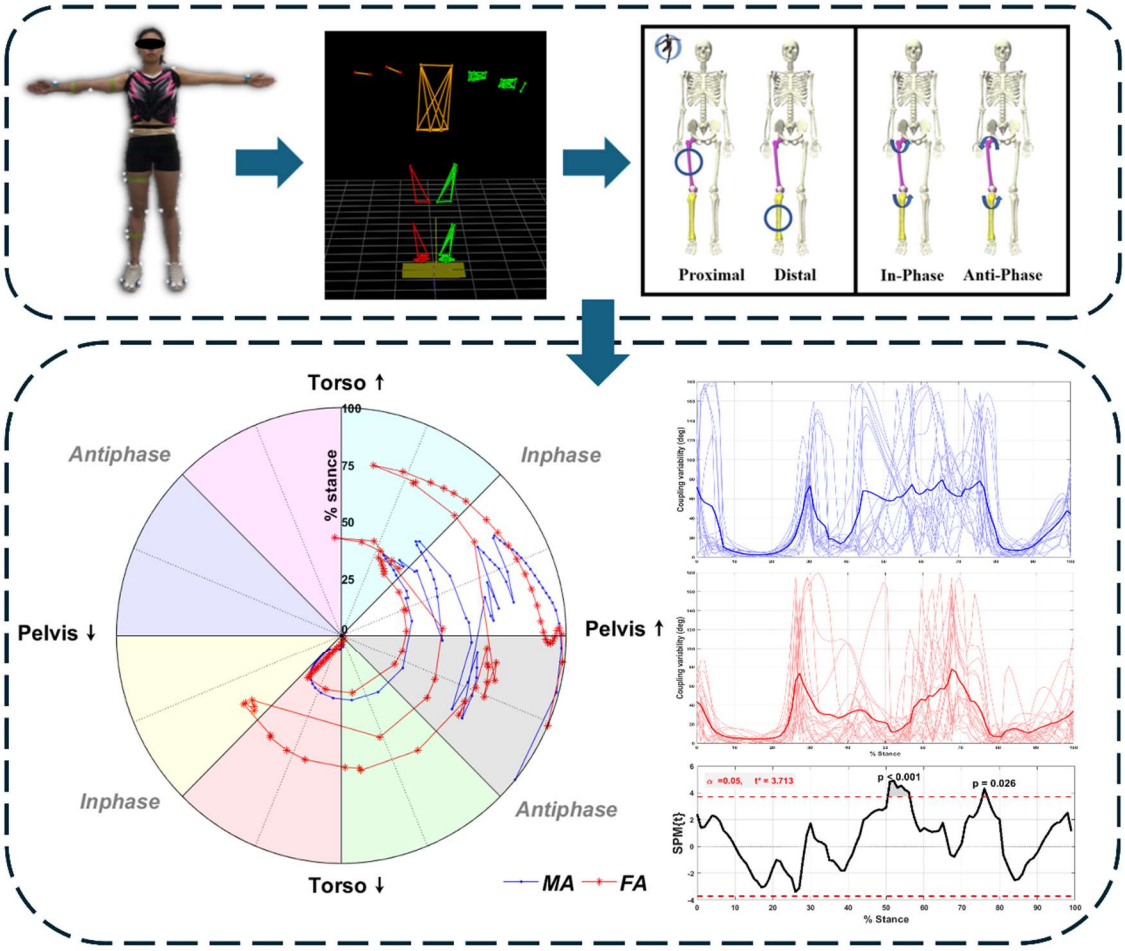
Introduction

Sidestepping requires maintaining dynamic stability during the execution of fast lateral motion [1]. The segmental Center of Mass (sCOM), which measures the relative amplitude of movement patterns between adjacent segments, has an influence on the efficiency of the motor. Changes in segmental coordination variability may lead to biomechanical overload, ultimately compromising performance. The objective of this study was to utilize vector coding to investigate the sCOM velocity differences between males and females during sidestepping, understanding sex-specific inter-segmental coordination patterns.

Methods

Eighteen male and eighteen female national-level athletes participated in performing sidestepping with a 52-marker set attached. Data was collected using an 8-camera Vicon motion capture system and one force platform. The sCOM was analysed using OpenSim and utilized for coordination analysis. Segmental color maps were employed to provide insight into inter-segmental coordination information, including femur-tibia, pelvis-femur, pelvis-torso, torso-humerus, and humerus-forearm. The time-varying coupling angles between males and females were analysed using an independent sample t-test, with a significance threshold at 0.05.

Results



During the entire sidestepping movement, the sCOM of the whole body was faster than females ($p<0.05$). The sCOM velocity mappings of the lower extremity during sidestepping (pelvis-torso, pelvis-femur, and femur-tibia) were all in-phase with proximal dominance in males, while females were anti-phase with distal dominance. Significantly higher coordination variability was observed in the pelvis-torso ($p<0.001$) and pelvis-femur ($p=0.002$) in males. In the following phase, the upper limb's coordination (torso-humerus and humerus-forearm), exhibited distal dominance in males but proximal dominance in females, and females showed higher variability ($p=0.005$). In addition, at the end of the

following stage, the segmental velocity pattern for both males and females was characterized by forearm dominance.

Discussion

Exploring the inter-segment coordination of sex-specific would provide a better understanding of the sCOM coordination pattern in sidestepping. The profiles of inter-segmental coordination patterns and variability may practically imply the development of sex-specific training programs to control dynamic balance.

Effect of Personalized Perturbation Training on Reactive Balance Skills and Perceived Balance Control in Older Adults

Ms. Celeste Thai, Dr. Noah Rosenblatt, Dr. Kristin Schneider, Dr. Ying Fang

Rosalind Franklin University, North Chicago, IL, United States

Introduction

Perturbation training has been shown to improve balance skills, and most existing protocols prescribe the same level of perturbations for all participants. However, this may undermine perceived control and cause overwhelming distress in some people. We developed an intervention that allows individuals to practice walking with perturbations at a self-selected level. This study aims to investigate the effect of this personalized intervention on reactive balance and perceived control and distress in older adults.

Methods

Preliminary data of 8 participants (4 females, age: 73±6 years, speed: 0.64±0.29 m/s) are reported. Participants completed a pre-assessment including walking trials with increasing perturbation levels, and determined the level that is challenging but manageable ($level_N$). They then completed three practice trials at $level_N$ and a post-assessment trial at $level_N$ (Figure 1A). We quantified reactive balance using recovery step length, perceived balance control using Updated Perceived Control over Falling Scale (UP-COF), and perceived distress using Subjective Units of Distress Scale (SUDS). We used paired t-tests to compare all outcomes before and after practice.

Results

There were no differences between pre- and post-practice outcomes for trip step length (pre vs. post: -0.03±0.1 m vs. -0.0042±0.14 m, p=0.672), slip step length (pre vs. post: 0.47±0.18 m vs. 0.46±0.15 m, p=0.338), UP-COF score (pre vs. post: 17±3 vs. 19±1, p=0.275), or perceived distress (pre vs. post: 2.3±1 vs. 2.2±0.9, p=0.351) (Figure 1C-F).

Discussion

Self-identified perturbation intensities ranged from level 4 to 10 out of 10 (Figure 1B). Most participants had a recovery step length that was more similar to a normal step after practice (Figure 1C-D). Although the mean UP-COP score did not change across all participants, those who had lower scores (less control over falling) during pre-assessment generally had increased scores after practice. Perceived distress did not change for most participants, likely because they chose intensities that caused no more than mild distress

(SUDS≤3). The preliminary data demonstrate the feasibility of this personalized intervention, and more participants are needed to draw stronger conclusions.

Images (Optional)

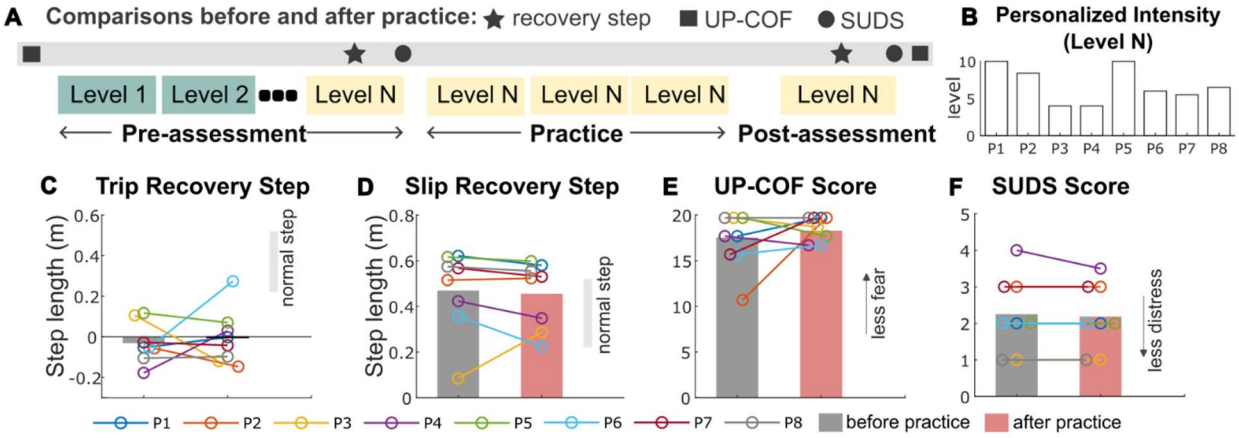

Figure 1. A) Study flow. Each box represents a walking trial with four perturbations (2 trip-like and 2 slip-like) at a given intensity. During pre-assessment, participants identified a challenging but manageable level by deciding whether to try the next level after each trial. The highest level attempted (Level N) was their self-identified level and used for practice and post-assessment. B) Self-identified perturbation level for each participant. C-F) Recovery step length, UP-COF score, and SUDS score for each participant. Bars represent the average of all participants.

Novel Cyclic-Stability Dynamics for Probing Motor Adaptation in Humans

Ms Yixin Zhang PhD Student, Dr. Calvin Kuo Assistant Professor, Dr. Jean-Sébastien Blouin Professor

University of British Columbia, Vancouver, BC, Canada

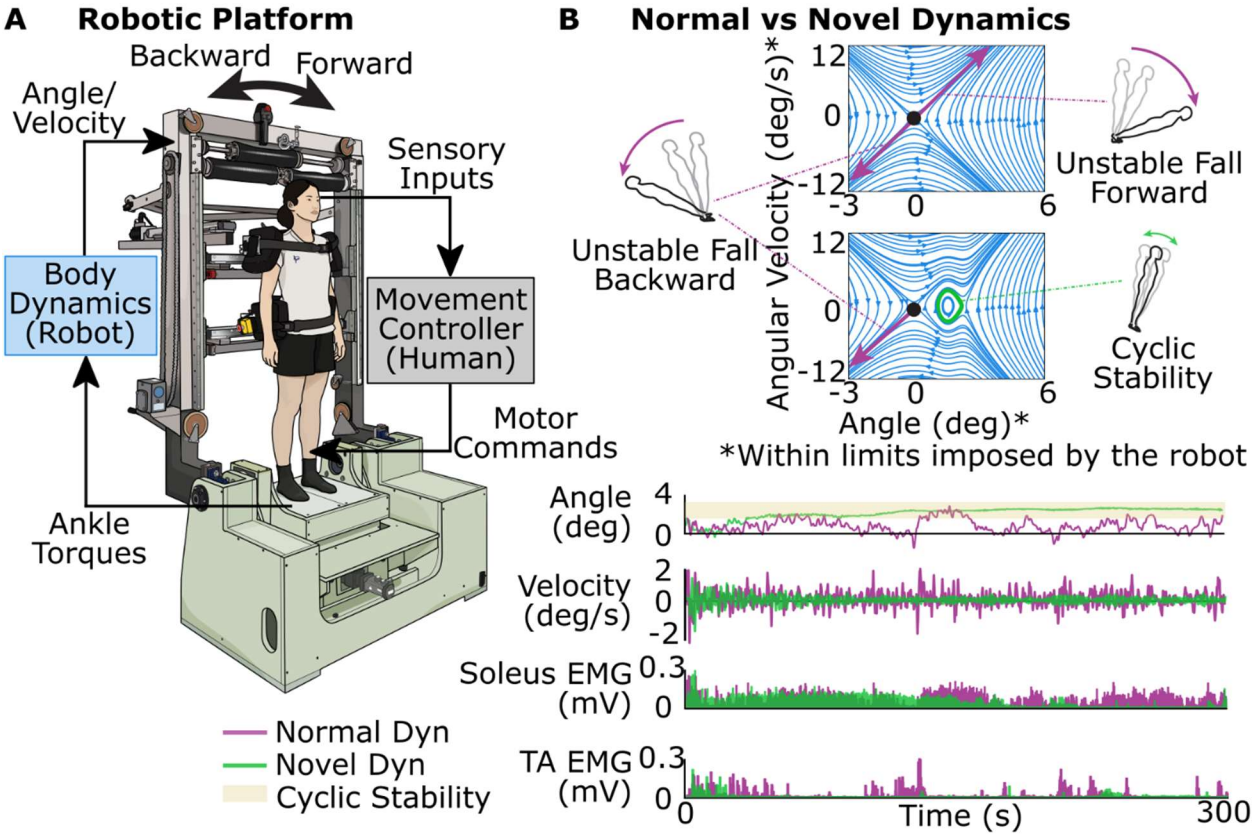
Introduction

Motor adaptation, even in tasks as simple as standing upright, engages complex neural processes, yet its underlying mechanisms remain unclear due to the lack of truly novel movement environments. To address this limitation, we introduce novel dynamics implemented on a human-in-the-loop standing balance robotic platform [1] that alters the natural physical laws of standing balance dictating the relationship between applied torques and body motion. We hypothesize that the novel dynamics will modify participant's natural standing behavior, reflected in changes in standing angle and velocity.

Methods

The robotic platform simulates and records anterior-posterior postural control as an inverted pendulum under normal dynamics, where a force plate measures ankle torques and a backboard tilts the participant forward and backward according to natural physical laws. The novel dynamics remap the relationship between ankle torques and body motion, featuring a region of cyclic stability between 1 and 3 standard deviations forward of the participant's preferred mean angle. The participant completed six 5-minute trials under randomized normal or novel balance dynamics.

Results



The participant's mean ± standard deviation standing angle under the normal and novel dynamics was 1.16 ± 0.26 degrees and 1.21 ± 0.20 degrees, respectively. The absolute angular velocity was 0.24 ± 0.03 degrees/second during normal dynamics and was reduced to 0.09 ± 0.004 degrees/second during novel dynamics. Root-mean-square (RMS) electromyography (EMG) of the soleus was 0.019 ± 0.007 mV during normal dynamics and was reduced to 0.007 ± 0.002 mV during novel dynamics. RMS EMG of the tibialis anterior was 0.012 ± 0.004 mV during normal dynamics and 0.011 ± 0.007 mV during novel dynamics.

Discussion

The novel dynamics enable direct probing of motor adaptation mechanisms by placing participants in a controlled environment that cannot exist under natural biomechanics. The

observed reductions in absolute velocity and soleus RMS EMG reflected adaptation to a new way of standing and exploitation of a stable and energy-efficient control strategy. Combined with reinforcement learning models, we can use the novel balance dynamics to reveal the mechanisms underlying the control of standing and probe learning deficits in varied populations.

Sex-Specific Patterns of Lower-Extremity Joint Stiffness Coordination Revealed Across Drop Heights during Drop Jump

Dr. Young Min Chun

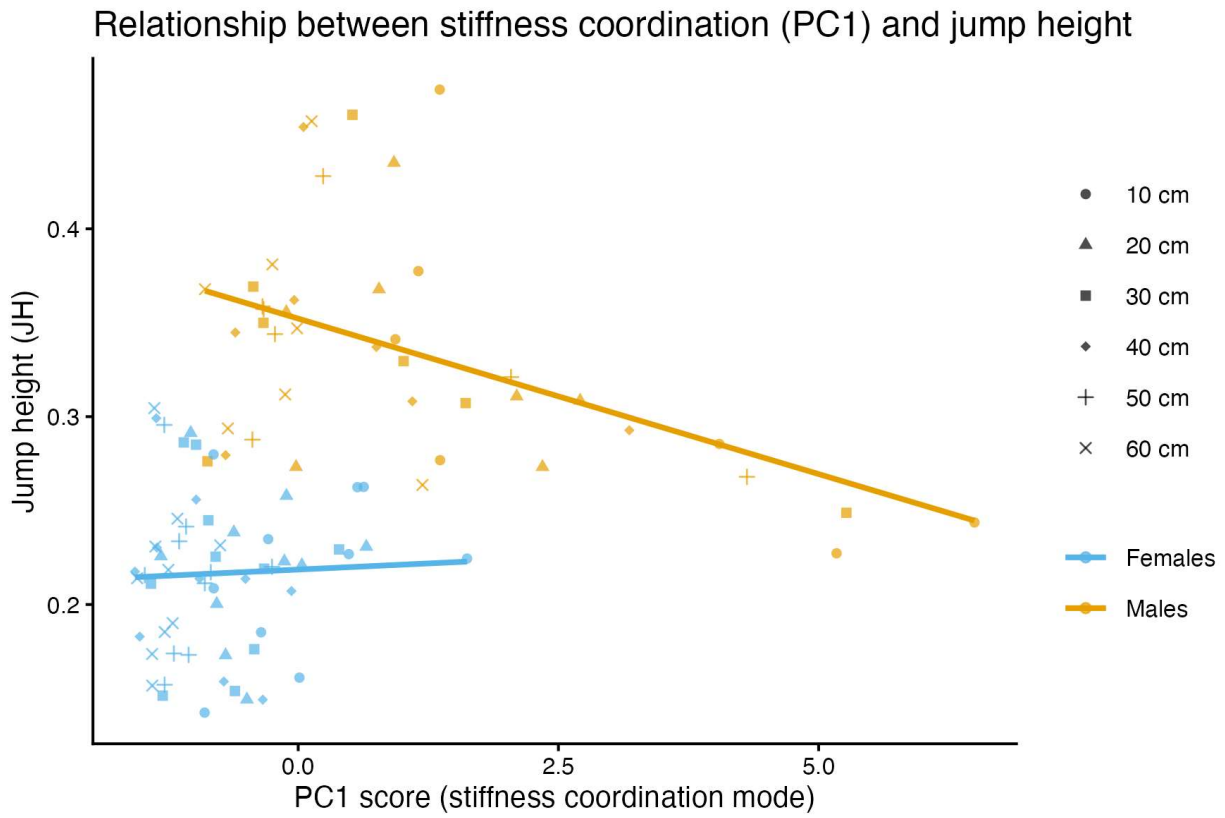
Sonoma State University, Rohnert Park, California, United States

Introduction

Lower-extremity joints play a critical role in attenuating external loads by generating joint moments in response to ground reaction forces during the weight-bearing movement. The contribution of each joint to load attenuation can vary with external demands and sex. Jumping performance may be influenced by joint coordination patterns through the use of stored elastic energy. The purpose of this study was to examine sex differences in lower-extremity joint stiffness coordination and how coordination patterns relate to jump performance across multiple drop heights.

Methods

Seventeen healthy and active college students (10 females, 7 males) performed three drop-jump trials from six box heights (10–60 cm in 10 cm increments). Joint stiffness was calculated using the joint angle and external joint moment during the eccentric phase of each jump. Left and right stiffness values were averaged for each joint and entered into a Principal Component Analysis (PCA) to identify coordination patterns using a customized R script. The primary principal component (PC1) was then used in a mixed-effects regression model to examine its relationship with jump height across conditions.



Results

PCA identified PC1 as a stiffness coordination, explaining 79% of total variance, with higher loading scores reflecting stiffer joint behavior. A significant Condition Sex interaction ($p < .001$) was observed in PC1. Post-hoc comparisons showed that males exhibited higher PC1 at lower drop heights (10–30 cm) but shifted toward lower PC1 at higher heights (40–60 cm). Females, in contrast, showed relatively small changes in PC1 across conditions and generally maintained a more compliant strategy. Mixed-effects regression indicated that the relationship between PC1 and jump height varied by both Condition and Sex (PC1 × Condition × Sex, $p < .001$).

Discussion

Males demonstrated stiff coordination at low drop heights but became more compliant as drop height increased, whereas females showed minimal modulation across conditions. This suggests that males adjust stiffness more dynamically to accommodate rising mechanical demands, while females maintain a consistent coordination strategy. Whether these differences reflect inherent sex-related neuromuscular control or arise from differences in relative loading remains unclear. Normalizing drop height or ground reaction forces to individual capacity may help distinguish these possibilities.

Multi-Factorial Older-Adult Turning Strategies during 180˚ Turns

Ms. Zahava Hirsch, Ms. Erin Kreis, Dr. Antonia Zaferiou Ph.D.

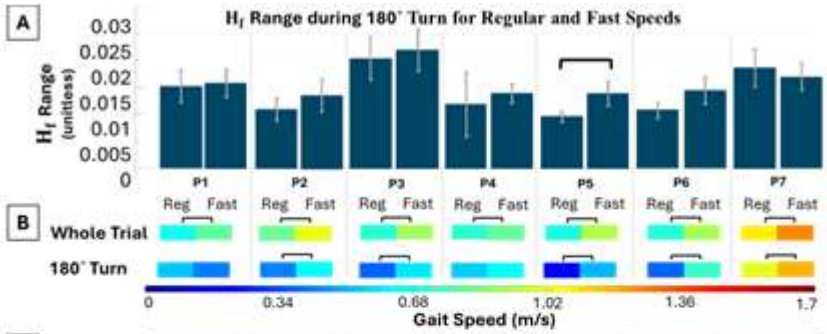
Stevens Institute of Technology, Hoboken, NJ, United States

Introduction

Falls are a leading cause of injury in older-adults and are eight times more likely to result in a hip fracture during turns[1]. Previous research defines three 180˚ turn-strategies: steps (multiple steps taken), mixed (steps and pivot), and pivot[2]. Fall-risk is multi-factorial and categorized by cut-offs in assessments, including the Dynamic Gait Index (DGI), Timed Up and Go (TUG) and International Falls Efficacy Scale (FES-I). This study analyzes 180˚ turns during regular and fast speeds to elucidate the relationship between turn-strategies with frontal-plane angular momentum (H_f), gait speed, and the assessments listed. Based on previous research[3], we hypothesize that participants with "worse" measures will utilize "safer" turn-strategies (steps) and will have no difference in H_f range or gait speed between speeds.

Methods

Seven older-adults (6f, age 73.9±4.49) completed a 180˚ turning course five times at self-determined regular and fast speeds, the DGI, TUG, and FES-I. A 13-segment whole-body kinematic model was built using optical motion capture data (OptiTrack USA) and used to calculate H_f and gait speed. H_f range was normalized to a dimensionless form. Turns were visually observed and categorized. Mann Whitney U was used to compare H_f range and gait speed per participant.



Results

Six participants had no change in H_f during the turn, indicating maintained postural control during faster speeds (Fig.1). P5 had significant difference in H_f and is the oldest participant. Five participants used the step strategy across all trials. P2 used all three strategies during regular speed, but only mixed and pivot during fast speed. P7 used only mixed and pivot across speeds and had the lowest FES-I and greatest DGI. While all participants' mean fast gait speed across the whole trial were significantly faster than regular, P1&4 did not change speeds during the 180˚ turn. P1's TUG and P4's FES-I score define them as fall-risk, indicating they may slow their gait and utilize a step strategy as a protective strategy.

Discussion

Participants with “worse” fall-risk assessments were observed utilizing conservative 180˚ turn-strategies.

Simulated Pregnancy Weight Gain Increases Foot Arch Deformation and Abductor Hallucis Activation During Walking

Dr Adrienne Henderson[1], Dr Lauren Williams[2], Ms Rachel Todd[1], Dr Dustin Bruening[1]

[1]Brigham Young University, Provo, UT, United States. [2]University of Utah, Salt Lake City, UT, United States

Introduction

The foot is responsible for supporting and propelling the body during gait, commonly experiencing dynamic loads above 100% body weight. Active muscle contractions coordinate with passive bony structures to support the foot's arch as it is deformed during loading. Increased body mass as experienced in pregnancy can further increase loads on the arch which could contribute to reported pregnancy foot pain. The purpose of this study was to characterize the foot arch's response to simulated weight gain. We hypothesized increased arch range of motion (ROM), peak plantarflexion moment, negative and positive work, and increased activation of the abductor hallucis muscle (ABDH) with added weight.

Methods

Twelve healthy participants (1.69±0.07m, 66.7±9.04kg) walked at 1.0-1.2m/s under 2 randomized conditions (weighted and unweighted) while kinematic and kinetic data were measured. An anteriorly weighted vest was used for the weighted condition with mass equal to weight gained by a matched pregnant participant from a previous study.[2] A surface electromyography sensor on the right ABDH recorded peak muscle activation during stance. A three-segment foot model was used to calculate arch ROM, peak plantarflexion moment, negative work, and positive work. Moment and work metrics were normalized to mass. T-tests determined significance between conditions.

Results

Arch ROM, negative work, and peak ABDH activation significantly increased with added weight but peak plantarflexion moment and positive work remained unchanged (Table 1).

Discussion

The increased arch ROM and negative power indicate that the arch experienced greater deformation with the added mass. The ABDH seems to be attempting to attenuate this deformation with increased activation. The lack of change in normalized arch plantarflexion moment suggests that the COP remained consistent between conditions despite the center of mass moving anterior.[2] Our results contrast slightly with the prior

matched pregnant participants, who did not alter ROM or negative power across trimesters.[1] This suggests even greater muscular attenuation in pregnancy to overcome the increase in both body weight and ligament laxity. Interventions aimed at supporting the foot's arch during pregnancy may help reduce muscular discomfort.

Images (Optional)

Table 1: Group means and standard deviation for key Midtarsal metrics and peak ABDH muscle activation with p-values.

	Normal	Weighted	p-value

Joint Contributions and Muscle Coordination During Single-Leg Lateral Jumps: Hip and Knee Joint Work Modulate Performance Despite the Ankle Being the Primary Contributor

Ms. Ainsley Durnin B.Sc., Dr. Jordan Cannon Ph.D.

University of Waterloo, Waterloo, Ontario, Canada

Ms. Ainsley Durnin

Introduction

Single-leg lateral jumps (SLJs) are complex multi-planar tasks with distinct biomechanical demands from vertical and forward jumps, yet remain under-researched [1]. Their unique demands enable exploration regarding multi-joint control and assess key aspects of athletic performance, but detailed biomechanical descriptions are lacking. Given the single-leg task demands, the hip is expected to play a key role as the connection between the trunk and lower limb. This study aimed to quantify joint contributions to whole-body dynamics and jump distance, and to examine hip muscle recruitment during maximal-distance SLJs.

Methods

Eighteen female athletes performed three maximal-distance SLJs from each limb. Full-body kinematics, kinetics, and hip muscle activation were recorded. Whole-body centre-of-mass (WB-COM) power and work were computed (dot product of ground reaction force with WB-COM velocity and its time integral, respectively). Inverse dynamics analysis calculated joint power and work (dot product of net joint moment with joint angular velocity and its time integral, respectively) across the lower limbs, trunk, and upper limbs. Linear regressions examined relationships among jump distance, WB-COM work, and joint work. Repeated-measures ANOVA compared joint contributions. Correlation analyses identified which hip muscles were recruited to meet hip joint demands.

Results

Work done on the WB-COM explained 68% of the variance in jump distance across participants. Total joint power underestimated WB-COM power by 23%. The ankle joint was the primary contributor ($p<0.001$) though only hip ($R^2=0.33$, $p=0.01$) and knee ($R^2=0.55$,

p=0.0004) work scaled with jump distance (Figure). No consistent group-level muscle coordination strategy was observed.

Discussion

Unexplained variance in jump distance by WB-COM work likely reflects unaccounted rotational kinetic energy in the WB-COM approach [2]. The inability of joint power to explain WB-COM variance likely stems from proximal-to-distal mechanical power transfer, via biarticular muscles, which the joint power approach cannot fully capture. Variability in individuals' muscle coordination strategy and relative hip joint contributions to task performance highlight limitations in relating muscle activation to joint, whole-body, and task performance at group-level. Segmental power flow and muscle synergy analyses are ongoing to better characterize multi-joint control during SLJs.

Effects of Simultaneous Asymmetric Crankarm Lengthening and Shortening During Cycling on Knee Biomechanics

Mr. Alejandro Ovispo-Martinez M.S., Mr. Tsung-Lin Lu M.S., Mr. Davin Gleaves, Ms. Quinn Wilsom, Mr Jacob Rygielski, Dr. Songning Zhang PhD

University of Tennessee, Knoxville, TN, United States

Introduction

Cycling is a common modality for knee-joint injury rehabilitation. Studies have investigated the effects of symmetrical shortening and asymmetrical shortening of crankarms on lower-limb mechanics during cycling. The effect of simultaneous shortening on one side and lengthening on contralateral side has not been previously investigated. Therefore, the purpose of this study is to investigate effects of combining asymmetrical lengthening and shortening of the crankarms during cycling on knee-joint biomechanics.

Methods

The study included six healthy and recreationally active individuals (Age:25+/-5.3 yrs, Height:1.74+/0.09 m, Weight:73.68+/15.7 kg). Participants pedaled at a work rate of 70 Watts and a cadence of 70 revolution per minute in four different crankarm conditions: 170mm crankarm length both legs, 185mm crankarm length on the non-dominant leg and a 170mm crankarm length on the dominant leg, and 185mm crank length on non-dominant leg and shortened crankarm lengths of 155mm and 140mm on the dominant leg. 3D Kinematic data were collected by a 12-camera motion analysis system, and pedal reaction forces (PRF) data were collected using a pair of custom-built instrumented pedals. A 2x4 (limb x crankarm length) repeated-measures ANOVA was used to evaluate selected variables ($p < 0.05$).

Results

Significant interactions of crankarm length and limb were found in the knee-joint range of motion (KROM) and peak PRFs. Specifically, KROM decreased from C1 to C4 (excluding C2) and PRF increased in C3 and C4 in the dominant limb. The KROM was greater in conditions C2-C4 compared to C1 and for PRFs, C3 and C4 were greater in the non-dominant limb. There were no significant differences in knee-extension moments (KEM) or knee-joint power (KPOW).

Discussion

The combination of asymmetrical shortening and lengthening influenced sagittal KROM and PRFs but with minimal to no influence on KEM and KPOW. The increase in crankarm length reduced PRF requirement in the dominant limb while increasing the PRFs on the non-dominant limb without an increase in knee loading. By reducing sagittal KROM without increases in KPOW and KEM, this study provides some evidence that we can implement asymmetrical crankarm lengths in cycling intervention without increasing loading to knee joint.

Running Volume and Stroller Use: Their Combined Effect on Injury Risk

Dr. Joseph Mahoney Ph.D.[1], Ms. Houn Kim[2], Dr. Andrew Friesen Ph.D.[2], Dr. Allison Altman-Singles Ph.D.[2]

[1]Alvernia University, Reading, PA, United States. [2]Penn State Berks, Reading, PA, United States

Dr. Joseph Mahoney

Dr. Andrew Friesen

Introduction

Running with a stroller allows parents to remain active while caring for young children, but postpartum runners may be vulnerable to overuse injury because of changes in lifestyle and training patterns [1]. Stroller running alters running kinetics and kinematics, which may modify musculoskeletal loading and injury risk [2]. This study examined how stroller use and total mileage are associated with overuse injury in parent runners.

Methods

Parent runners completed a retrospective survey about running from birth to 3 years after having a child. Participants reported average weekly mileage, the percentage of their total weekly miles run with a stroller, and whether they sustained an overuse injury. Responses with missing injury status or mileage were excluded. Binary logistic regression with total weekly mileage and the percentage of weekly miles run with a stroller as predictors evaluated associations with overuse injury risk.

Results

188 respondents with complete mileage data were included. Stroller users reported 18.6 ± 19.6 total weekly miles with 48.1% ± 31.0% of them being stroller running miles. Higher total mileage was associated with increased odds of overuse injury, with an odds ratio of 1.02 for each additional mile ($p = 0.039$). A higher percentage of miles run with a stroller was associated with lower estimated odds of injury, with an odds ratio of 0.62, although this effect was not statistically significant ($p = 0.45$).

Discussion

These findings suggest that stroller use may reduce overuse injury risk, although this trend did not reach statistical significance. This pattern is consistent with previous work showing that biomechanical markers linked to injury risk are reduced during stroller running [2]. The regression results affirm that increased running volume is the primary driver of injury risk in this population: each additional weekly mile was associated with a 2% increase in overuse injury risk, similar to previous running overuse injury studies [3]. Overall, these results support the safety of running strollers for parent runners while highlighting the importance of managing total training volume.

Evaluating Feasibility of Portable Motion Capture Systems in Clinical Settings

Dr. Alyson March, Dr. Cherice Hill

University of Rochester, Rochester, NY, United States

Introduction

Biomechanics research goes hand-in-hand with clinical practice to analyze human motion and track disease presentation, progression, and rehabilitation. Integration of motion analysis into clinical settings is advantageous to enable analysis of representative populations and improve clinical outcomes. Traditionally, motion analysis is restricted to academic labs, but OpenCap enables motion tracking and evaluation of kinematics with just 2-3 iOS devices. Data can then be processed in OpenSim using muscle-driven simulations, enabling estimation of kinetics without additional equipment. However, it is currently unclear how motion analysis with OpenCap could fit into a clinical workflow. In this study, we assessed the feasibility of using OpenCap+OpenSim to evaluate walking kinetics, focusing on the time and expertise needed for data collection and processing.

Methods

Participants (n=10) completed 5 walking trials across 3 embedded force plates while data was collected using the OpenCap app on 3 iPads. Ground reaction forces (GRF) were estimated via muscle-driven simulations using OpenSim, as detailed in the OpenCap github. Each step was evaluated individually, and the time for model convergence was recorded. Maximum vertical GRF (vGRF) estimated from muscle-driven simulations was compared to peaks measured from force plates. GRFs were normalized by participant body weight.

Results

Preliminary evaluation of 40 steps has been completed (2 steps from 2 trials/participant). Three step simulations did not converge, giving the muscle-driven simulations a 93% convergence rate. The average time for simulation completion was 20±14 minutes (Figure 1A). Preliminary analysis of discrete GRF peaks for five participants demonstrates the maximum vGRF estimated by OpenCap trends greater than the measured force from force plates (Figure 1B).

Discussion

Currently, the muscle-driven simulations require significant time and expertise for completion, which would be difficult to integrate within a time-packed clinical workflow.

While use of a supercomputer may decrease the time for analysis, this requirement would reduce the accessibility of data analysis in a clinical setting. To maximize accessibility, OpenCap may be combined with portable tools to measure GRF, such as portable force plates or pressure insoles. On-going work will evaluate additional steps and complete statistical comparisons of discrete peaks and continuous curves for the measured and estimated vGRF.

A Domain-Agnostic, Frequency-Based Method for Structuring Biomechanical Signals during Cyclic Activities

Miss ChengYue Zhang[1,2], Miss Amy Coyle[1], Dr. Paula Branco[3], Dr. Richard Moulton[1]

[1]HAS-Motion Inc., Kingston, Ontario, Canada. [2]University of Toronto, Toronto, Ontario, Canada. [3]University of Ottawa, Ottawa, Ontario, Canada

Introduction

Structuring biomechanical signals for large-scale analysis on arbitrary cyclic activities is challenging as current methods require domain knowledge or labelled training data. Here, we propose a domain-agnostic, train-free cycle segmentation pipeline.

Methods

Our pipeline structures a kinematic signal given its sampling rate f_s by: (1) estimating the signal's fundamental frequency f_0 via the Harmonic Product Spectrum algorithm [1], (2) identifying recurring patterns S by seasonal decomposition, (3) extracting a template with duration $T = 1/f_0$ from S, and (4) identifying cycles with a Euclidean-distance-based similarity search to the template (Figure 1).

Public datasets used for evaluation include healthy participants treadmill-walking (Slow, Normal, Fast speeds; n=42 [2], n=10 [3]) and participants with Parkinson's Disease overground-walking (ON, OFF medication; n=26 [4]).

We compared our pipeline with domain-knowledge-based methods [5-8], deep-learning methods [9], and a peak-detection-based method [10]. Domain-agnostic approaches (our pipeline and [10]) processed 6 different signals to test generalizability. We used Linear Mixed-Effects Models (LMM) with methods as fixed effects and participants (with nested trials) as random effects, to assess each method's identified cycle counts and durations against simultaneously collected force platform data. We calculated the duration Root Mean Square Error (RMSE) on a per-trial basis.

Results

Methods with 95% confidence intervals overlapping the 0-difference line were our pipeline (all signals), [6-8], and [10] (3 signals) in counts LMM, but only our pipeline (all signals) and [8] in durations LMM.

The best and worst of our pipeline's predictions had a median RMSE of 18.7±0.7ms (Fast) and 38.6±2.3ms (OFF). Both were superior to all other methods.

Discussion

Our pipeline outperforms [5-7, 9-10] and is comparable to method [8]. Given its domain-agnostic nature, future work will expand applicability to additional cyclic activities.

Images (Optional)

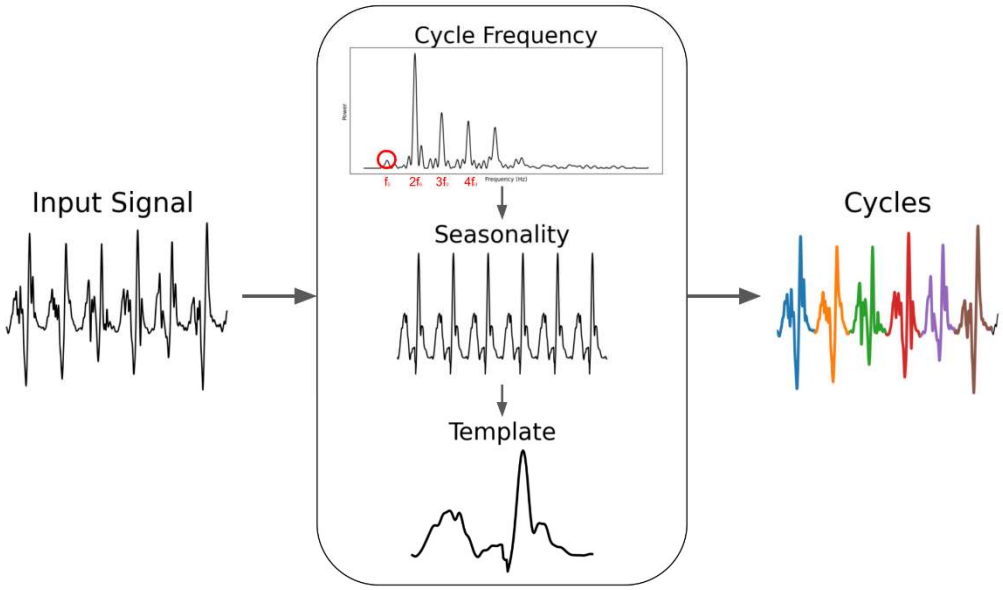

Figure 1: Overview of our pipeline. Starting from a kinematic signal and its sampling rate, the fundamental frequency f_0 (circled out in red) is detected out of its harmonics ($2f_0$, $3f_0$, $4f_0$, etc.) to estimate cycle duration. Then the signal's seasonality is identified. A cycle template is extracted from seasonality. Cycles are identified by a Euclidean-distance-based similarity search algorithm to the template.

Co-contraction presents asymmetrically in adults walking overground

Mrs. Julie Ferrell-Olson MSc, Dr. Hannah D. Carey PhD, Mrs. Ashlyn Wormsley, Dr. Andrew Sawers CPO, PhD

University of Illinois Chicago, Chicago, IL, United States

Introduction

EMG signals during gait are often assumed to be symmetric between legs. [1,2] However, it remains unclear whether agonist-antagonist co-activation (i.e., co-contraction) [3] is also symmetric while walking, as most studies of co-contraction in unimpaired adults record EMG from a single leg. Identifying between-leg differences in co-contraction may change how we interpret differences in neuromuscular control between populations. The objective of this study was to determine if co-contraction is symmetric between legs. We hypothesized there would be significant between-leg differences in co-contraction at the ankle, knee, and hip due to lateralization of motor function.

Methods

This was a secondary analysis of EMG data in a public dataset collected from unimpaired adults walking overground at their preferred speed. [4] Co-contraction values for agonist-antagonist muscle pairs at the ankle, knee, and hip were calculated as the ratio of the less active to more active muscle multiplied by the sum of both muscles. [3] A “high” and “low” co-contraction leg was identified for each participant. Differences between high and low co-contraction values were evaluated using paired t-tests.

Results

104 participants (54 females), 21-86 years of age, were included in the analysis. Significant between-leg differences in co-contraction (mean [SD]) were observed at the ankle (0.12 [0.05] vs. 0.09 [0.04]), knee (0.22 [0.07] vs. 0.17 [0.06]), and hip (0.22 [0.07] vs. 0.16 [0.07]); all $p<0.001$) (Figure 1).

Discussion

The asymmetry in co-contraction observed in this secondary analysis of unimpaired adults may reflect motor lateralization, wherein each leg is specialized for distinct functions (e.g., stability vs. precision). Our results also suggest that some co-contraction in individuals with unilateral impairments, such as stroke or amputation, may reflect typical between-

limb asymmetries rather than purely pathological or compensatory mechanisms. To better differentiate the effects of impairment on co-contraction, future studies should collect bilateral EMG in control participants. Ongoing work will test whether kinematic and kinetic asymmetries accompany co-contraction asymmetry, helping determine if co-contraction asymmetry has a neural or mechanical origin.

Images (Optional)

Decreased Rate of Force Development in Simulated Walking Increased Double Support Times

Mr. Nicholas Yaple, Dr. Anne Martin

Pennsylvania State University, State College, PA, United States

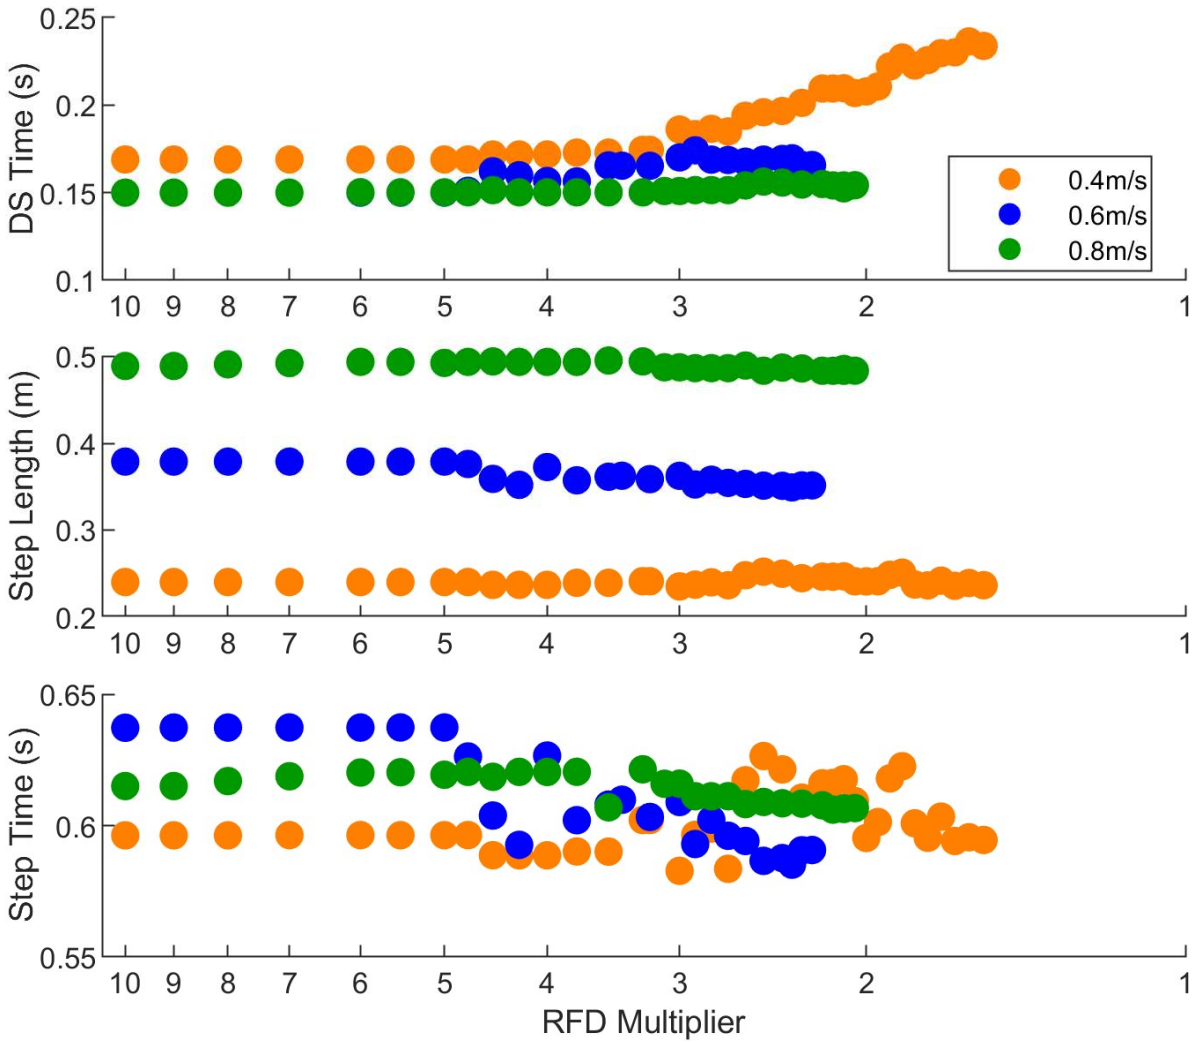
Introduction

The rate of force development (RFD) may contribute to spatiotemporal disturbances post-stroke, such as increased time spent in double support (DS). A reduced RFD may extend the time required to complete weight transfer, leading to longer steps. It is difficult to test and isolate experimentally, so simulations may offer insight. Previously, we simulated reduced joint torques using a 2D skeletal model but found low DS times and high RFDs. We hypothesized that a lower peak RFD would increase DS time and change step length and time to better mimic post-stroke gait.

Methods

Using a 2D skeletal model (two ankles, two knees, and a shared hip joint) with ideal motor driven joints and a minimum allowable DS time of 0.15s, we generated predictive walking simulations by minimizing energetic cost while gradually reducing the RFD via torque rate limits. The RFD limit was determined using previous experimental data scaled by an RFD multiplier. For each speed (0.8m/s, 0.6m/s, and 0.4m/s), the RFD multiplier started at x10 (unconstrained) and was incrementally reduced until the optimization failed.

Results



As the RFD decreased, DS times increased, particularly for the slowest speed (0.150s to 0.154s at 0.8m/s; 0.150s to 0.166s at 0.6m/s; and 0.151s to 0.234s at 0.4m/s). Step lengths slightly decreased (0.489m to 0.483m at 0.8m/s; 0.379m to 0.352m at 0.6m/s; and 0.240m to 0.237m at 0.4m/s) and step times clustered around 0.625s. The RFD limit could not be reduced to biologically observed levels (minimum of 2.05x at 0.8m/s; 2.25x at 0.6m/s; and 1.55x at 0.4m/s), which could impact findings.

Discussion

These results support the hypothesis that reduced peak RFD may increase DS time, which typically increases post-stroke. The increase was dependent on speed, where slower speeds had a larger increase in DS time. Our hypothesis of step length changing was weakly supported because while it decreased for all speeds, the difference was small. Thus, as the RFD decreases, it appears that it is energetically optimal to increase DS time

and slightly modify step length and time, indicating that limiting the RFD has an impact on gait.

How Competing Movement Objectives Reshape Motor Coordination

Dr. Ava Lakmazaheri[1], Ms. Jordan Feldman[1], Ms. Angeline Prasanna[1,2], Dr. Patrick Slade[1]

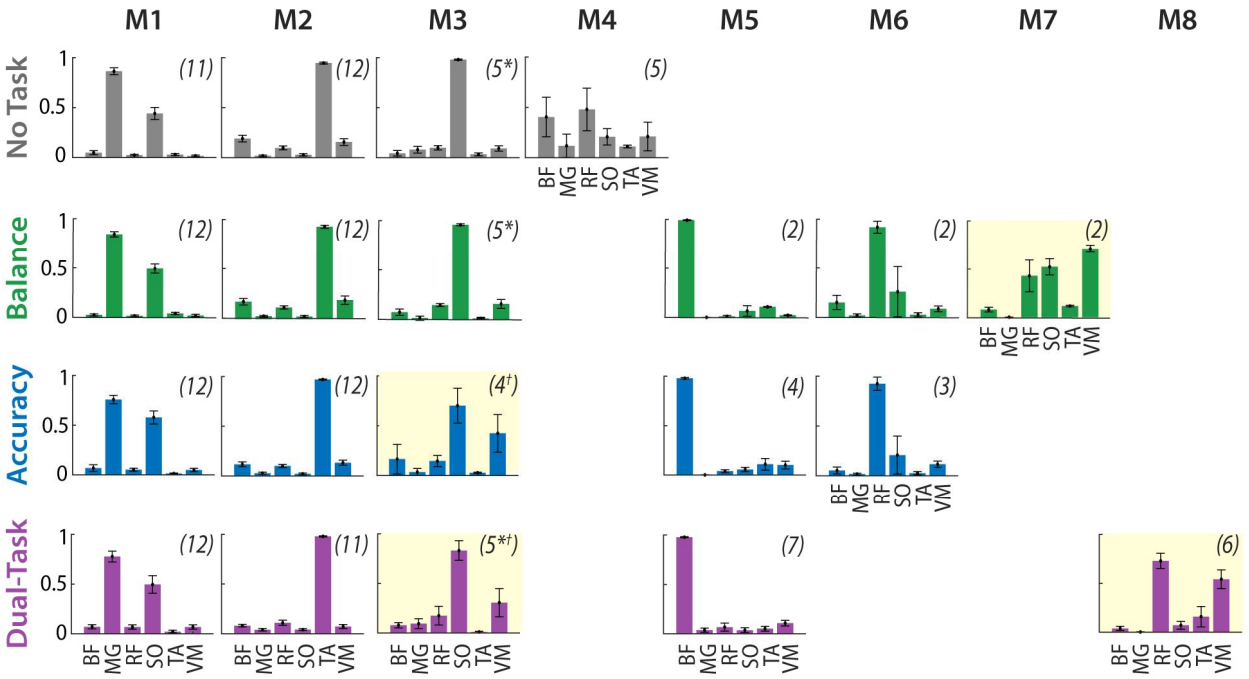
[1]Harvard University, Cambridge, MA, United States. [2]École Polytechnique Fédérale de Lausanne, Lausanne, Vaud, Switzerland

Introduction

Gait is modulated by multiple objectives, typically isolated in the study of motor control. Muscle synergies can reflect changes in functional complexity for motor tasks or impairments. We assessed synergy changes under competing task demands to advance understanding of real-world locomotor control.

Methods

Twelve adults walked overground at a slow self-selected speed in two-minute trials performing (i) no additional task, (ii) a “balance” task, with large mediolateral visual perturbations, (iii) an “accuracy” task, placing feet on variable-distance markers, and (iv) “balance” and “accuracy” tasks simultaneously. Electromyography was collected bilaterally from the biceps femoris (BF), rectus femoris (RF), vastus medialis (VM), soleus (SO), medial gastrocnemius (MG), and tibialis anterior (TA). Gait cycles were pre-processed and normalized to MVC. Non-negative matrix factorization extracted the minimum number of synergies to account for ≥95% of total variance per subject-trial. Hierarchical clustering identified shared synergies across subjects, with a critical value of R≥0.92 identifying similarity across tasks [1].



Results

All conditions included modules for propulsion (M1: MG-SO) and dorsiflexion (M2: TA). A diffuse synergy (M4) was decomposed into separable anterior (M5: RF) and posterior (M6: BF) proximal control in single-objective tasks. An additional module (M3) reflected either ankle stiffness (SO) or, when “accuracy” was included, precision shank positioning (SO-VM). A “balance”-specific synergy emerged for enhanced postural support (M7: RF-SO-VM). In the dual task, M1-M3 and M5 persisted, alongside a new hip-knee synergy (M8: RF-VM). At low (no task) and high (dual-task) complexity, many subjects were represented per module (N=5-7); motor repertoire was most varied for single-task demands (N=2-5).

Discussion

While single-task demands led to specialized motor modules, these were nonlinear in combination. Control strategies were restructured to satisfy conflicting requirements (fine vs. robust control) with minimal redundancy. As such, greater task complexity did not guarantee a higher number of motor modules. We also observed a nonlinear relationship between task complexity and inter-subject variability, suggesting smaller solution spaces with competing demands. “Accuracy”-specific synergies were uniquely preserved in the multi-objective task, suggesting a hierarchical structure of motor control. Study of additional tasks may yield further insight into this structure.

Pre- and Post-Pubertal Females Show Differences in Hip and Pelvis Kinematics During Walking

Ms. Avery Kratzer BSE, Prof. Cara Lewis PT, PhD, FAPTA

Boston University, Boston, Massachusetts, United States

Introduction

Adolescent female athletes incur hip injuries at three times the rate of their male peers, with the risk of injury increasing as females mature [1]. This increased injury risk may result from altered loading, driven by kinematic changes at the hip during adolescence. To better address hip injury risk in adolescent female athletes, it is essential to understand how kinematics change across adolescence in a repetitive everyday loading task (i.e., walking). Thus, the purpose of this preliminary study was to compare hip, pelvis, and thigh kinematics during walking in pre- and post-pubertal females.

Methods

Six pre-pubertal females (9.8±1.5 years; 1.4±0.2 m; 34.5±4.6 kg; 1.1±0.2 m/s) and 10 post-pubertal females (22.1±2.2 years; 1.7±0.1 m; 62.1±8.3 kg; 1.3±0.1 m/s) walked at a self-selected speed for two minutes on a treadmill. Kinematic data were recorded using 10-camera motion capture and processed in Visual3D. Hip, pelvis, and thigh angles in the sagittal and frontal planes were used for analysis. Peak angles were extracted for each stride, and the average across all strides of the dominant limb was calculated for each individual. Independent t-tests (α=0.05) were conducted to compare peak angles between the pre- and post-pubertal groups.

Results

The post-pubertal group demonstrated 3.2±1.0° greater peak hip abduction during swing and 3.5±1.4° less anterior peak pelvic tilt, compared to the pre-pubertal group (Figure 1). No significant differences in the remaining peak hip, pelvis, and thigh angles were detected between groups in this preliminary analysis ($p>.05$).

Discussion

The increase in hip abduction and decrease in anterior pelvic tilt during walking pre- to post-puberty in this study aligns with previous work in running [2] and standing [3], respectively. These kinematic changes may increase hip loading [4], potentially

contributing to the heightened risk of overuse injuries in female athletes during adolescence. Future work will use musculoskeletal simulations to assess the influence of these kinematic changes on hip loads.

Images (Optional)

Split-Belt Locomotor Adaptation of Inter-Limb Kinematics and Kinetics Under Different Practice Structures

Ms. Beier Lin[1], Dr. Sarah N. Kraeutner[2], Dr. William E. McIlroy[3], Dr. Courtney L. Pollock[1]

[1]University of British Columbia, Vancouver, BC, Canada. [2]University of British Columbia, Kelowna, BC, Canada. [3]University of Waterloo, Waterloo, ON, Canada

Introduction

Compared to blocked practice, random practice is suggested to decrease practice performance but enhance motor learning in upper-limb reaching tasks by increasing problem-solving demands. Single sessions of blocked split-belt lower-limb gait training have been shown with savings in kinematic and kinetic variables. However, effects of random practice on retention and transfer of locomotor adaptation remain underexplored. This study investigated whether blocked vs. random split-belt practice differentially impacted retention and transfer of between-leg gait kinematic and kinetic symmetry between testing days.

Methods

Twenty-six young adults were randomized to a Blocked (n=13; 6 female; age 24.9±5 years) or Random practice group (n=13; 7 female; age 27.2±4 years) for a single-session of split-belt treadmill walking. Fast and slow belt speeds were individualized based on the participant's fast overground gait speed. On Day 1, the blocked group completed four repeated 2.5:1 split-belt blocks (total 18.5 min) alternated with 30s tied-belt (1:1 ratio) walking. The random group experienced the same total exposure but split-belt ratios (2.5:1 and 2:1) and speeds changed every 15 or 30s. Within 24hrs post-training, both groups completed a retention test at novel split-belt 3:1 ratio and a transfer test with reversed fast leg at 1:3 ratio. Kinematic and kinetic measures of between-leg step length symmetry (SLS) and propulsive force symmetry were computed from embedded force plates. For each metric, linear mixed-effects models tested group differences in magnitude of adaptation (Day 2 first 10 strides – Day 1 first 10 strides) for each test block.

Results

The blocked group showed significantly greater magnitude of adaptation in SLS than the random group for both retention (mean difference: 0.14, $p<.05$) and transfer (mean difference: 0.15, $p<.05$) tests. No effect of Group was found on the magnitude of adaptation in propulsive force symmetry for either test block.

Discussion

Our findings suggest that blocked practice produced superior retention and enhanced transfer of SLS during split-belt walking, while SLS in the random group was largely maintained without further improvement. These results indicate the benefits of random practice observed in other motor domains (i.e., reaching adaptation) may not directly generalize to locomotor adaptation under the training parameters used here.

Measuring Coordination Variability with Inertial Measurement Units Using the Velocity Ellipse Method: A Pilot Study Comparing Agreement with a Motion Capture System

Mr Ben Jones[1,2], Dr Jon Wheat[3], Dr Kane Middleton[2], Dr David Carey[2], Dr Ben Heller[1]

[1]Sheffield Hallam University, Sheffield, South Yorkshire, United Kingdom. [2]La Trobe Universtiy, Melbourne, Victoria, Australia. [3]Nottingham Trent University, Nottingham, Nottinghamshire, United Kingdom

Introduction

Measures of coordination variability quantify stride-to-stride changes within the interaction between two joints or segments and have been linked to running-related injury [1]. The velocity ellipse method (VEM) quantifies coordination variability using angular velocity data, which is more robust to noise than angle-based measures [2]. However, we believe that the VEM has only ever been implemented by differentiating angular displacement data. Inertial measurement units (IMUs) measure angular velocities directly via their gyroscope and can facilitate field-based measurement of coordination variability. This study developed a method for implementing the VEM with IMUs and quantified its agreement with a motion capture system.

Methods

Twenty-seven runners completed eight minutes of running on an instrumented treadmill. Lower limb marker data were collected and used to compute thigh and shank angular velocities, whilst Blue Trident IMUs attached to these segments measured angular velocity directly. IMU data were transformed into segment coordinate systems using a functional calibration [3]. Twenty strides were identified using a vertical force threshold and peak shank resultant acceleration, for the marker and IMU data, respectively. The area of ellipses formed around the data points at each time-normalised percentage of the gait cycle on angular velocity – angular velocity plots were calculated [2]. Velocity ellipse area waveforms from the motion capture system (VEM_{MC}) and IMUs (VEM_{IMU}) were assessed for agreement using a normalised cross-correlation.

Results

The amplitude of velocity ellipse area waveforms varied between participants. Normalised cross-correlations between VEM_{MC} and VEM_{IMU} ranged from 0.859 to 0.969 (Figure 1), with a mean of 0.931.

Discussion

Normalised cross-correlations indicated high similarity between VEM_{IMU} and VEM_{MC} waveforms, although qualitative differences existed between signals from the systems. These were potentially due to the misalignment of coordinate systems and time asynchronisation. Nevertheless, our method demonstrated promise for simpler and cheaper analyses of coordination variability, particularly in field-based settings, although researchers and practitioners should make judgements on the suitability of VEM_{IMU} waveforms based on their specific context. Further research could also investigate alternative movements and segment pairings.

Images (Optional)

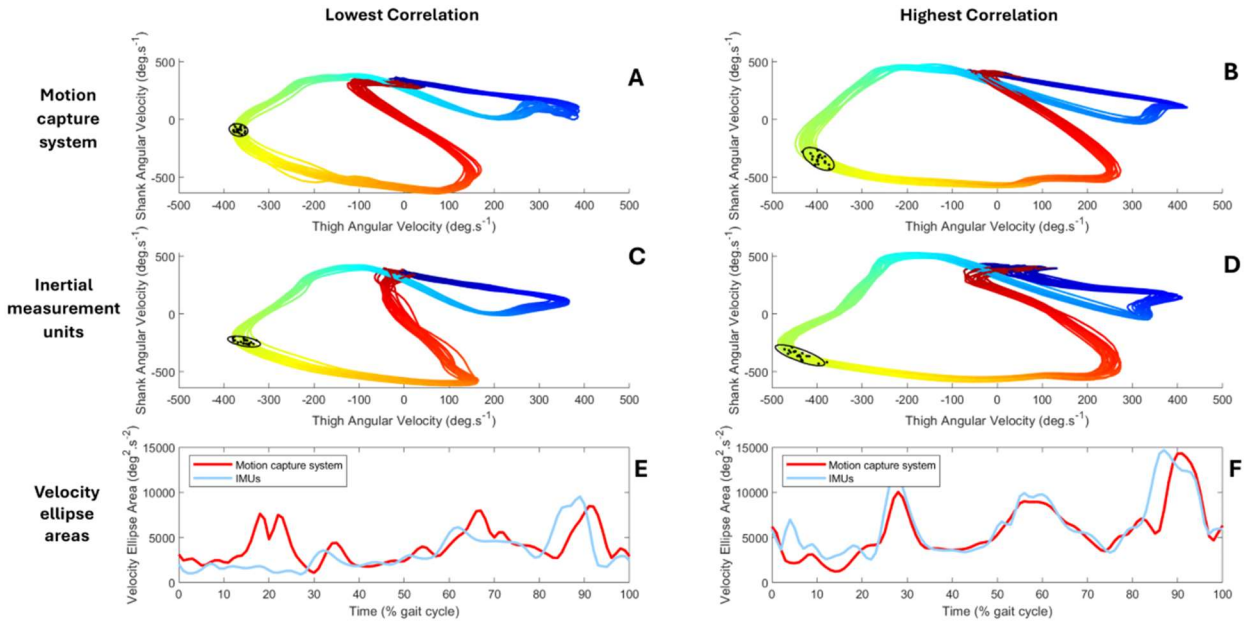

Figure 1: Comparison of angular velocity – angular velocity plots (A, B, C, D) and velocity ellipse area signals (E, F) for the pairs of signals with the lowest (left; 0.859) and highest (right; 0.969) normalised cross correlation between the motion capture system (A, B) and inertial measurement units (C, D). The jet colourmap indicates time as a percentage of the gait cycle, with dark blue indicating footstrike (0%) and dark red indicating the next ipsilateral footstrike (100%). Ellipses are drawn at 60% of the gait cycle.

The Effects of Varied Step Lengths on Hip-to-Hip and Knee-to-Knee Joint Moment Ratios in Walking Lunge Exercises

Dr. Ben Meyer

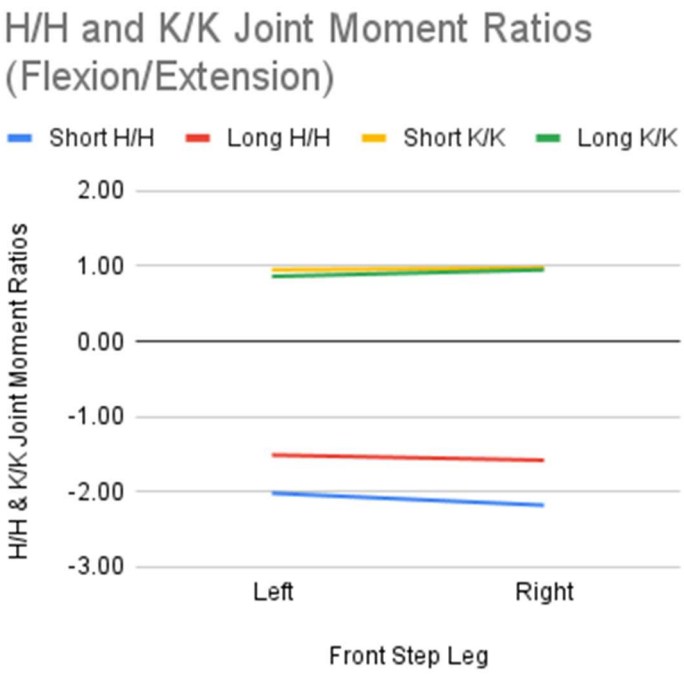
Shippensburg University, Shippensburg, PA, United States

Introduction

The purpose of this project was to analyze the effects of utilizing varied step lengths during walking lunge exercises on front hip to trail hip (H/H) and front knee to trail knee (K/K) joint moment ratios. Hip-to-knee joint moment ratios have been used to analyze squats [1], but the use of H/H and K/K joint moment ratios in lunge exercises is novel. This project contributes to the literature by establishing H/H and K/K joint moment ratios during walking lunges. It was hypothesized that participants would have significantly larger H/H and K/K joint moment ratios in the walking lunges utilizing a shorter step length.

Methods

Thirty-six males and thirty-six females (age = 19 ± 2 yrs; mass = 75 ± 20 kg; height = 1.75 ± 0.10 m) performed four sets of unloaded walking lunges. Participants' movements were recorded with eight Basler cameras at 100 Hz, while ground reaction forces and moments were obtained via two AMTI force plates at 1000 Hz. The video and force plate data were processed using The MotionMonitor™ software in order to compute hip and knee joint moments for each limb. The flexion/extension joint moment values at the lowest vertical position of the entire body center of mass were used in the analysis. The relationships between joint moment ratios and lunge step lengths were assessed using two-way factorial ANOVA tests. Statistical significance was set at $\alpha = 0.05$.



Results

Joint moment ratios did not differ between left and right limbs and were pooled together. The H/H joint moment ratio was significantly larger ($p < 0.001$) with a short step (-2.10 ± 1.05) than with a long step (-1.55 ± 0.44). The K/K joint moment ratio was not significantly different ($p = 0.060$) between short step (0.96 ± 0.31) and long step (0.91 ± 0.42).

Discussion

Results indicate that there is a significant relationship between walking lunge step length and H/H (but not K/K) joint moment ratios. The H/H and K/K ratios will provide useful insights into the mechanics of lunges.

The Effects of Varied Step Lengths on Front and Trail Leg Hip-to-Knee Joint Moment Ratios in Walking Lunge Exercises

Dr. Ben Meyer

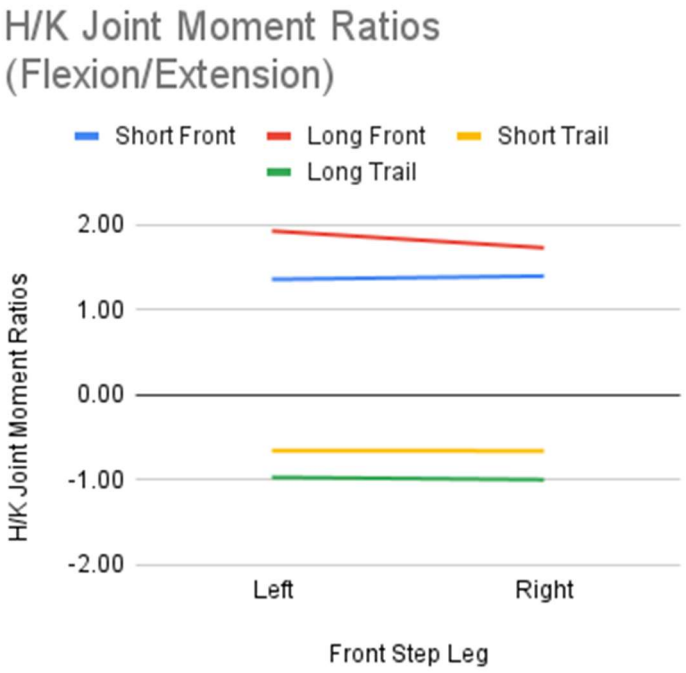
Shippensburg University, Shippensburg, PA, United States

Introduction

The purpose of this project was to analyze the effects of utilizing varied step lengths during walking lunge exercises on front and trail leg hip-to-knee (H/K) joint moment ratios. Previous research has established the importance of H/K moment ratios during back squats and elevated split squats [1]. This project adds to the literature by determining H/K joint moment ratios during walking lunges. It was hypothesized that participants would have significantly larger front and trail leg H/K joint moment ratios in the walking lunges utilizing larger step lengths.

Methods

Thirty-six males and thirty-six females (age = 19 ± 2 yrs; mass = 75 ± 20 kg; height = 1.75 ± 0.10 m) performed four sets of unloaded walking lunges at their normal depth and pace. Participants' movements were recorded with eight Basler cameras capturing at 100 Hz, while ground reaction forces and moments were obtained via two AMTI force plates sampling at 1000 Hz. The video and force plate data were processed using The MotionMonitor™ software in order to compute hip and knee joint moments for each limb. The flexion/extension joint moment values at the lowest vertical position of the entire body center of mass were used in the analysis. The relationships between joint moment ratios and lunge step lengths were assessed using two-way factorial ANOVA tests. Statistical significance was set at $\alpha = 0.05$.



Results

Joint moment ratios did not differ between left and right limbs and were thus pooled together for subsequent analyses. The H/K joint moment ratios were significantly larger using a long step than a short step (front, $p < 0.001$; trail, $p < 0.001$) with the front leg (long, 1.83 ± 1.03; short, 1.38 ± 0.59) and the trail leg (long, -0.99 ± 0.26; short, -0.65 ± 0.23).

Discussion

Results indicate that there is a significant relationship between walking lunge step length and H/K joint moment ratios. Walking lunges performed with a larger step length have larger hip muscle utilization as indicated by the larger H/K joint moment ratios.

Robust Single-Camera Knee Flexion Estimation under Self-Occlusion via Semi-Supervised Non-Linear p-Laplacian Label Propagation

Mr Behnam Gholami, Dr David Hollinger, Dr Xiaojun Zhai, Dr Bernard Liew

University of Essex, Wivenhoe Park, Colchester, United Kingdom

Mr Behnam Gholami

Dr David Hollinger

Dr Xiaojun Zhai

Introduction

Introduction: Optical marker-based motion capture (MBMC) is the gold standard for gait analysis but requires multi-camera, lab-based setups. Recent single-camera, markerless Human Pose Estimation (HPE) offers a low-cost alternative, yet lower-limb applications in healthcare are limited by noise, occlusion, and gap-filling errors. We present a train-free Graph Signal Processing (GSP) framework using semi-supervised label propagation with non-linear p-Laplacian regularisation to refine single-camera markerless motion capture (MLMC) knee kinematics in frontal and sagittal views.

Methods

Methods: Four healthy adults walked along a 7 (m) walkway at self-selected speed under institutional ethical approval (ETH2425-0307). Full-body 3D kinematics were captured with Theia3D using eight Sony RX0 II RGB cameras (120 Hz) in a radial configuration. For the single-camera condition, one frontal and one sagittal view were retained per trial. 2D hip, knee and ankle positions were extracted frame-wise using OpenPose and converted to frontal- and sagittal-plane knee angles. Our method represents joint trajectories as signals on a spatiotemporal skeleton graph with temporal edges for continuity and spatial edges for segment rigidity. A non-linear p-Laplacian ($p = 1.3$), solved via Iterative Reweighted Least Squares, operates on the residual between Theia3D “ground truth” and OpenPose

estimates, with confidence-gated edge weights to handle self-occlusion. Performance was evaluated using Mean Absolute Error (MAE) and Root Mean Square Error (RMSE) against Theia3D and compared with published error benchmarks.

Results

Results: In frontal views, OpenPose knee angles showed high variability (MAE=6.23°). The proposed method reduced MAE to 0.55°, substantially suppressing jitter while preserving peak flexion. In occluded sagittal views, OpenPose errors averaged MAE=6.08° (RMSE=7.51°), consistent with (Wade et al., 2023). Our framework reduced errors to MAE=1.00° (RMSE= 3.17°), recovering plausible trajectories despite substantial self-occlusion.

Discussion

Discussion: Non-linear p-Laplacian smoothing via Iterative Reweighted Least Squares (IRLS) solver enabled the single-camera MMC pipeline to surpass the 5° clinical accuracy threshold and outperform established benchmarks for occluded tracking, while preserving sharp transitions required for gait event detection.

How Is Motivation During Gait Training Influenced by Physical Assistance and Performance Feedback?

Mr. Blake Karavas SPT, MS[1], Dr. Julia Manczurowsky PT, DPT, PhD[2], Dr. Sheng-Che Yen PT, PhD[1], Dr. Lester Leung MD, MSc[3,4], Dr. Peter Whitney PhD[1], Dr. Charles Hillman PhD[1,5], Dr. Christopher Hasson PhD[1]

[4]Tufts University School of Medicine, Boston, MA, United States. [5]Institute for Cognitive and Brain Health, Boston, MA, United States

Introduction

Gait deviations are common following neurological disease, and rehabilitation often includes manual guidance by a physical therapist to improve walking function. While physical assistance, like visual feedback, is intended to enhance therapeutic outcomes, their influence together on patient motivation remains unclear. Motivation is critical in gait retraining for shaping engagement and effort, which supports the neuroplastic processes underlying motor adaptation. Here, we examine the interaction of assistance, feedback, and motivation in rehabilitation to better understand their psychological connection.

Methods

Thirty-five healthy participants walked on a treadmill and increased their right leg's mechanical work to achieve a 20% greater stride while perturbed by hamstring stimulation and mechanical resistance. A physical therapist assisted participants' right shank to achieve the stride target for 10 min (2.5 min trials x 4). Participants were randomized to see feedback of either their combined mechanical work (participant + therapist; N = 17) or comparative work (participant vs. therapist; N = 18). After each trial, they reported their perceived exertion (RPE) and pain (VAS). After training, the Intrinsic Motivation Inventory (IMI) was completed. For each group, we used Spearman rank correlations to explore how IMI subscale scores (enjoyment, choice, value, competence, relatedness, effort, pressure) relate to cumulative anterior-posterior assistance force.

Results

The control group had greater perceived competence than the comparative group ($p = 0.04$), but no significant correlations to assistance ($p > 0.05$) for either group. Though none reached significance ($p > 0.05$), controls had strongest correlations of assistance with pressure ($r = 0.36$) and effort ($r = -0.35$), and comparatives with competence ($r = 0.37$) and relatedness ($r = 0.4$). The correlation of force to RPE and VAS were small and not significant.

Discussion

Results suggest the degree of short-term manual assistance does not strongly influence motivation, exertion, or discomfort in healthy, artificially-impaired individuals during goal-directed walking. Depending on feedback type, assistance and motivation had moderate, non-significant trends that suggest participants may feel differently about their performance when their contributions are directly compared to the therapist's. However, further study is needed to determine whether these perceptions translate into positive locomotor adaptations and long-term learning benefits in clinical populations.

The Effect of Running Speed and Footwear Midsole Compliance on the Biomechanics of Sub-Elite to Elite Distance Runners Wearing Advanced Footwear Technology Spikes

Mr. Bradley Needles, Mr. Luis Morata Moreno, Dr. Alena Grabowski

University of Colorado Boulder, Boulder, Colorado, United States

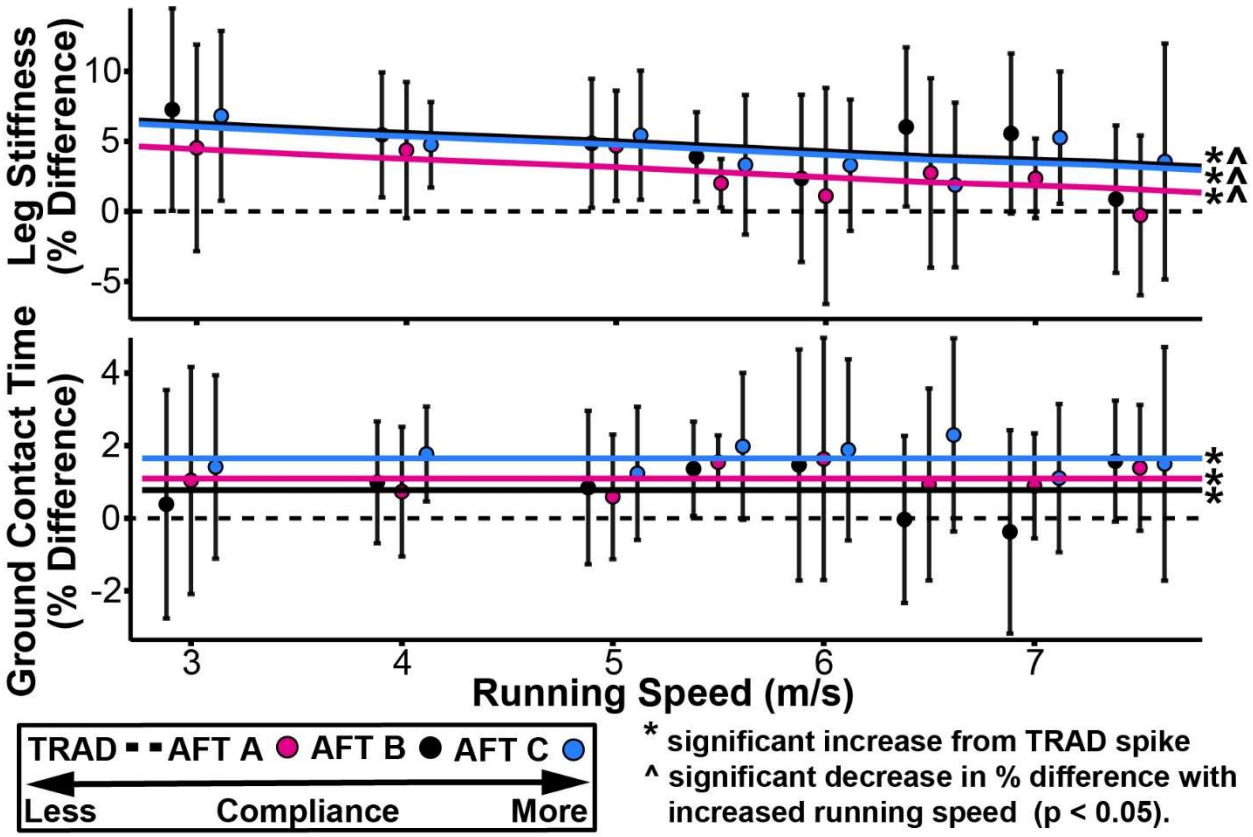
Introduction

Distance runners have achieved improved race performance and running economy while wearing compliant (low stiffness) advanced footwear technology (AFT) spikes compared to stiffer traditional spikes [1], [2], which may be due to increased leg stiffness and ground contact time [1]. However, leg stiffness has been reported to increase with running speed at speeds faster than 5 m/s [3]. Based on the increased midsole foam compliance of AFT spikes, we hypothesized that distance runners wearing AFT spikes would experience increased leg stiffness and ground contact time compared to traditional spikes. Additionally, we hypothesized that the magnitude of increase in leg stiffness and ground contact time while wearing AFT spikes compared to traditional spikes would decrease as running speed increases.

Methods

8 sub-elite to elite distance runners ran at 3, 4, 5, 5.5, 6, 6.5, 7, & 7.5 m/s on a force measuring treadmill while wearing 3 custom AFT spikes (AFT A, AFT B, AFT C) and a traditional spike (TRAD) with midsole stiffness values of 170, 159, 140, & 412 N/mm, respectively. We measured ground reaction forces (1000 Hz) and compared leg stiffness and ground contact times between spike conditions and across running speeds using linear mixed models.

Results



When runners wore AFT spikes, leg stiffness and ground contact time increased by an average of 3.8% and 1.2%, respectively, compared to the TRAD spikes across all running speeds ($p < 0.018$). The percentage difference in leg stiffness between the AFT spikes and TRAD spikes decreased by 0.6% for each 1 m/s increase in running speed ($p = 0.002$) while the percentage difference in ground contact time between the AFT spikes and TRAD spikes was not different across running speeds ($p=0.76$).

Discussion

The difference in leg stiffness while wearing AFT and traditional spikes may decrease as running speed increases, potentially leading to attenuated performance improvements

relative to traditional spikes as race speed increases. As a result, runners may experience race performance improvements by wearing AFT spikes with midsole stiffness values tuned for faster running speeds.

Hip Moments Differ by Sex at Different Walking Speeds

Ms. Caitlyn Finnerty MS, BS, Ms. Ria Rao BS, Prof. Cara Lewis PT, PhD, FAPTA

Boston University, Boston, MA, United States

Introduction

Biological sex influences movement kinematics, but its specific effects on hip moments remains understudied. As females typically have a wider pelvis, joint loading and hip moments likely differ when engaging in tasks such as walking. The altered joint loading may contribute to increased risk for hip pain in females. Based on sex-specific differences in pelvic morphology, we expect that peak internal hip moments will differ between males and females during walking.

Methods

Data were obtained from a larger dataset investigating movement and morphology in individuals with and without hip pain. This analysis included 129 females (26.7 ± 7.9 yrs; 1.67 ± 0.07 m; 65.03 ± 9.82 kg) and 59 males (26.3 ± 8.5 yrs; 1.80 ± 0.07 m; 79.35 ± 11.54 kg) who walked on an instrumented treadmill at a prescribed (1.25 m/s) and preferred speed. Females (1.29 ± 0.17 m/s) walked at faster average preferred speed than males (1.25 ± 0.17 m/s). Peak internal hip moments in the sagittal and frontal planes were calculated and normalized to body mass. Generalized linear models with Generalized Estimating Equation corrections were used to assess sex effects on hip moments in RStudio.

Results

At the prescribed speed, females walked with 8.5% lower peak hip extension ($p = .0009$) and 9.4% lower adduction ($p = .0084$) internal moments, but 7.9% greater peak hip abduction moments ($p = .0002$) than males. At the preferred speed, females produced 10.2% greater peak hip abduction internal moments compared to males ($p = .0001$).

Discussion

Hip moments differed by sex at both walking speeds, but sex-related biomechanical differences were most apparent when males and females walked at the same speed. While hip abduction moments remained higher in females than males at the preferred speed, the reduction in hip extension and adduction moment was not evident, most likely due to the faster walking speed in females. Preferred speed captures natural walking patterns and is representative of loading experienced at the hip during activities of daily living. These findings emphasize the importance of accounting for sex when interpreting gait mechanics and designing injury reduction research protocols.

Images (Optional)

Impact of Theia3D Software Updates on Hip Kinematics and the Effectiveness of Reference Frame Realignment

Ms. Camilla Antognini[1], Dr. Ariana Ortigas-Vásquez[2], Dr. Adrian Sauer[3], Dr. Christopher Knowlton[1], Dr. Michael Utz[3], Dr. Philip Malloy[1], Dr. Markus Wimmer[1]

[1]Rush University Medical Center, Chicago, Illinois, United States. [2]ETH, Zurich, Zurich, Switzerland. [3]Aesculap AG, Tuttlingen, Baden-Württemberg, Germany

Introduction

Markerless motion capture systems are continuously updated as new algorithms are introduced, raising concerns regarding the longitudinal consistency of kinematic outputs. Recent revisions to Theia3D included updated biomechanical models and modified hip joint center definitions, but how these changes affect consistency between versions remains unclear. This study applied a reference frame alignment method, REFRAME, to hip kinematic data processed with Theia3D v2023 and v2024 to determine whether observed differences primarily reflect changes in segment coordinate system orientation or true differences in the underlying motion.

Methods

Ten healthy adults (5M/5F; age 26.8 ± 5.6 years; BMI 21.5 ± 1.8 kg/m^2) were recruited to perform five walking trials each (right side only). Markerless data were collected with an eight-camera Miqus system (Qualisys), processed in Theia3D using versions v2023 and v2024, and exported to Visual3D (HAS-Motion) for hip kinematic analysis. REFRAME was applied to reorient v2024 pelvic and femoral frames toward v2023 by minimizing hip angle root-mean-square error across planes, with femoral medio-lateral rotation constrained to maintain clinical interpretability.

Results

Greater differences between software versions were observed in the frontal and transverse planes, with v2024 producing more abducted and externally rotated hip kinematics (Figure 1). After implementing REFRAME, inter-version differences decreased across all planes, with root-mean-square error reducing from 5.6° ± 1.9° to 2.2° ± 0.5° (sagittal), 3.4° ± 0.6° to 1.0° ± 0.1° (frontal), and 4.0° ± 0.9° to 2.1° ± 0.3° (transverse). These reductions corresponded to mean rotational adjustments of 4.5° ± 2.0°, -7.6° ± 2.0°, and -3.8° ± 1.7°

about the pelvic x-, y-, and z-axes, and -4.9° ± 2.0°, and -1.4° ± 2.3° about the femoral y- and z-axes.

Discussion

Overall, this study indicates that Theia3D update from v2023 to v2024 introduced systematic hip kinematic differences primarily driven by changes in reference frame definitions. Although post-hoc alignment substantially reduced these discrepancies, residual offsets persisted, especially in the transverse plane, suggesting contributions from broader tracking-algorithm modifications, including those associated with new training datasets. Therefore, the persistence of inter-version differences, even after REFRAME, underscores the need for cautious interpretation when comparing hip kinematic data across software versions.

Gait variability reveals divergent control strategies in frontal gait disorders and Parkinson's disease

Dr. Carolin Curtze[1], Dr. Marian L. Dale[2,3], Dr. Martina Mancini[2]

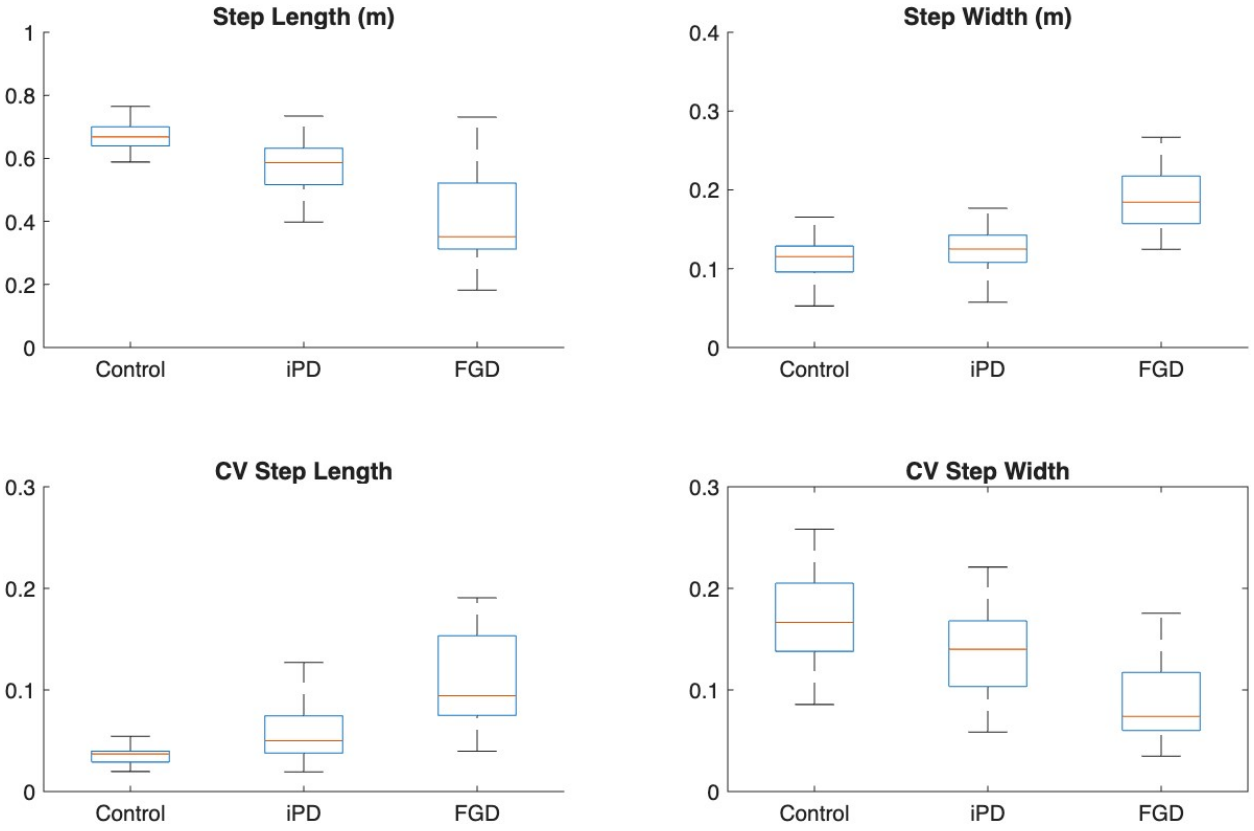
[1]Montana State University, Bozeman, MT, United States. [2]Oregon Health & Science University, Portland, OR, United States. [3]Portland VA Medical Center PADRECC, Portland, OR, United States

Introduction

Human walking naturally involves small step-to-step variations in foot placement. Variability in lateral foot placement suggests the need for active control to maintain balance while walking in the frontal plane, whereas fore-aft foot placement variability reflects the extent to which humans harvest the passive dynamic properties of the leg in sagittal-plane motion [1]. These differences typically result in greater variability in step width than in step length, potentially indicating plane-specific differences in neural control demands. Unlike healthy adults, individuals with neurological gait disorders often adopt a wide-based gait [2]. However, how these gait disorders alter plane-specific control strategies remains unclear. We therefore compared step length and step width among healthy older adults, individuals with frontal gait disorders (FGD), and those with idiopathic Parkinson's disease (iPD).

Methods

Participants included individuals with idiopathic Parkinson's disease (iPD, n=72; tested OFF medication), frontal gait disorders (FGD, n=16), and healthy older adults (n=32). They completed 3 walking trials at preferred-speed on an 8-m instrumented walkway. Mean step length and width and their within-subject coefficients of variation (CV) were calculated. Group differences were examined using one-way ANOVAs with pairwise comparisons. In addition, t-tests were used to determine if step-length variability exceeded step-width variability within each group.



Results

The mean and within-subject CV of the step length and step width are presented in Figure 1. As anticipated, the step width variability was greater than the step length variability in older adults with and without iPD, but in FGD step length and step width variability were similar.

Discussion

Healthy older adults and individuals with iPD showed the expected pattern of greater step-length than step-width variability, consistent with typical plane-specific control in which sagittal-plane motion relies more on passive dynamics and frontal-plane motion requires active stabilization. In contrast, individuals with FGD exhibited similar variability in step length and step width, indicating a disruption of this plane-specific organization. This suggests that the wide-based, short-stepped gait of FGD reduce the need for precise active control in the frontal plane, allowing passive stability to compensate for impaired lateral balance regulation.

Step Ratio Divergence in Very Slow Walking

Dr. Carolynn Patten PhD, PT, FAPTA[1,2], Dr. Anita Bagley PhD, MPH[3], Ms. Sanjana Sivakumar BS[4], Ms. Trina Moy BS[4], Dr. Rebecca Boxer MD, MS[4], Ms. Theresa E. McGuirk MS[1,2]

[1]University of Washington, Seattle, WA, United States. [2]VA Puget Sound Health Care, Seattle, WA, United States. [3]Shriners Hospital for Children, Northern California, Sacramento, CA, United States. [4]UC Davis Health, Sacramento, CA, United States

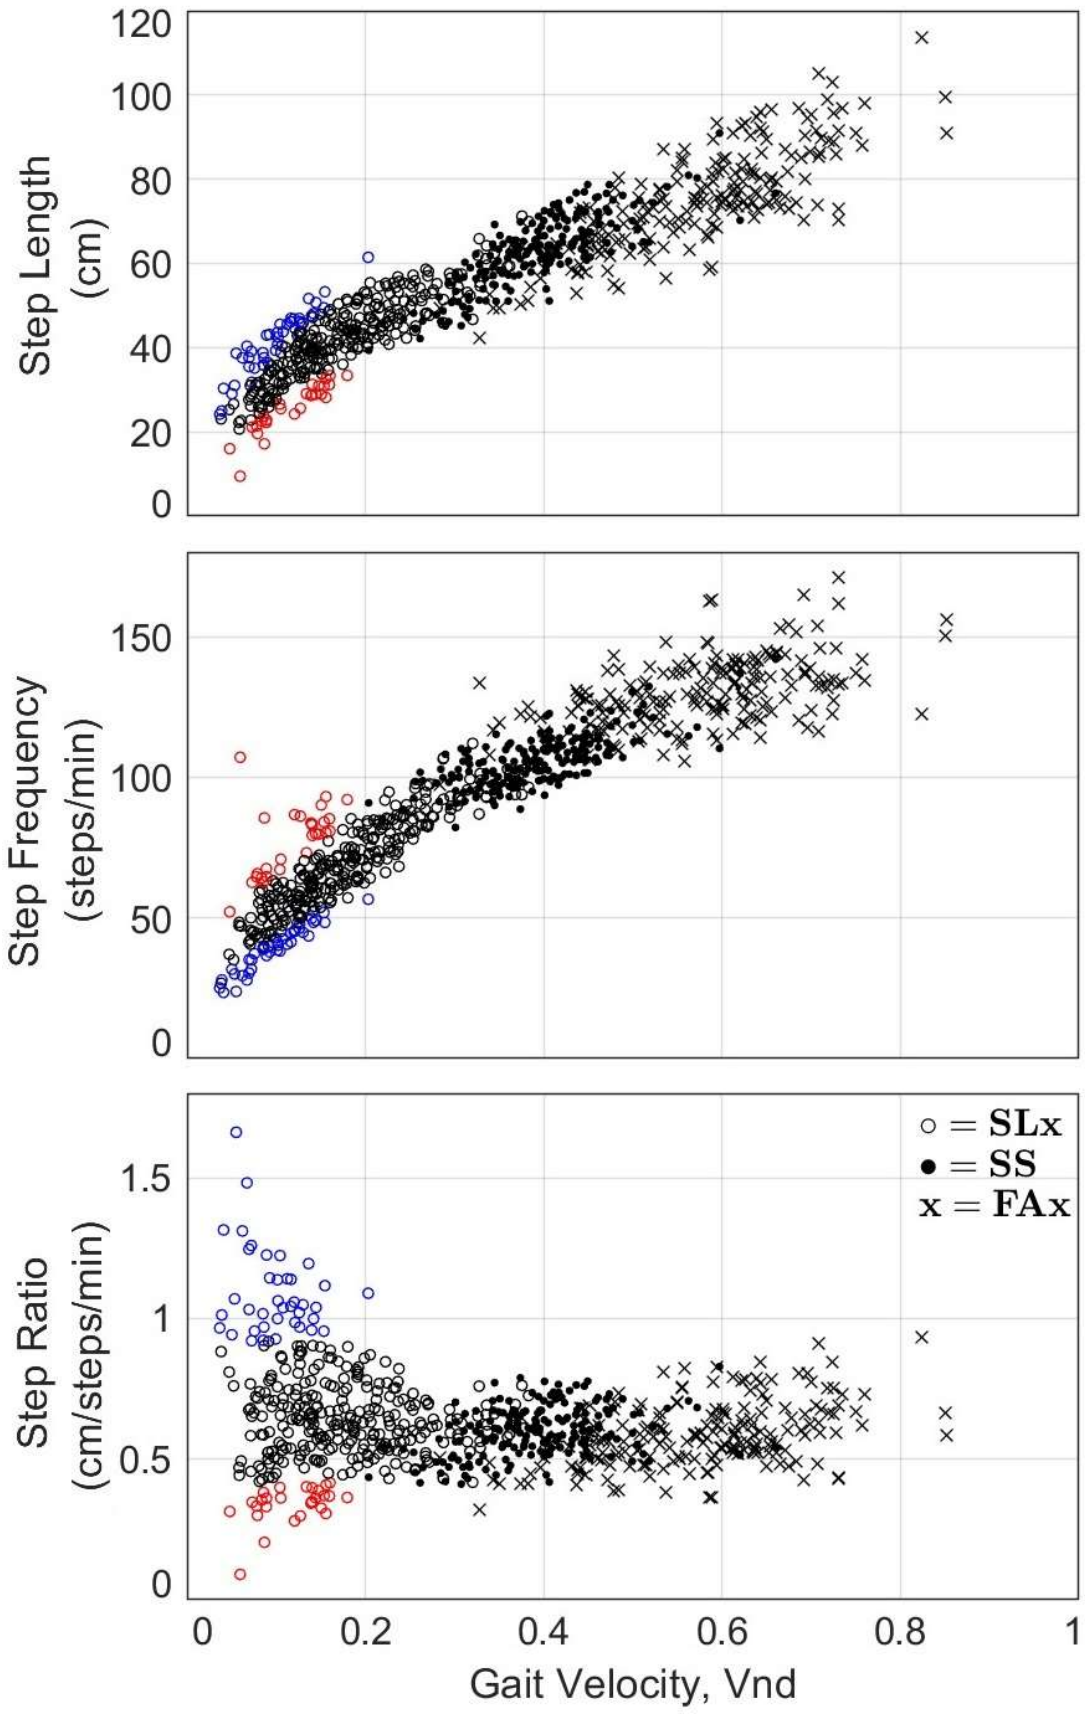
Introduction

Human bipedal gaits (walking, running), are defined as distinct forward progression solutions along the speed continuum. Very slow walking (VSW) has been considered an extension of typical walking behavior, with heuristic speed thresholds used to predict functional decline[1]. In health, Step Ratio (Step Length/Frequency) is mostly invariant across a wide range of walking speeds revealing an heuristic value near 0.6 cm/steps/min [1]. Deviation from this ratio would therefore identify a distinct behavior. Here we sought to determine if different spatiotemporal ratios emerge at very slow speeds suggesting that VSW is distinct from habitual gait.

Methods

Participants walked across a pressure-sensing floor/mat without assistive devices at: slowest (SLx), self-selected (SS), and fastest (FAx) speeds. Multiple attempts were provided to familiarize and assure the participant achieved their slowest speed. StepRatio (step length/frequency) was calculated by stride[1], with mean and coefficient of variation (CV) calculated by gait task and examined relative to nondimensional gait velocity (Vnd)[2]. Self-reported participant health history was acquired.

Results



192 adults of varied health history (18-97yrs (56.68(23.98), 126F) participated, producing: Vnd mean(sd): SLx=0.169(0.078), SS=0.391(0.071), FAx=0.5672(0.109) and StepRatio mean(sd): SLx=0.656(0.048), SS=0.595(0.012), FAx=0.583(0.022). At Vnd<0.2 StepRatio revealed three distinct solutions with subsets diverging to: High (blue, n = 34, 1.077(0.16)), Low (red, n = 29, 0.343(0.045)), and Mid (black, n = 129,0.588(0.113)) values (Fig1).

Discussion

In addition to confirming StepRatio invariance of ~0.6 across typical and fast walking conditions, we observed divergence of coordination strategies among individuals able to attain speeds of Vnd<0.2 reflecting adoption of strategies distinct from habitual walking.

The High StepRatio pattern involves production of longer step lengths while maintaining lower step frequency while Low StepRatio involves shorter step lengths at higher step frequency (Fig 1). These atypical patterns suggest differences in tolerance for position of body center of mass relative to base of support. Moreover, this clear divergence in StepRatio demonstrates VSW does not involve linear scaling of spatiotemporal ratios that characterize typical walking.

Distance-to-Attractor Gait Anomaly Detection for Continuous Monitoring of Reactive Balance: Preliminary Validation

Dr. Cecilia Monoli, Dr. Anna C. Render, Assoc. Prof. Peter C. Fino

University of Utah, Department of Health and Kinesiology, Salt Lake City, Utah, United States

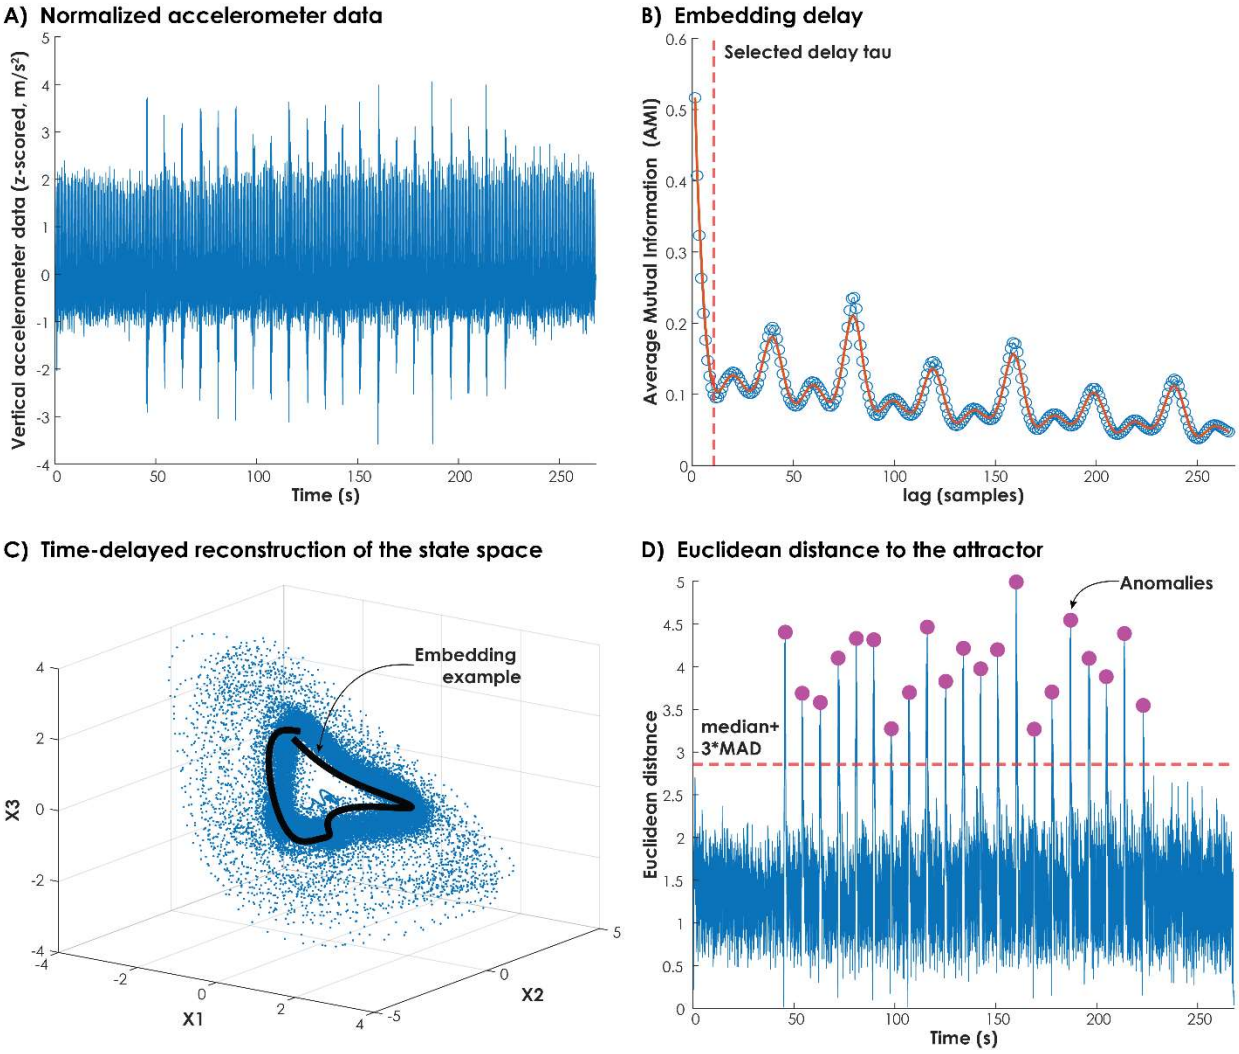
Introduction

Continuous monitoring of free-living mobility enables quantification of spatiotemporal gait and balance using wearable sensors. However, detecting reactive balance episodes, such as trips or slips, remains challenging due to high variability and noise in real-world gait. Here, we sought to apply an anomaly-detection framework that identifies deviations from an individualized gait attractor in state space (Ravi et al., 2021 *J Exp Biol*) to detect gait disruptions using wearable inertial sensors.

Methods

IRB approval and informed consent were obtained. For this validation, a single participant walked on a slip-belt instrumented treadmill at 1.0 m/s for 5 minutes. Unilateral slip-like perturbations were intermittently applied after heel strike (21 perturbations, peak 6 m/s^2, Δspeed 0.8 m/s). Two inertial measurement units placed on the sacrum (~L5) and upper thoracic region recorded triaxial acceleration and angular velocity (128 Hz). Kinematic data were processed using the anomaly-detection algorithm, which applied filtering, normalization, construction of time-delay embeddings, and generation of a phase-aligned mean attractor (Figure). Euclidean distance to the attractor was computed at each time, and anomalies were defined as values exceeding the median + 3×median absolute deviation (MAD). The algorithm was evaluated for both sensors using different input signals: vertical acceleration only or all three accelerometer axes, measuring its performance as the number of detected perturbations relative to the actual number delivered. Data collection is ongoing (1/10).

Results



All perturbations were detected with the lumbar sensor, achieving perfect performance with vertical acceleration only (accuracy = 1.00) and slightly lower accuracy with all three axes (accuracy = 0.91). The sternum sensor detected perturbations with lower accuracy

using vertical acceleration alone (accuracy = 0.91) and worse performance when using all axes (accuracy = 0.62).

Discussion

These preliminary results show that our attractor-based algorithm can reliably detect slip-like perturbations from wearable inertial sensors, with lumbar sensors performing best. Future work will validate the identification of the anomalies and their durations against established balance-recovery metrics, evaluate algorithm robustness in daily-life environments, optimize sensor placement, and refine individualized thresholds for practical fall-risk monitoring.

A Mechanical Device to Simulate Heel Strike and Early Stance Dynamics

Doctoral student Cédric Dessureault B.Ing.[1], Doctoral student Gaspard Diotalevi M.Sc.A.[1], Research assistant François Martel ing.[1], Professor Cécile Smeesters ing., Ph.D.[1], Engineer Chantal Gauvin ing. M.Sc.A.[2], Professor Denis Rancourt ing., Ph.D.[1]

[1]Université de Sherbrooke, Sherbrooke, Québec, Canada. [2]IRSST, Montréal, Québec, Canada

Introduction

Standard devices for evaluating footwear safety on slippery surfaces are not designed to replicate key gait characteristics such as heel strike dynamics, evolution of ground reaction forces (GRFs), slip initiation, changes in contact area and pressure distribution at the shoe-ground interface. In this study, an inverted pendulum was used to develop SLIPPY, a passive mechanical device with high repeatability [1] designed to simulate heel strike and early stance dynamics.

Methods

Human walking GRFs and heel strike kinematics were collected as reference data to tune SLIPPY's mechanical properties and assess its ability to reproduce participant-specific early stance GRFs. Participants walked on a dry surface wearing standardized shoes. Vertical and horizontal GRFs were recorded on force platforms at 2400 Hz, and kinematics were captured at 240 Hz. For each participant, GRFs from ten dry steps were averaged, and three representative trials were selected: one closest to the mean and two within ±1 SD. A simplified SLIPPY dynamic numerical model was used to identify the system stiffness and damping coefficients that best reproduce each participant's GRF curves. SLIPPY was then configured with these impedance values and participant-specific heel strike initial conditions. The device was launched three times per reference trial, and resulting GRFs were compared with human curves.

Results

Preliminary results show that the numerical model simulates the first 300ms of early stance GRFs with MRE of <6.37%. Estimated impedance values fall within ranges typically reported in the literature (Table 1). SLIPPY-generated vertical GRFs consistently display a heel strike transient, a feature usually absent from numerical inverted pendulum models.

Discussion

Early tests show that SLIPPY already produces human-like gait features, including M-shaped vertical GRFs [1] and a heel strike transient. Present results indicate that impedance parameters identified from human data should bring SLIPPY's GRFs closer to participant-specific reference curves. Upcoming trials will evaluate how accurately the device can simulate GRFs during heel strike and early stance across a wider range of conditions.

Autoregressive Modeling to Evaluate Dynamic Stability During Running after Anterior Cruciate Ligament Reconstruction

Mr. Charles Eisner[1], Dr. Kristen Morgan PHD[2], Dr. Brian Noehren PT PHD FACSM[1], Dr. Meredith Owen PHD[1]

[1]University of Kentucky, Lexington, KY, United States. [2]University of Connecticut, Mansfield, CT, United States

Introduction

Asymmetries in ground reaction forces (GRFs) persist years after anterior cruciate ligament reconstruction (ACLR), which may lead to increased reinjury risk and long-term joint degeneration. Autoregressive (AR) modeling analyzes the stability of a time series through functions dependent on previous values. Research utilizing AR modeling found ACLR individuals display dynamic gait instability during running compared to a control group. This study's purpose is to characterize the dynamic stability of running in ACLR individuals throughout late stages of rehabilitation.

Methods

Fourteen individuals (5F/9M, 20±5 years, 1.8 m, 72.8 kg) completed instrumented running gait analysis at 6- and 12-months post-ACLR. Fourteen uninjured individuals matched for height and weight (5F/9M, 20±5 years, 1.8 m, 70.0 kg) participated in an identical running gait analysis. GRFs were collected at 2000 Hz and filtered with a 4^{th} order lowpass Butterworth filter at 35 Hz. Vertical GRF peaks were isolated, organized into a time series, and detrended. A second order AR model was fit to the GRF timeseries data. Model coefficients (AR1 and AR2) and stationary triangle were used to assess differences in stability between the two timepoints. The distance formula was used to calculate the total distance from the plotted coefficients to the triangle center (distance). AR1 and AR2 coefficients and distance were compared with pairwise t-tests between the 6- and 12-month data collections for ACLR participants. ACLR participants and controls were compared via independent t-tests at the 12-month timepoint.

Results

AR1 coefficients for were significantly different ($p<0.05$) between timepoints for those with ACLR. At 12-months, AR2 coefficient and distance were significantly different between groups (Table 1).

Discussion

Between 6- and 12-months, ALCR participants had significant improvements in interlimb (AR1) stability and no significant differences in intralimb (AR2) stability. However, when compared to uninjured individuals at 12-months, a common return-to-sport timepoint, intralimb instability and total distance from the most stable point of the triangle persist. These results suggest that while between limb stability improves, individuals post-ACLR still have worse intralimb stability. While much focus is placed on improving between limb symmetry (represented by AR1), improving same limb step-to-step symmetry may also be critical for long-term success.

Improved Accuracy of the Center of Mass Position Through Kalman Filtering of Kinematic and Kinetic Information

Dr Charlotte Le Mouel

CNRS, Paris, Ile-de-France, France

Introduction

The position of the body center of mass (CoM) is critical for evaluating balance. It can be calculated using either kinematic or kinetic methods. Each of these methods has its limitations, and it is difficult to evaluate their accuracy as there is no ground truth to which the CoM can be compared. Here, I use as ground truth the fact that, during the flight phase of running, the acceleration of the CoM is equal to gravity. I evaluate the accuracy of kinematic models of different complexity, and propose a novel method for calculating the CoM by combining kinematic and forceplate measurements.

Methods

Two open access datasets of human treadmill running were used, with a total of ten subjects running at speeds ranging from 2.5 to 4 m/s. The CoM was calculated for three kinematic models of increasing complexity. A novel method is proposed to estimate the CoM position using a Kalman filter combining kinematic and kinetic information.
For each model, the acceleration during flight was compared to gravity to determine the acceleration error. The position error was obtained by comparing the position to an indirect estimate of position obtained from kinetics.
A linear regression was used to predict foot placement from the CoM state during the previous flight phase.

Results

The error in acceleration ranges from 14 % of gravity for the most complex model to 36 % for the simplest model. The error in position ranges from 6 to 12 mm (27 % to 56 % of the CoM movement over a gait cycle).
When using the novel method, the acceleration error drops to between 1.1 and 3.1 % and position error to between 2.6 and 3.2% for all kinematic models. Moreover, the proposed method provides a more reliable evaluation of foot placement control.

Discussion

State-of-the-art kinematic models of the CoM were have poor accuracy. The novel method greatly improves the accuracy of CoM measurements. This can provide a more reliable

evaluation of balance indicators during locomotion, such as foot placement control.
The code for calculating this optimal combination is available in both Python and Matlab at: https://github.com/charlotte-lemouel/center_of_mass

A Deep Learning Pipeline to Extract Clinical Gait Metrics from Single Camera Recordings

Mr. Chris Vellucci, Miss Emma Ratke, Miss Akanksha Guleria, Dr. Shawn Beaudette

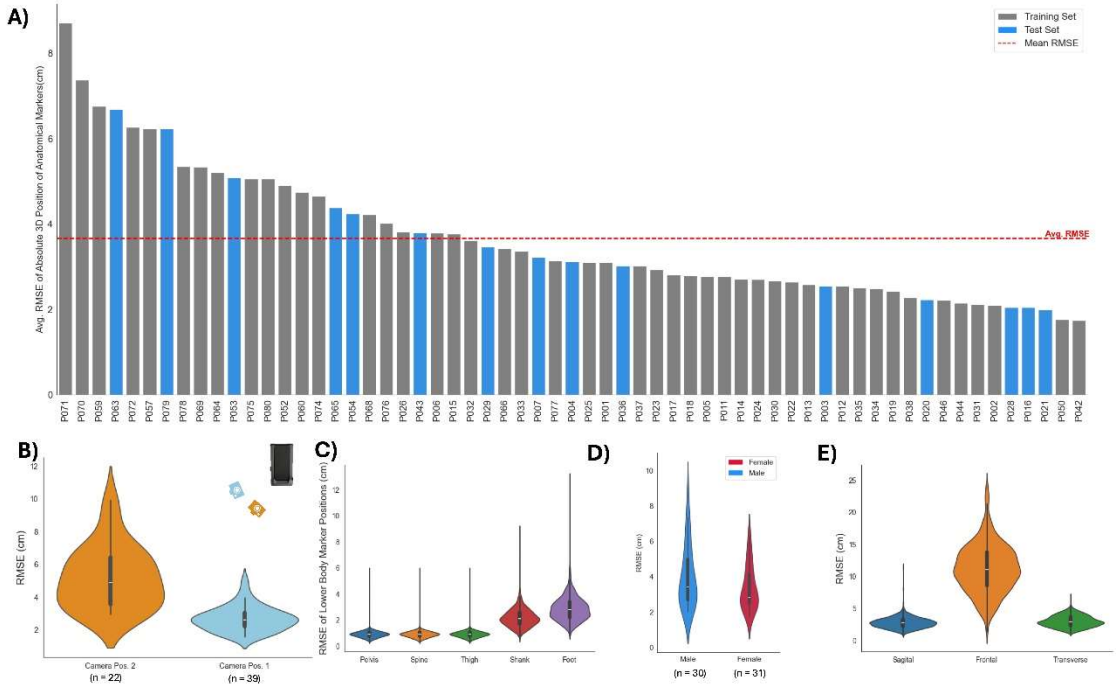
Brock University, St. Catherines, ON, Canada

Introduction

Recently, open-source single camera pose estimation approaches have been adopted due to their relative ease of use and accessibility; however, data quality can be a concern. This study developed a methodology to estimate 3D lower body kinematics from multiple single camera viewpoints using deep learning.

Methods

61 participants (32 female, mean height 1.7 m, BMI: 23.6 kg/m^2) completed 10 minutes of treadmill walking. Kinematics were tracked concurrently using an IMU motion capture suit (XSENS Awinda), and 2D video cameras. 2D joint centres were extracted from video data using open-source pose estimation software (MediaPipe, Google, USA). Raw 2D pose data and the 3D lower body anatomical landmarks derived from the IMU data were processed using similar steps which included a low-pass filter (fc=6 Hz), gap-filled for missing frames, and subtracted the right ankle before being saved for training and validation of the deep learning model. A Long Short-Term Memory (LSTM) recurrent neural network was trained using these data. Data were split by participant into an 80/20 training-validation set. Hyperparameter search was completed using Bayesian Optimization with five-fold cross validation. Model performance was evaluated using leave-one-out validation (LOOV), and computed RMSE test statistics.



Results

Results from the LOOV demonstrated that the final model was able to predict the 3D positions of 34 landmarks with a mean RMSE of 3.21 cm +/- 2.40 (SD) (Figure 1.A). Sagittal and transverse plane segment positions showed good agreement with the research standard (Figure 1.C). The pelvis, spine, and thigh joint absolute positions showed good agreement with the research standard (Figure 1.D). Camera position 1 showed significantly lower RMSE then Camera Position 2 ($p<0.001$) (Figure 1.B). RMSE was not associated with biological sex ($p = 0.12$), or height ($p = 0.49$) (Figure 1.D).

Discussion

Results demonstrate that accurate 3D kinematics can be obtained from a single consumer grade camera. Performance can be optimized if expert models are trained for specific movements and that the camera orientation relative to the participant is optimized for both observation of the movement and the performance of open-source computer vision algorithm. Future work will evaluate the sensitivity of this approach to detect clinically relevant phenomenon.

The relationship between toe flexor strength and positive foot work during sloped walking in older and younger adults

Mr. Christopher L. Long[1], Dr. Daniel J. Davis[1], Dr. Jason R. Franz[2], Dr. Kota Z. Takahashi[1]

[1]University of Utah, Salt Lake City, Utah, United States. [2]UNC Chapel Hill and NC State University, Chapel Hill, North Carolina, United States

Introduction

Older adults perform less positive foot work than younger adults, and these differences are more pronounced during challenging tasks such as walking uphill [1] or against impeding forces [2]. Toe flexor strength also declines with age [3] and may contribute to these task-specific energy deficits. Therefore, this study investigated whether toe flexor weakness associates with positive foot work during walking and helps to explain task-specific deficits in older adults.

Methods

Twenty-six younger (13F/13M, 24±3.3 yrs) and nineteen older (9F/10M, 70±5.9 yrs) adults walked barefoot on an instrumented treadmill at 1.2 m/s under three slope conditions: decline (−5°), level (0°), and incline (+5°). We estimated foot power distal to the calcaneus using unified deformable (UD) analysis [4], then integrated the positive portion of the power curve to compute positive foot work. Isometric toe flexor strength was measured using a toe grip dynamometer [5] and normalized to body mass. A linear mixed-effects model tested the association between toe flexor strength and positive foot work, controlling for age group, slope, and their interaction.

Results

Older adults had 33.7% weaker toe flexors than younger adults ($p<0.001$). However, toe flexor strength was not associated with positive foot work, controlling for age group and slope ($p=0.304$). Older adults generated less positive foot work during incline walking only, after controlling for toe flexor strength ($p=0.005$).

Discussion

In this sample, toe flexor strength was not associated with positive foot work during walking. Older adults still produced less positive work during incline walking, even after accounting for individual differences in toe strength. These findings suggest that task-specific deficits may be driven by factors beyond toe flexor strength, such as diminished

energy return from plantar structures (e.g., fascia, fat pads) or altered motor control strategies.

Evaluation of Three-IMU-Sensor Configurations for Estimating Kinematics and Kinetics of Treadmill Running using Optimal Control

Mrs. Chuyi Wang[1], Ms. Maria Camila Mejia Taborda[1], Mr. Tobias Luckfiel[2], Dr.-Ing. Marlies Nitschke[2], Prof. Dr. Anne D. Koelewijn[1]

[1]Chair of Autonomous Systems and Mechatronics, Department of Electrical Engineering, Friedrich-Alexander-Universität Erlangen-Nürnberg (FAU), Erlangen, Bavaria, Germany. [2]adidas AG, Herzogenaurach, Bavaria, Germany

Introduction

Inertial motion capture (IMC) systems using inertial measurement units (IMUs) enable natural and unrestricted gait analysis. Previous research has shown that IMU setups, e.g., with three sensors, can maintain acceptable accuracy while improving usability [1], while using a shank sensor alone has also shown good accuracy [2]. However, different combinations of three IMU sensors have not yet been compared. Furthermore, the previous study [1] evaluated overground running, whereas treadmill running differs since there is no forward body movement. Therefore, we evaluated how well sensor configuration with three IMUs can estimate running kinematics and kinetics for treadmill running.

Methods

Twenty-four healthy participants ran at a self-selected speed on an instrumented treadmill wearing three types of running shoes. We recorded the motion using an optimal motion capture (OMC) system and 7 IMUs on the pelvis and lower limbs. Three IMU setups, namely pelvis–thighs (PT), pelvis–shanks (PS), and pelvis–feet (PF), were tested. We reconstructed running motion by solving an optimal control problem with a sagittal-plane musculoskeletal model in which muscular effort and IMU tracking error were minimized [3]. We validated against processed OMC data (inverse kinematics and dynamics) by testing the agreement to the IMC results using the coefficient of multiple correlation (CMC).

Results

Results reflect preliminary analysis of five participants (Fig. 1). Joint angles showed high CMCs across all configurations, with PS and PF performing better than PT. Joint moment CMCs were lower, especially in the hip. Differences among shoe types (A–C) were small, with all three shoes exhibiting comparable accuracy trends, similar to the OMC data.

Discussion

Running kinematics and kinetics can be reconstructed with reasonable accuracy using only three IMUs, independent of shoe type. Both PS and PF configurations showed reliable accuracy, with PF recommended for ankle angle estimation, while PS provides a practical alternative where foot-mounted sensors are impractical. Overall, sparse IMU setups can effectively capture running biomechanics and reduce participant burden during gait analysis.

Images (Optional)

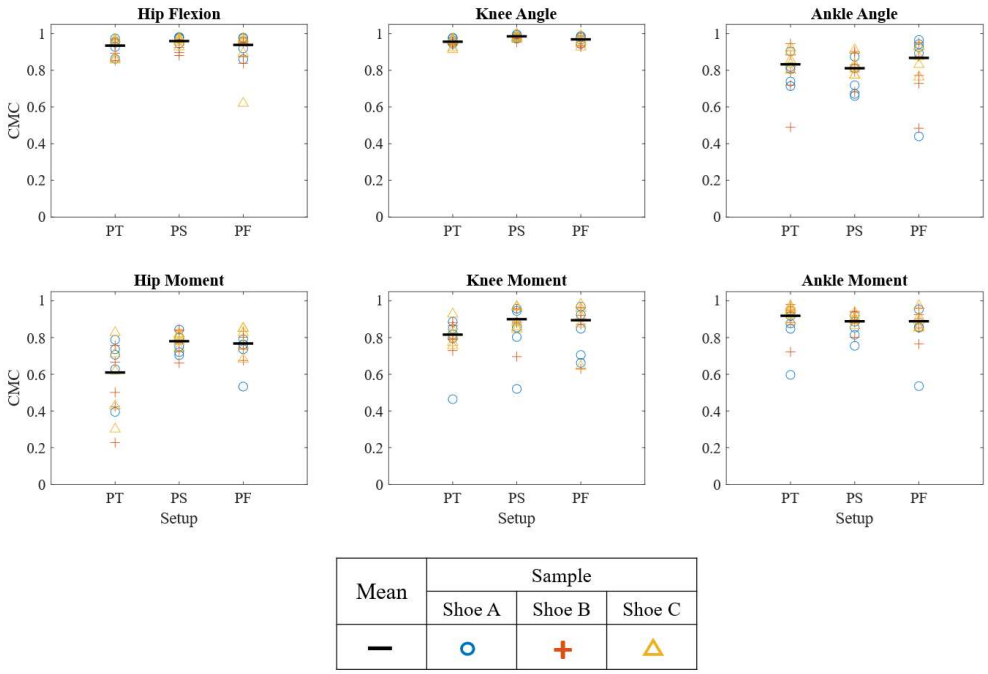

Figure 1. CMCs between joint angles and moments measured with different IMC setups versus OMC across three shoe types. Individual running cycle values for participants are shown as blue circles (Shoe A), orange plus signs (Shoe B), and yellow triangles (Shoe C). Black bars indicate the mean CMCs across all shoes and participants.

Distal-to-Proximal Redistribution of Joint Work is Costly in Aging Runners

PhD student Clément Lemineur Lemineur[1], Full professor Grégory M Blain[1,2], Associate professor Pauline Gerus[1]

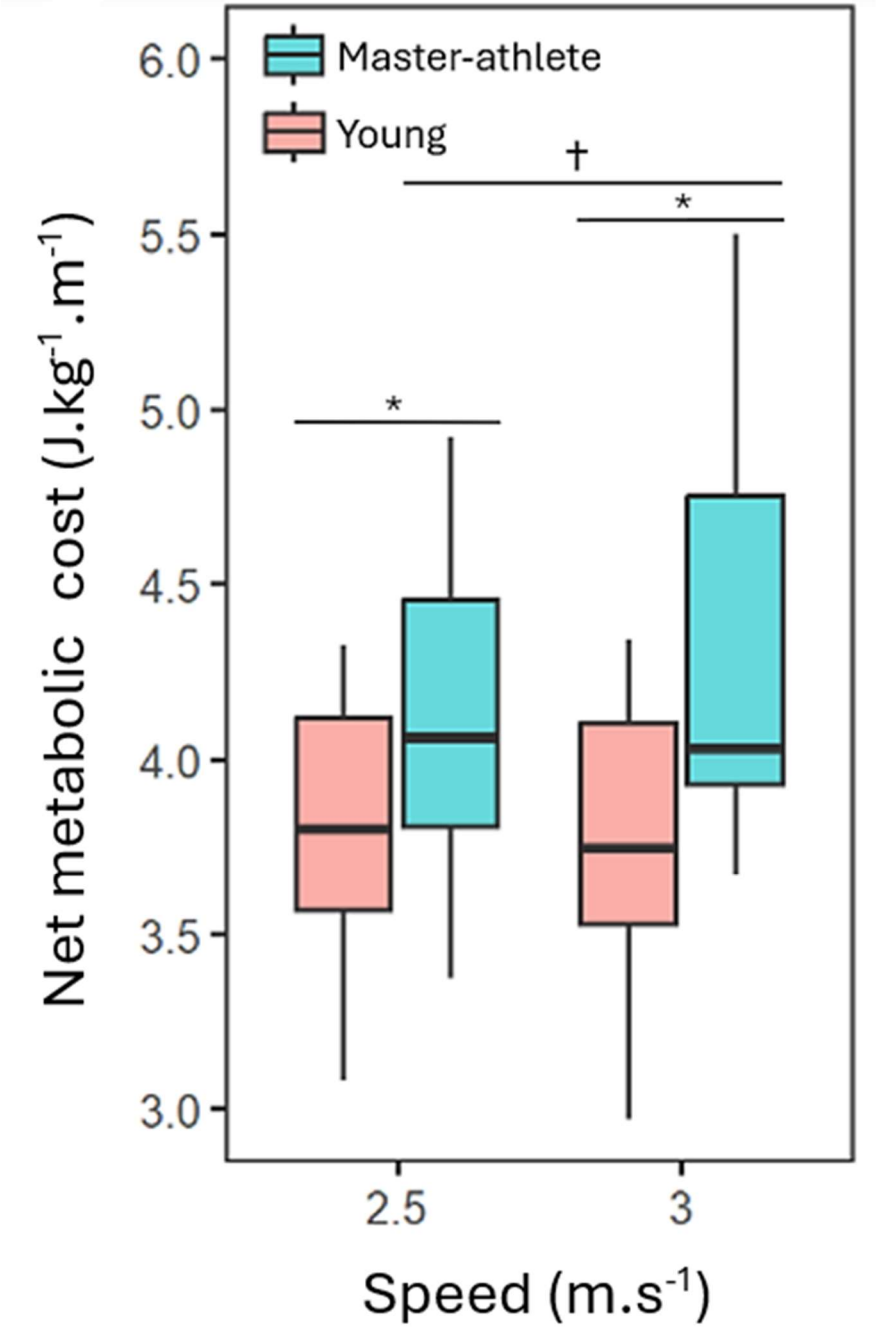
[1]Université Côte d'Azur, Nice, Nice, Provence-Alpes-Côte d'Azur, France. [2]Utah Valley University, Biology Department, Salt Lake City, Utah, United States

Introduction

The net metabolic cost of running (Cnet) typically increases with age and contributes to declines in endurance performance. Similar observations have been made during walking, and this might be explained by older adults relying more on hip muscles and less on the ankle for propulsion, in response to a decrease in the maximal strength of the plantar-flexors. Research question: Do age-related changes in propulsion strategy contribute to the higher metabolic cost of running?

Methods

Eighteen young adult runners (26.1±3.9 years; 63.8±10.0 kg; 60.3±6.5 $ml \cdot kg^{-1} \cdot min^{-1}$) and eighteen master athletes (63.4±2.7 years; 67.4±10.8 kg; 45.2±6.1 $ml \cdot kg^{-1} \cdot min^{-1}$) completed two experimental sessions. The first session included an assessment of maximal isometric plantar-flexion moment and a VO_2MAX test. The second session involved running at 2.5 and 3 m/s on an instrumented treadmill, with concurrent recordings of kinematics, ground reaction forces, and gas exchange. Joint mechanical work during propulsion (ankle, knee, and hip) were computed using net joint moment and angular velocity. Cnet was quantified using indirect calorimetry. Linear mixed models tested the effects of group, speed, and joint-specific mechanical work contributions on Cnet.



Results

Master-athletes had ~28% ($p < 0.001$) lower maximal plantar-flexion strength than young athletes. Cnet was significantly higher in master athletes ($p=0.003$) and increased from 2.5 to 3 $m.s^{-1}$ in this group, but not in young adults. In the linear mixed model, positive ankle work was significantly greater in young athletes ($p = 0.02$), whereas positive hip work was greater in master athletes and was positively associated with Cnet ($p = 0.0497$). In this model, 28% of the variance in Cnet was explained by hip work ($R^2 = 0.28$), and when individual differences were accounted for, the variance explained increased to approximately 80% ($R^2 = 0.80$).

Discussion

Master athletes showed reduced plantar-flexors strength and produced less ankle work, leading to a compensatory increase in hip work. This distal-to-proximal shift aligns with age-related neuromuscular declines at the ankle and likely contributed to the increased metabolic cost during running, as hip propulsion is less economical due to its limited ability to store and release elastic energy.

Sagittal-Plane Gait Differences Between Faster and Slower Marathon Runners Captured By Markerless Motion Capture at Mile 21: Faster Runners Exhibit Greater Hip Extension During Late Stance

Dr. Colin Bond PhD, MBA

Sanford Research, Fargo, North Dakota, United States

Introduction

Three-dimensional running biomechanics are typically studied in laboratory settings, which may not reflect the mechanical demands of endurance running. Lab protocols often involve treadmills, short durations, and rested participants, limiting their relevance to the fatigue states experienced during marathons. Markerless motion capture enables high-fidelity, scalable gait analysis in natural environments. Despite widespread interest in optimizing running performance, little is known about how joint-level kinematics differ between faster and slower runners during the later stages of a marathon, when fatigue is pronounced. The purpose of this study is to compare lower-extremity sagittal-plane kinematics between faster and slower runners at mile 21 of a competitive marathon.

Methods

Data were collected using eight synchronized Qualisys Miqus Video Plus cameras that captured 50 linear feet of course at mile 21. Of 359 recorded runners, 34 (43.8±11.7y, 1.76±.09m, 75.6±11.3kg) consented to research use of their data. Markerless pose estimation was performed using Theia3D. Sagittal-plane hip, knee, and ankle joint angles were computed and gait events identified using Visual3D. Runners were stratified into fast and slow groups based on their pace and the median pace (10.0 $km \cdot h^{-1}$) for the first 21 miles. Group differences across the stance phase were assessed using statistical parametric mapping with a two-sample t-test ($\alpha = 0.05$) using Sift.

Results

There was an effect of group on sagittal-plane hip angles as faster runners exhibited greater hip extension angles during late stance, with a peak difference of 2° between groups. There was no evidence of an effect of group on sagittal-plane knee or ankle angles.

Discussion

Faster runners exhibited greater hip extension during late stance, which may reflect enhanced propulsion or greater reliance on hip musculature under fatigue. No group differences were observed in knee or ankle kinematics, suggesting that performance

differences at this stage may be more apparent proximally. This study demonstrates the feasibility of using markerless motion capture to identify gait differences in a real-world marathon setting. Future work should examine how these patterns relate to running economy, injury risk, or pacing strategy, and whether similar trends emerge at other race stages.

Classifying Marathon Runners by Lower-Extremity Compression Behavior Using Markerless Motion Capture at Mile 21: Associations With Demographics, Training History, and Injury History

Dr. Colin Bond PhD, MBA

Sanford Research, Fargo, North Dakota, United States

Introduction

Biomechanical analyses of running are typically conducted in laboratory settings, which may not reflect the demands of a competitive marathon. Markerless motion capture enables high-resolution gait analysis in natural environments. The lower-extremity can be modeled as a spring, with compression during early stance reflecting impact absorption. Compression characteristics may be linked to running performance and injury risk. The purpose of this study is to examine associations between compression and runner characteristics.

Methods

Data were collected using eight synchronized Qualisys Miqus Video Plus cameras spanning 50 linear feet of course at mile 21. Of 359 recorded runners, 34 (43.8±11.7y, 1.76±.09m, 75.6±11.3kg) consented to research use. Markerless pose estimation was performed using Theia3D. Spring length was calculated as the distance from the model's center of mass to the foot segment center of mass, then normalized to initial contact length to account for body size, and gait events were identified in Visual3D. Runners were stratified into lower-compression (LC), defined by smaller spring deformation across early stance, and higher-compression (HC) groups by applying k-means clustering to principal component scores derived from spring length waveforms during weight acceptance. Statistical analyses included two-sample t-tests (pace through mile 21, body mass index) and chi-square tests (sex, injury history, experience, weekly mileage). Significance was set at $\alpha = .05$.

Results

Out of 34 runners, 15 were classified as LC and 19 as HC. There were no significant differences between groups in pace through mile 21 ($p = .09$) or body mass index ($p = .78$). Group membership was not associated with sex ($p = .23$), injury history in the prior 12 months ($p > .99$), years of running experience ($p = .134$), or weekly running milage in the prior 3 months ($p = .361$).

Discussion

Compression-based grouping did not associate with pace, anthropometrics, sex, or injury and training history, suggesting that impact attenuation behavior may be driven more by biomechanical or neuromuscular factors than runner characteristics. This study demonstrates the feasibility of classifying runners by compression behavior using markerless capture during competition, offering new opportunities to study performance and injury risk in natural race environments.

Images (Optional)

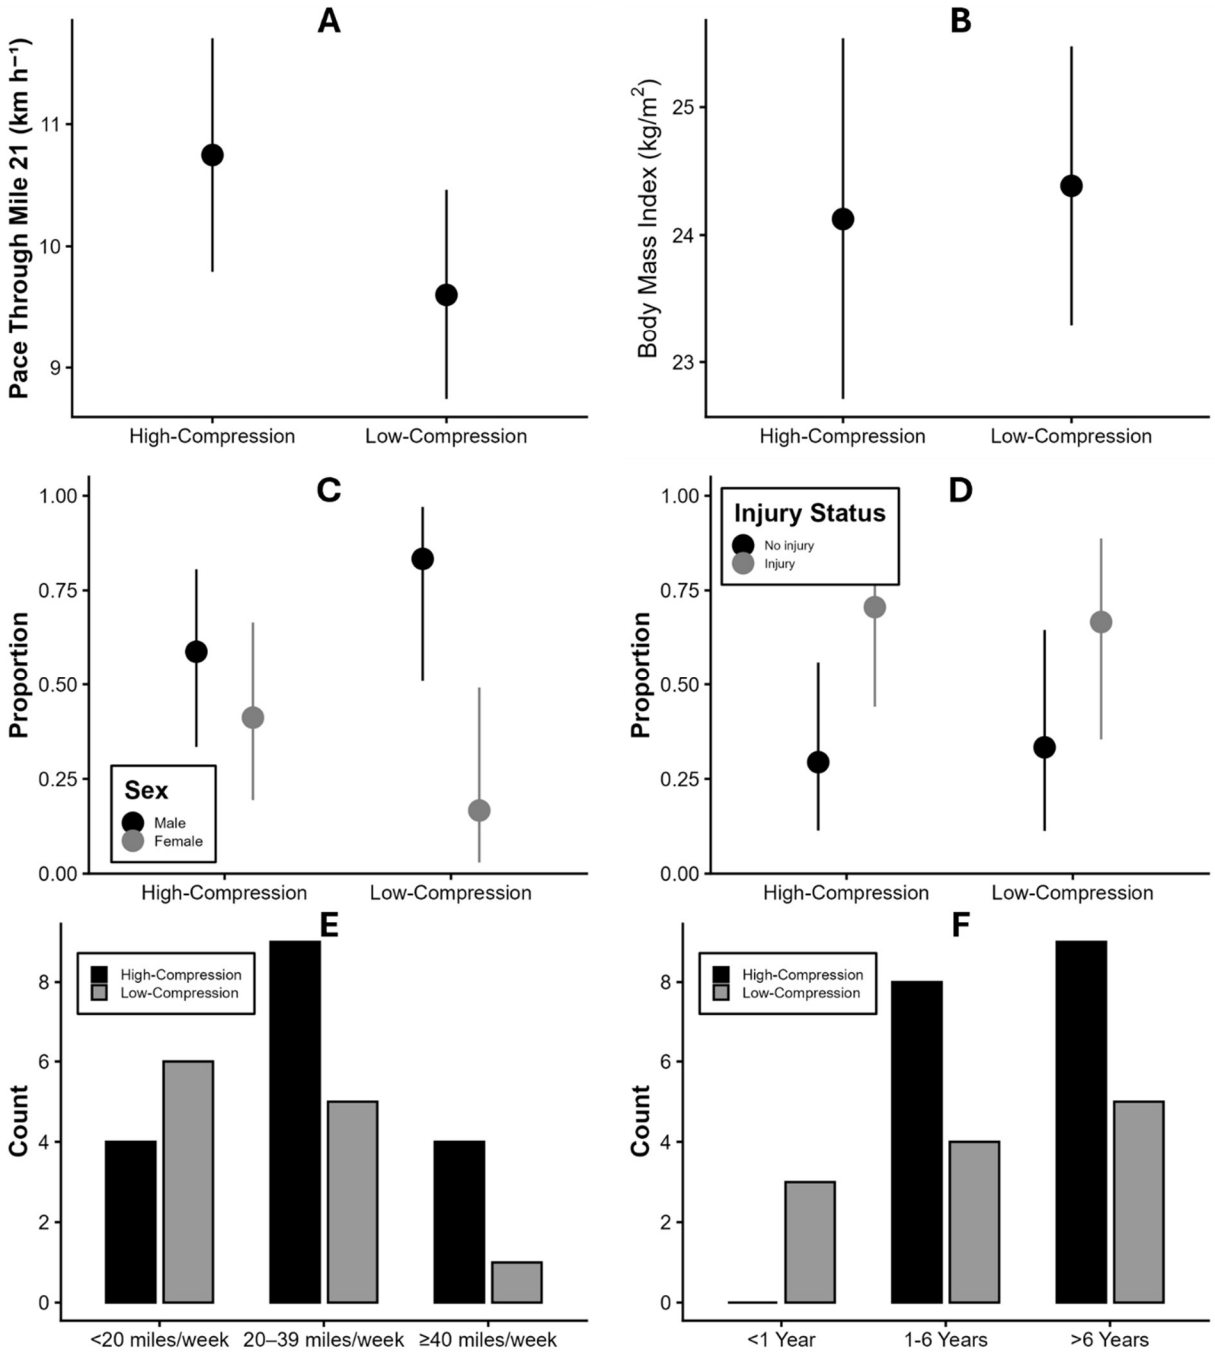

Figure 1. Mean ± 95% confidence interval for mean for pace through mile 21 (A) and body mass index (B). Proportion ± 95% confidence interval for proportion for male (black) and female (grey) (C) and for those with an injury in the prior 12 months (black) and without (grey) (D). Lower Extremity Acceleration Asymmetries During Running in Participants With Achilles Tendinopathy: A Case Series

Dr. Dave Heller PhD, Ms. Emily Grither, Ms Barbara Heard, Ms Kaitlyn McConnell, Ms Skylar Menner, Dr. Emily Tomlinson PT, DPT, OCS, Dr. Yaqiong Wang PhD, PT, DPT, OCS

Rockhurst University, Kansas City, MO, United States

Introduction

Achilles tendinopathy is common in runners. Previously, we noted asymmetries in acceleration during a drop landing task in a runner with unilateral insertional Achilles tendinopathy (IAT). This subsequent analysis aimed to investigate asymmetries in acceleration of the lower extremities during gait in participants with and without Achilles tendinopathy.

Methods

3 recreational runners, (M, 50y) ran on a treadmill barefoot. One with right IAT, one with left mid-tendon Achilles tendinopathy (MAT) and one healthy (H). We placed accelerometers on each thigh and leg, sampling 3D acceleration. Speed changed randomly every 30 seconds for 5 minutes. We calculated the peak, mean, standard deviation (StDev), and range of net acceleration for each segment. We analyzed data using nonparametric statistics and tests. We compared each measure for each segment without multiple-comparison correction. We hypothesized that IAT and MAT would exhibit significantly higher values for all measures on the affected segment and that H would show no asymmetry.

Results

We found asymmetries in measures of net acceleration across all participants, including, surprisingly, in the healthy participant (Table 1). For IAT at the thigh all measures were statistically significantly lower for the affected (right) limb ($p < .010$). At the leg, the affected limb exhibited statistically significantly lower mean and higher StDev and range of net acceleration ($p < .010$). For MAT, the affected (left) leg exhibited statistically significantly higher values for all measures ($p < .020$) while the affected thigh exhibited significantly lower peak and range of net acceleration but higher mean net acceleration ($p < .020$). Contrary to our hypothesis, H also exhibited statistically significant asymmetries for all measures at the thigh ($p < .008$) and for peak, mean, and range of net acceleration at the leg ($p < .004$).

Discussion

In addition to being an indicator of injury, gait asymmetries could also precede injuries. Our results raise questions about whether asymmetries in gait simply represent typical individual variability or could be early indicators of potential injury risk. A future potential longitudinal study could follow healthy individuals to determine whether those with gait asymmetries are more likely to experience injury.

Foot Progression Angle Variability in Children with Cerebral Palsy

Ms Colina Matthews[1], Dr Kevin Dibbern[2], Dr David Kingston[1]

[1]University of Nebraska at Omaha, Omaha, NE, United States. [2]University of Nebraska Medical Center, Omaha, NE, United States

Introduction

Foot progression angle (FPA), the angle between the line of the heel and second metatarsal head with gait progression, is typically averaged over multiple steps or trials to a single directional alignment for a subject. This approach may mask step-by-step variations in clinical populations, which may misrepresent the level of impairment. The purpose of this study was to quantify step-by-step variability in children with cerebral palsy (CP) and typically developing (TD) peers to analyze the distribution and consistency of participant foot placement.

Methods

31 CP (GMFCS I and II) and 17 age-matched TD children were fitted with 54 retro-reflective markers on the lower limbs, tracked by a 20-camera motion capture system, and walked barefoot on a 10-meter level walkway over eight embedded force plates for a minimum of 8 trials(3-10 steps per trial). Data were processed in Visual3D and midstance FPA was calculated for each step. Subject-level means and the individual step-to-step absolute deviations from that mean were calculated. Linear Mixed Effects models (LMM) compared step-by-step FPA in groups and GMFCS levels.

Results

LMMs showed a large effect of group *($F(2,31.4) = 4.8$, $p = .014$, $\eta^2_p = 0.187$) and an increasing foot-placement inconsistency trend with impairment (Geometric means:* TD = 5.3°, CP1 = 8.3°, CP2 = 13.4°). Data were log transformed to correct skew. Large differences, over three times greater, in step-to-step FPA were observed for CP children at GMFCS II compared to than TD peers. Children at GMFCS I had a moderate effect.

Discussion

CP children at GMFCS II had more step-by-step variability than their TD peers; suggesting reduced foot-placement consistency. Step-by-step FPA could be used as a marker to capture fluctuations in gait and as a tool to identify children who could benefit from

stability and motor control interventions. Future work should target larger sample sizes and explore how orthoses, speed, and treadmill compared to overground walking affect FPA variability.

Portable Ground Reaction Force Estimation Using IMU-Based Motion Capture: A Two-Tier Trust Framework

Dr Domitille Princelle PhD

Movella Technology B.V., Enschede, Twente, Netherlands

Introduction

Ground reaction forces (GRFs) and Center of Pressure (CoP) are fundamental to clinical gait and sport performance interpretation, informing joint loading and fall risk assessment. Yet clinical and sport assessments conducted in laboratory conditions compromise ecological validity. Portable alternatives using inertial motion capture (IMC) estimate GRFs via machine learning, optimization, or Virtual Pivot Point (VPP) theory [1, 2]. However, existing VPP implementations show limited horizontal force accuracy and lack hardware flexibility. We present a two-tier trust framework with improved CoP estimation and solver, balancing portability against consistency while supporting real-time (MVN-Live) and post-processing (MVN-HD) analysis.

Methods

We validated using Wang et al. dataset's [3]: Xsens Link, Moticon insoles, and instrumented treadmill reference from 8 healthy adults across six walking speeds (0.9–5.4 km/h) and dynamic tasks (jump, land, lunge). VPP was positioned at 0.5×Body Height above center of mass per sensitivity analyses [2]. Tier 1 (IMU-only, 5/8 participants) estimates CoP from the biomechanical model; Tier 2 (IMU+Insoles, all 8 participants) incorporates direct CoP measurement. Each tier supports Live (NNLS) and post-processing (quadratic programming). Accuracy: assessed via Pearson's correlation (ρ) and RMSE (%BW).

Results

MVN-HD consistently outperformed MVN-Live across all tasks. For walking, MVN-HD achieved minimum RMSE of 0.8–6.1% BW across force components (ρ=0.8–0.99) (Table 1). For dynamic tasks, MVN-HD reduced vertical RMSE by 10 percentage points with improved correlations.

Tier 1 HD matched Tier 2 accuracy; Tier 2 enabled validation on all participants through consistent contact detection; though insole hysteresis ranked Tier 2 Live below Tier 1 Live.

Discussion

MVN-HD remained within clinically meaningful thresholds [4]; MVN-Live offers real-time feedback. Compared to Castellaz et al. [1], MVN-HD reduced vertical RMSE by 10 percentage points for walking, with improved horizontal accuracy. Tier 1 maximizes portability; Tier 2 maximizes consistency, whose accuracy depends on insole quality. This framework offers unperturbed GRF profiling in real-life scenarios for rehabilitation and monitoring, with future validation planned for Activities of Daily Living.

Speed-Dependent Changes in Human Neuromotor Control Priorities During Walking

Mr. Ehsan Tahvilian, Dr. Arash Arami PhD

University of Waterloo, Waterloo, Ontario, Canada

Mr. Ehsan Tahvilian

Introduction

Human walking can be modeled using optimal control frameworks, where movement emerges from balancing multiple objectives such as stability, effort, and smoothness. Inverse optimal control (IOC) seeks to infer these objectives by estimating cost weights that reproduce observed gait patterns. However, IOC solutions are not unique, and small differences in tracking accuracy can produce different weight estimates. Here, we examine how inferred neuromotor priorities change with walking speed while accounting for ambiguity across equally valid IOC solutions.

Methods

Ten healthy adults walked on a split-belt treadmill at five speeds between 0.4 and 1.2 m/s. For each participant and speed, inverse optimal control (IOC) was run for multiple iterations, and five normalized RMSE values were computed for hip, knee, and ankle angles, as well as horizontal and vertical ground reaction forces. Each solution was represented in a five-dimensional error space, and the first Pareto front was identified. The space was divided into 0.05-wide bins, and Pareto solutions were ranked by their distance to an ideal point defined by minimum errors. All solutions within the best bin were treated as equally good fits. To assess speed effects, 1000 bootstrap samples were generated, and linear models were used to test weight-speed relationships.

Results

Three IOC weights showed clear and consistent relationships with walking speed across bootstrap samples. The CoM acceleration weight decreased with speed in 100% of iterations (linear trend, $p<0.05$), indicating reduced emphasis on regulating body acceleration at higher speeds. The foot-sliding weight increased in 95.8% of iterations ($p<0.05$) and showed a mild but significant quadratic pattern, with higher-order models improving fit ($p=0.014$). The stability-related weight increased in 100% of bootstrap fits

($p<0.05$), suggesting greater balance demands with speed. In contrast, the torso-orientation weight showed a significant trend in only 21.6% of cases ($p>0.05$), indicating no reliable speed dependence.

Discussion

As walking speed increases, neuromotor control priorities shift systematically. Reduced emphasis on CoM acceleration suggests looser regulation of body dynamics, while increased weighting of foot sliding and stability reflects greater demands for secure contact and balance. In contrast, torso orientation shows no consistent speed-dependent change.

ISC3D: A Toolbox for Generalized 3D Transformation From Anatomical to Elevation Angles for Intersegmental Coordination Analysis

Mr. Elad Siman Tov, Dr. Nili Krausz

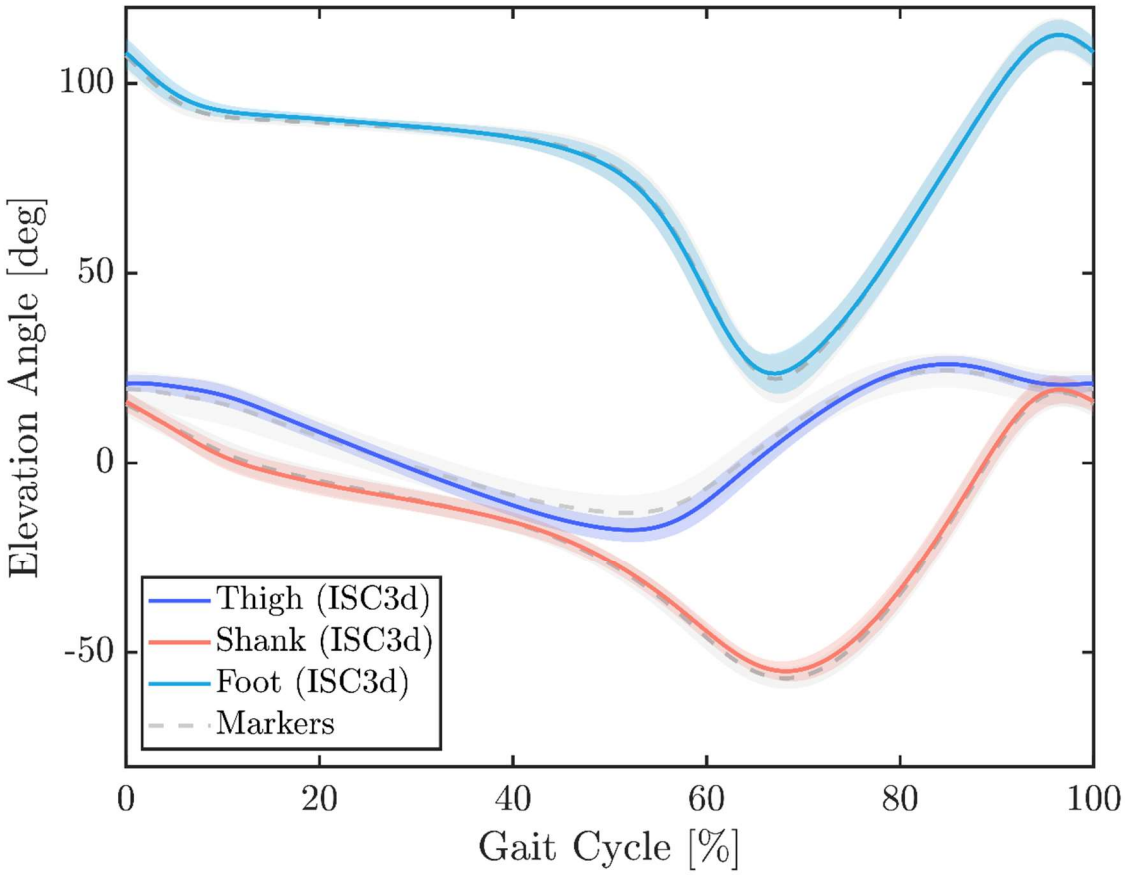
Technion, Haifa, Israel, Israel

Introduction

It is standard to present kinematic data with joint angles. However, elevation angles (measured from the global vertical axis) may reveal attributes of human motion not evident from joint angles alone. An important finding [1], is that the elevation angles of the thigh, shank, and foot in the sagittal plane form trajectories that lie on a Covariation Plane (CVP). Known as the Law of Intersegmental Coordination (ISC), this phenomenon was observed across gaits, speeds, and inclines. However, few biomechanics studies report elevation angles, and until now elevation angles had to be computed directly from surface markers. This challenges computation, bypassing established motion capture software and standard anatomical joint angle definitions, and limiting meta-analyses. To bridge these gaps, we developed ISC3d, an algorithm that directly transforms from joint angles to streamline 3D elevation angle computation. Our algorithm and code can be accessed online (https://www.mathworks.com/matlabcentral/fileexchange/182726-isc3d).

Methods

Elevation angles were reconstructed by multiplying joint angle rotation matrices with corresponding segment rotation matrices. Reference frames adhered to ISB standards. ISC3d was validated against a baseline marker-based method for 10 able-bodied (AB) subjects (n=6127 strides) [2]. Agreement between ISC3d and the baseline was quantified using RMSE and squared Pearson correlation (r^2) per segment. Outlier removal was completed using the generalized Extreme Studentized Deviate test.



Results

The angles computed by ISC3d were correlated with the baseline (Thigh: RMSE 4.975 ± 2.121°, r^2=0.977 ± 0.024; Shank: RMSE 2.563 ± 1.163°, r^2 =0.995 ± 0.004; Foot: RMSE 1.853 ± 0.993°, r^2 =0.998 ± 0.002). The thigh elevation angles showed largest deviations between methods, perhaps since standard motion capture systems approximate joint centers. The mean and standard deviation (shaded) angles for a given AB walking condition are shown in Figure 1.

Discussion

This work provides the biomechanics community with a new, faster method for analysis, that achieved elevation angle estimation comparable with results computed from raw marker data. It also opens the door to analyze ISC in previously published datasets that only reported joint angles. Finally, it can shed light on the role of global coordinates in human movement.

How Does Pushing a Cart Affect Spinal Curvature?

M.Sc. Elisa Romero Avila, Mr. Finn Jamros, Prof. Dr. Catherine Disselhorst-Klug

Institute of Rehabilitation and Prevention Engineering, Applied Medical Engineering, RWTH Aachen University, Aachen, NRW, Germany

Introduction

Repetitive manual tasks (e.g. lifting, lowering, pushing, and pulling) are recognized as potential risk factors for back pain and related musculoskeletal disorders. Although the effects of lifting and lowering have been extensively investigated, less research has focused on the biomechanical consequences of pushing and pulling activities. Video rasterstereography provides a validated method for analyzing spinal posture during such tasks by the 3D reconstruction of the spine curvature, and each vertebra's rotation.

The aim of this work is to analyze spinal curvature adaptations when pushing different external loads to simulate a cart pushing task.

Methods

Thirty healthy subjects were asked to push three different load conditions (no load, 80 N, 160 N) while walking on a treadmill at 3 km/h. For analyzing the changes in the spinal curvature, video rasterstereography was considered (DIERS Formetic 4Dmotion, DIERS International GmbH). Reflective markers were placed on the seventh cervical vertebra and on the left and right posterior superior iliac spine to define anatomical reference points. A 3D model of the spine was generated from the rasterstereography data to obtain the per-vertebra angles, as well as spine parameters. These parameters included the kyphotic and lordotic angles, trunk inclination, and kyphosis and lordosis apices.

Results

A significant increase in the trunk inclination was observed as the pushed load increased. Additionally, the kyphotic angle significantly decreased with increasing load, while no changes were observed in the lordotic angle. Analysis of the apices showed that the kyphosis apex significantly increased with increasing loads, while the lordosis apex significantly decreased. These results were supported by the per-vertebra analysis, which showed higher angle gradients between adjacent vertebrae in the loaded pushing condition compared to the no-load condition.

Discussion

The results from this study demonstrate that pushing different loads leads to adaptations in spinal posture. These adaptations include a greater forward inclination of the trunk, changes in the spine curvature in the transition between the thoracic and lumbar spine region and increases in the angle gradients between adjacent vertebrae. Although these adjustments are necessary for executing the task, repetitive performance could have implications in musculoskeletal health.

Gait Biomechanics Phenotypes Reflecting Bilateral Interdependence in Severe Knee Osteoarthritis

Ms Naomi Loughlin[1], Dr Elise Laende[1], Mr Jereme Outerleys[2], Dr Kevin Deluzio[2]

[1]University of Waterloo, Waterloo, Ontario, Canada. [2]Queen's University, Kingston, Ontario, Canada

Introduction

Knee osteoarthritis (OA) is a heterogeneous condition characterized by joint degeneration and altered gait patterns. Traditional radiographic assessments inadequately capture functional diversity, particularly in bilateral OA populations. This study aimed to identify distinct gait-based subgroups among individuals with severe knee OA and explore associations with clinical features, including contralateral knee OA severity.

Methods

Gait kinematics were collected from 153 participants with severe medial knee OA using a Theia markerless motion capture system during a walking task at a self-selected pace. Hierarchical clustering, incorporating gait speed, age, sagittal- and frontal-plane knee angles (principal component (PC) scores from principal component analysis of joint angle waveforms), was applied to identify subgroups. Between-cluster differences in demographics, contralateral knee OA status, and gait parameters were analyzed using ANOVA/Kruskal-Wallis and chi-squared tests ($\alpha = 0.05$).

Results

Two distinct clusters emerged. Cluster 1 (n = 93) exhibited faster gait speed (1.10 m/s) and greater range of sagittal-plane motion with a greater proportion of asymptomatic contralateral knees (28%). Cluster 2 (n = 60) showed slower gait speed (0.81 m/s), reduced flexion-extension patterns and was predominantly female (70%) with more severe contralateral OA (46.7%). Significant inter-cluster differences were observed in gait speed, sagittal-plane PC2 and PC3 scores, sex distribution, and contralateral knee OA severity ($p < 0.05$).

Discussion

Functional heterogeneity exists within radiographically uniform severe knee OA, consistent with literature of gait heterogeneity among OA patients [1]. Cluster 1's faster gait with greater range in flexion-extension suggests preserved function whereas Cluster 2's slower gait and altered flexion-extension pattern associated with stiff-kneed gait suggest greater

impairment. The association of these distinct compensatory gait strategies with contralateral knee OA severity highlights bilateral interdependence [2].

Therefore, gait-based assessment may enhance radiographic OA classification, enabling more personalized diagnostic and intervention strategies. However, the exclusion of lateral knee OA cases limits the generalizability of these findings. Future work should aim to validate the subgroups longitudinally to evaluate their prognostic relevance.

Visual Environment Complexity and Cue Congruency in Virtual Reality: Impact on Gait Parameters in Young Adults

Ms Emily Marino BSc Candidate, Ms. Kristen De Melo MSc, PhD Candidate, Dr. Lori Ann Vallis PhD

University of Guelph, Guelph, Ontario, Canada

Ms Emily Marino

Ms. Kristen De Melo

Introduction

Visual information is critical for guiding safe locomotion, particularly when navigating complex environments or responding to conflicting visual cues [1]. This study used a modified Simon Task paradigm [2] to examine how spatial cues influence gait during visually guided locomotion through two different environments.

Methods

Participants with no history of impaired cognitive function or physical impairments were fitted with retroreflective markers (OptiTrack, 100 Hz; Corvallis, USA) and instructed to walk through two distinct virtual reality (VR) environments (forest vs. hallway), wearing a VR headset (HTC Vive Pro 2) while avoiding a virtual sinkhole. The direction of transient changes around the sinkhole were cued by arrows that appeared at the top of the virtual scene in one of three locations: congruent (e.g. leftward arrow on left side of screen), incongruent (e.g., leftward arrow on right side of screen) or neutral (center of the screen). It is hypothesized that more complex environments (forest) and incongruent location cues would result in more cautious gait patterns, e.g. greater step width, reduced velocity and increased time to leading edge of the sinkhole. ANOVA statistical analyses were conducted in SPPSS (Version 30).

Results

Preliminary analyses (n=3; 2M, age 22.3 ± 4.93) revealed no statistically significant differences ($p>0.05$) for either environment or cue location conditions for the gait parameters explored to date, however, study recruitment and data processing is ongoing.

Discussion

If these preliminary results do not change, it would indicate that young adults are able to integrate and interpret complex spatial visual cues and safely negotiate intricate environments with minimal disruption in ongoing gait patterns [2]. When complete, study findings will contribute to our knowledge of how visual complexity and cue congruency influence gait during VR-based navigation tasks; this information is critical for future studies involving special populations, e.g. older adults who may struggle with maintaining dynamic balance during similar locomotor tasks.

High Ground Reaction Forces Decrease Metatarsal Bone Strength in Runners

Ms. Emma Slavin[1], Ms. Julia Nicolescu[1], Dr. Adam Tenforde[2], Dr. Irene Davis[3], Dr. Karen Troy[1]

[1]Worcester Polytechnic Institute, Worcester, MA, United States. [2]Spaulding Rehabilitation Hospital, Charlestown, MA, United States. [3]University of South Florida, Tampa, FL, United States

Introduction

The metatarsals are a frequent site for bone stress injuries (BSIs), a common overuse injury in runners. Ground reaction forces load the metatarsals during running, creating metatarsal strain and stimulating bone remodeling. Remodeling facilitates bone adaptation and strengthening [1]. We hypothesized that increased vertical ground reaction forces (vGRFs) during running would be associated with improved metatarsal structure.

Methods

Participants included six healthy females (age: 20.8 ± 1.6) running ≥24 kilometers/week. Gait mechanics were collected using a ten-camera motion capture system (Vicon) while the participants ran barefoot with a forefoot strike pattern across two force platforms (AMTI) at 2.65 m/s. vGRF data were processed and normalized to body weight to identify peak vGRF during stance. High-resolution quantitative computed tomography (Scanco) images were analyzed to assess right 2nd metatarsal macrostructure. Pearson's correlations were calculated between peak vGRF and bone strength and quality measurements. Due to our small sample size, $r \geq 0.81$ were significant ($p \leq 0.05$), and $r \geq 0.7$ were considered potentially important.

Results

Peak vGRF was negatively correlated with numerous metatarsal macrostructural properties, including metatarsal principal and polar moments of inertia (Figure 1; $r = \leq -0.92$), bone mineral content, bending strength index, cross-sectional area, compressive strength index ($r = -0.84$), and bone volume ($r = -0.87$).

Discussion

The hypothesis that increased vGRFs during running would be associated with improved metatarsal structure was not supported. Runners who experienced greater vGRFs had smaller, weaker metatarsals. These results suggest that high loading magnitudes may reduce the metatarsal's ability to remodel and strengthen in response to load. Bone

remodels in response to high loading magnitudes and rates [2], and excessive turnover could impair adaptations like increased strength. Alternately, high vGRF could indicate poor running biomechanics. A combination of low bone strength and high vGRF may increase an athlete's risk for BSI.

Sex Differences in Collegiate Cross-Country Runners' Gait Patterns Across Different Treadmill Speeds

Dr. Eric Foch[1], Dr. Richard Brindle[2], Dr. Kevin Foch[3]

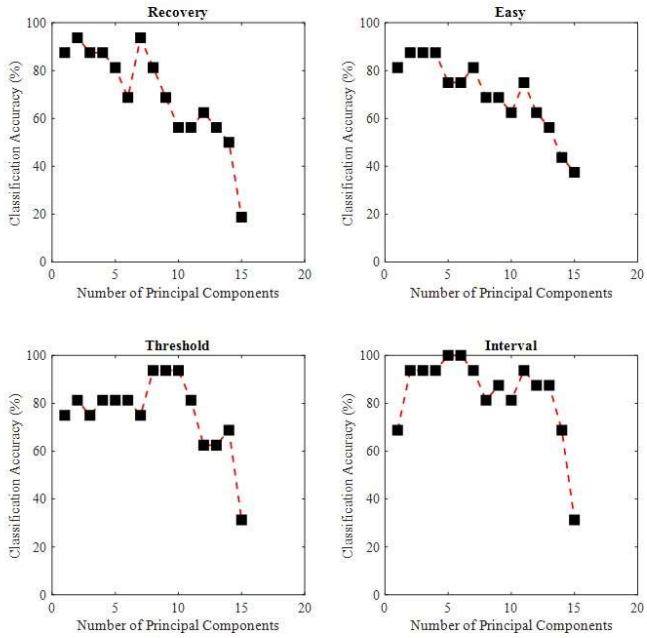
[1]Central Washington University, Ellensburg, WA, United States. [2]Shaw Sports Turf, Shaw Industries Group, Inc., Dalton, GA, United States. [3]High Point University, High Point, NC, United States

Introduction

To determine biomechanical differences between female and male runners, principal components analysis (PCA) with a support vector machine (SVM) classifier may separate running subgroups. Limited research exists examining running biomechanics between female and male competitive runners across different running speeds. Therefore, the purpose of this study was to determine if PCA with a SVM classifier could separate and classify collegiate female and male cross-country runners based on lower extremity biomechanics during running at different speeds.

Methods

Sixteen healthy collegiate cross-country runners (n = 8 female) participated. Runner's self-selected 'easy' pace was used to determine treadmill speeds for each one-minute condition: recovery, easy, threshold, and interval. Three-dimensional marker coordinates and ground reaction forces were collected and processed. Ankle, knee, and hip joint: angles, angular velocities, and moments were computed. Discrete values were extracted at foot-strike and at maximum during the first 60% of stance. Variables were averaged and combined into separate matrices for PCA. Principal component (PC) scores were rank ordered by effect size (d) and used as input for the linear SVM. Correlation coefficients (r) between top-ranked PCs and standardized discrete variables were calculated.



Results

Accuracy of classifying female and male collegiate cross-country runners ranged from 87.5 - 100% across the four treadmill speed conditions (Figure 1). There were high correlations ($r \geq 0.8$) between PC1 and peak dorsiflexor moment for the recovery and easy conditions. For the threshold condition, there were high correlations for all joints examined (PC1 and dorsiflexor moment, PC2 and peak knee extensor moment, PC4 and peak hip extension angle). Finally, for the interval condition, a high correlation was identified between PC1 and plantarflexion velocity.

Discussion

Sex differences in running biomechanics were found primarily in the sagittal plane which is similar with a previous multivariate biomechanical investigation. With inferential biomechanical investigations, only frontal plane hip and knee differences were reported between healthy female and male runners. Collectively, PCA with a SVM classifier can aid in explaining the complex interaction between lower extremity biomechanics and sex during running that inferential investigations may be missing.

Lower-Limb Joint Kinetics of Turning Gait in Young Adults

Ms. Erin Kreis, Dr. Jun Liu PhD, Dr. Mitchell Tillman PhD, Ms. Zahava Hirsch, Dr. Antonia Zaferiou PhD

Stevens Institute of Technology, Hoboken, New Jersey, United States

Introduction

Approximately 35-45% of steps are a part of turns. However, most studies focus on straight-line gait (SLG) [1]. The purpose of this study was to analyze how lower-limb net joint moments (NJM) are modulated in the "step" turn strategy [2]. We hypothesized that frontal and transverse plane NJM would be modified during turns versus SLG.

Methods

Healthy female young adults (n=7; 20.4 ± 1.13 years) completed 12 SLG and 90-degree left turn trials along a T-shaped intersection. Optical motion capture (Optitrack) and force plates at the intersection (Bertec) were used. Lower-limb internal NJM were calculated during the stance phase contacting the force plates. Turns were classified as "step" turns if the right foot was closest to the center of the intersection [2]. Trials without acceptable force plate contact were excluded. Data from four participants remained for analysis. A two-sided paired-sample t-test was used to evaluate differences in mean peak NJM between SLG and step turns (α=0.05).

Results

Frontal Plane: Turns had a larger peak ankle evertor (p=0.044) and hip adductor (p=0.049) NJM, and smaller peak ankle invertor (p=0.023) NJM than SLG (Fig.1). **Transverse Plane:** Turns had a larger peak ankle (p=0.011) and hip (p=0.003) external rotator NJM, and smaller peak knee external rotator (p=0.006) NJM than SLG (Fig.1).

Discussion

Supporting the hypothesis, young adults modified lower-limb NJM in the frontal and transverse planes during turns. Further analysis indicates differences could be due to frontal plane lean and redirection of the ground reaction force to align with the new direction of travel. Compared to prior work, ankle NJM results exhibited opposite trends, whereas knee and hip NJM were similar [3]. Data collections are ongoing to expand the sample of young and older adults. Further exploration of NJM across cohorts will improve

our understanding of turn strategies and could have implications for osteoarthritis and joint health.

TCN Based Deep Learning Enables Task-Agnostic Ground Reaction Force Estimation Using Wearable Sensors

Mr. Ethan Baird, Mr. Matthew Lerner, Dr. Aaron Young

Georgia Institute of Technology, Atlanta, GA, United States

Mr. Ethan Baird

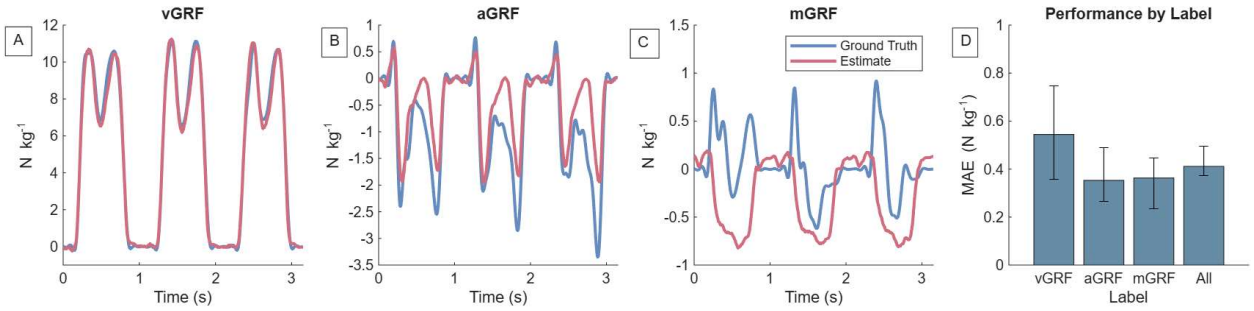
Mr. Matthew Lerner

Introduction

Musculoskeletal biomechanics data provide key insights for development in injury treatment, athletic performance, and disability management. This data relies on the accurate collection of ground reaction force (GRF) data with expensive stationary force plates to make joint-level calculations. Cost effective GRF estimation algorithms [1, 2] make such calculations more accessible with portable and wearable devices, but are limited in their ability to generalize predictions across subjects and tasks. Here, we translate established success in Temporal Convolutional Network (TCN) based task-agnostic joint state estimation [3] to GRF estimation with wearable sensors.

Methods

We trained a TCN on 18 unique tasks from six subjects to estimate full time series GRF: vertical (vGRF), anterior-posterior (aGRF), and mediolateral (mGRF). Features included kinematics measured with a wearable set of lower-limb inertial measurement units (IMU) and kinetics measured with pressure-sensing insoles.



Results

Task-agnostic subject independent vGRF estimation yielded an r^2 of 0.92. Also, the model outperformed many published works in vGRF estimation during level ground walking with an r^2 of 0.98 and a mean absolute error (MAE) of 5.5% bodyweight (BW). Estimation of aGRF showed similar performance to prior works with an MAE of 3.6% BW, but the model failed to accurately track the mGRF trajectory with an MAE of 3.7% BW and an r^2 of 0.32.

Discussion

We demonstrate the feasibility of leveraging TCN-based architecture to attempt task-agnostic GRF estimation using a small dataset. Early success gives us reason to believe that changes to model architecture and size of training data could improve model performance beyond the state of the art for generalizable estimation. Improvements to mGRF estimation performance are especially important to address before this estimator can be applied in the field. One possible change is to incorporate more granular feature mapping in a “CNN-TCN” approach that analyzes a high-resolution time series pressure map of the insole. Such improvements have the potential to increase the accuracy of affordable GRF data collection methods, enabling high quality biomechanics studies in the real world.

Lower-Limb Heat Flux During Walking Shows Site-Dependent Magnitude but Uniform Time Dynamics

Ms Eunbean Yang M.S., Mrs Sukyung Park Ph.D.

Korea Advanced Institute of Science and Technology (KAIST), Daejeon, Daejeon, Korea, Republic of

Ms Eunbean Yang

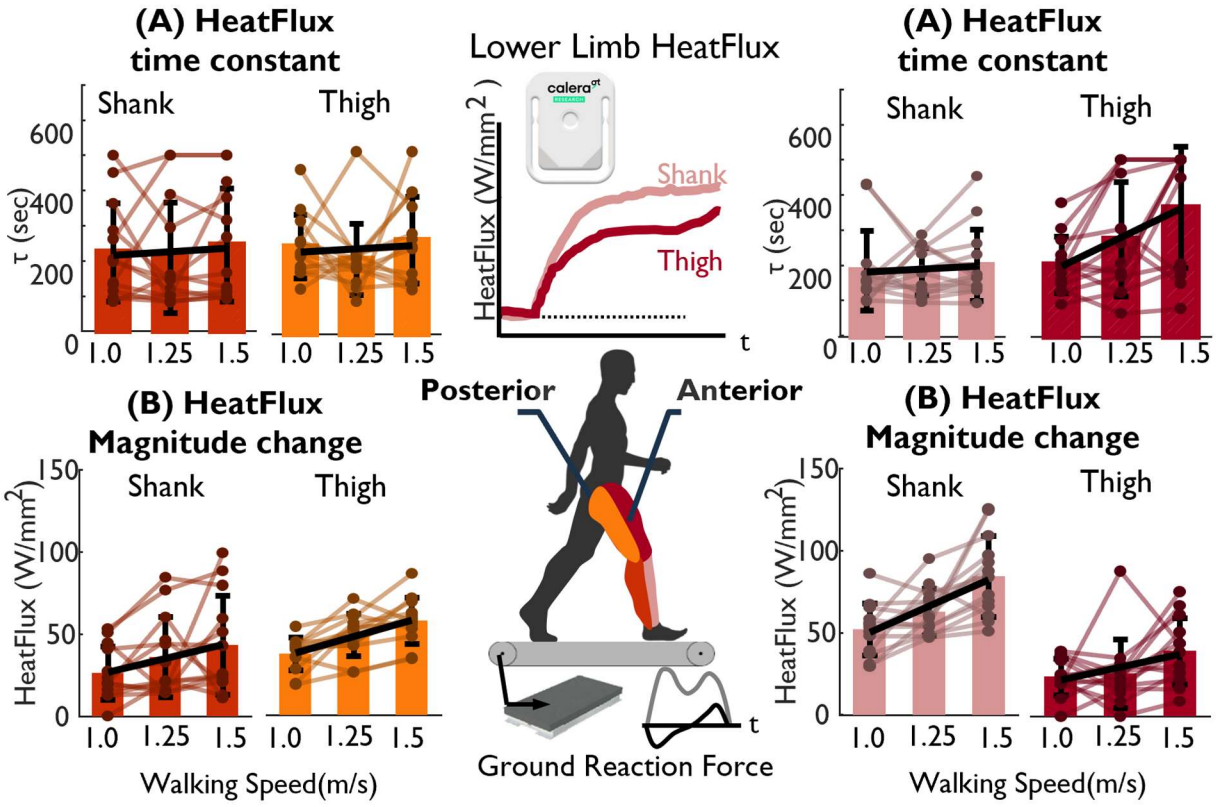
Introduction

Heat generated by muscle contraction during movement constitutes a major component of total energy expenditure. Conventional calorimetry-based methods are limited in applicable exercise modalities and cannot isolate muscle-specific thermal responses[1],[2]. Wearable heat-flux sensors now enable continuous monitoring of localized thermal signals, yet, the dynamic characteristics of lower-limb heat-flux responses during walking have not been systematically quantified. This study aimed to characterize the first-order response dynamics of skin heat flux at multiple lower-limb sites during walking at different speeds.

Methods

Twelve healthy adult males performed treadmill walking for 20 minutes at three speeds (1.0, 1.25, and 1.5 m/s) in randomized order. Skin heat flux was measured at four locations: the anterior and posterior aspects of the thigh and shank. GRF(Ground reaction forces) were measured by force plates. Heat flux signals were fitted to a first-order system response model to estimate the time constant and steady-state increase, and differences across speeds and anatomical sites were analyzed.

Results



Approximately 95% of shank trials exhibited first-order response characteristics, compared to 70% for the thigh. Atypical responses such as continuous increase or superposition of dual first-order responses were observed at the thigh. The time constant remained consistent at approximately 200 seconds across all sites and speeds. Steady-state heat flux increase was significantly greater at higher speeds for all sites ($p<0.05$), with the shank showing approximately twice the magnitude of the thigh. Correlation analysis revealed

significant associations between peak propulsive GRF and heat flux increase at both of the shank (r = 0.62) and thigh (r = 0.45).

Discussion

This study quantified lower-limb skin heat flux dynamics during walking. While time constants were uniform across sites and speeds, steady-state heat flux was higher at the shank and increased with speed, likely reflecting differences in muscle activation and local thermal physiology. Correlations between steady-state increase and peak propulsive GRF suggest that skin heat flux captures mechanical output during locomotion. These findings highlight the potential of wearable heat-flux sensing for monitoring muscle-specific metabolic demand.

Development and Validation of a Force-Based Self-Paced Split-Belt Treadmill to Assess Force and Speed Perception During Walking

Mr. Evan Shrier[1], Dr. Andrew Hooyman PhD, GStat[2], Dr. Natalia Sánchez Aldana PhD[2]

[1]Chapman University, Orange, California, United States. [2]Chapman University, Irvine, California, United States

Introduction

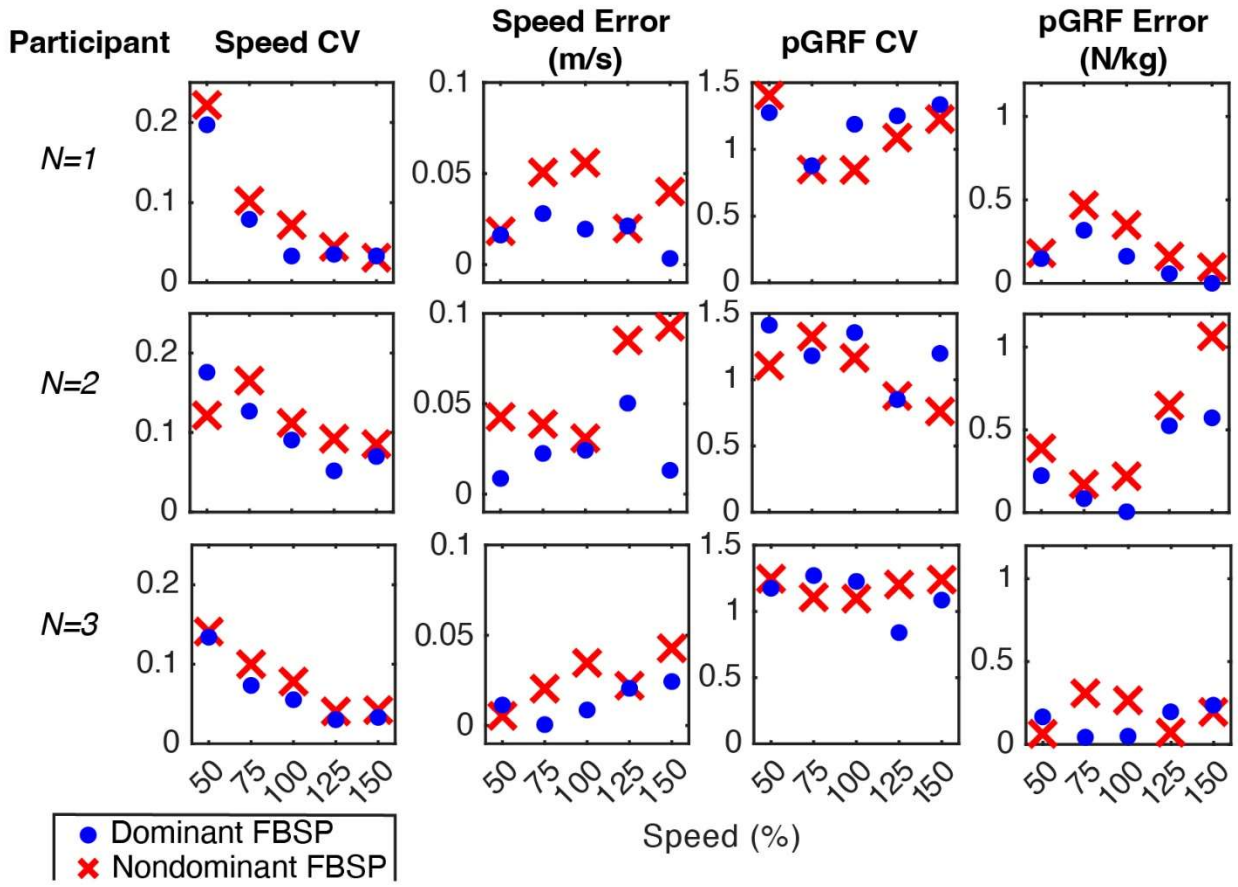
Perception of force and speed during locomotion is fundamental to balance, coordination, and gait adaptation. Humans can perceive inter-limb speed differences [1], critical for coordinating walking patterns following motor perturbations [2]. Perceiving inter-limb force differences enables targeted force production as part of interventions [1]. Speed and applied force vary concurrently [3], suggesting coupling between these variables. Despite their importance, how force and speed are perceived during locomotion remains poorly understood.

Objective: Develop and validate a novel force-based self-paced (FBSP) split-belt treadmill to assess force and speed perception during walking.

Methods

To develop the FBSP system, a dual-belt GRAIL system was programmed with a fixed speed belt while the other was self-paced based on peak propulsive force (pGRF). Participants walked at five speeds (50–150% of self-selected) with either their dominant or non-dominant leg in FBSP mode, for 10 trials of 2.5 minutes. Visual and auditory information from the treadmill was blocked. Participants were instructed to apply force with the self-paced leg to produce a treadmill speed matching the fixed belt. Validation was conducted with N=3 participants (aged 23–40; two female, one male). Speed and pGRF between fixed and FBSP legs were compared using mean and coefficient of variation (CV).

Results



CV of speed difference ranged from 3.01% to 22.2%, showing a J-shaped pattern with greater variability at lower speeds. Speed differences between the FBSP belt and fixed belts ranged from 5.77×10^{-4} to 0.05m/s. Participants matched dominant leg speed with less error (0.017m/s difference) than the non-dominant leg (0.039m/s). No consistent performance pattern was observed across speeds. The CV of pGRF ranged from 76.1% to

141.2%, with differences between FBSP and fixed legs ranging from 2.73×10^{-4} to 1.07N/kg. No consistent effect of dominance was seen for pGRF.

Discussion

Participants perceived inter-limb speed differences during locomotion and were able to generate forces to match speeds between limbs. Preliminary findings show an effect of dominance on task performance. Further testing will assess perception across speeds, ages, and between the dominant and nondominant leg.

Stride Matters: How Crocs Straps Affect Walking Velocity

Dr Fabricio Saucedo Ph.D.

Penn State Altoon, Altoona, PA, United States

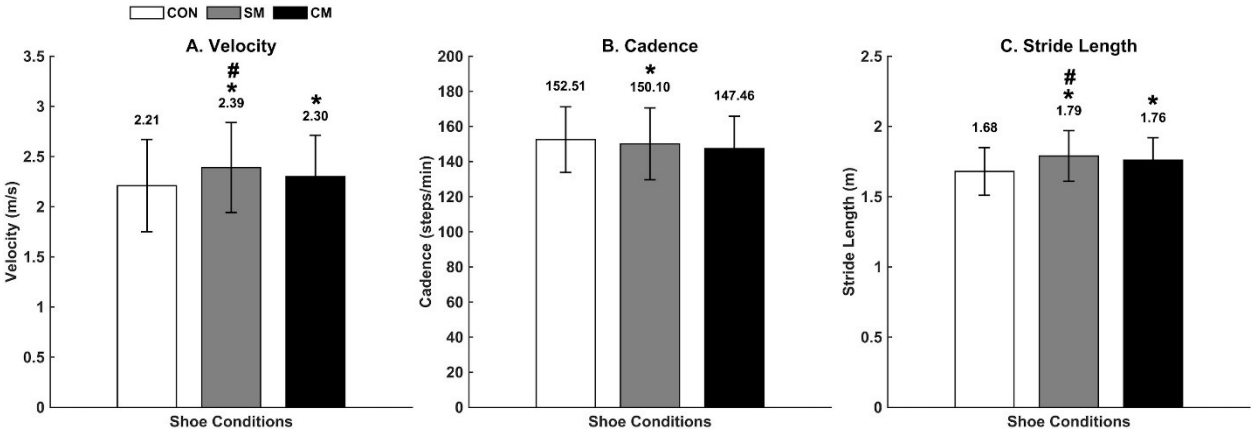
Introduction

Shoes have an impact on health and quality of life. With shoes like the classic clog manufactured by Crocs® being commonplace in the food and medical industry, its significant shift to mainstream markets in recent years begs the question of whether there are benefits or risks associated with wearing this style of shoe, specifically in gait performance. Poor fit and failure to use the heel-strap properly or at all raise concerns about whether shoes like Crocs® are detrimental to walking performance. Despite growing popularity for comfort and convenience, their biomechanical impact on gait remains under-investigated. The purpose was to examine the effect of Crocs® with and without heel-strap on walking performance. We hypothesized that participants would display greater walking velocity when walking with the heel-strap, versus strapless and socked.

Methods

Randomized within-subject design was used with a convenience sample of 31 college-aged adults free of impairments. Seven Xsens MVN Awinda inertial measurement units recording at 120 Hz were used to track participants in three conditions during the timed 10-meter walking test (TMW): (i) Socked (CON): walked in socks (ii) Sports-mode (SM): Walked in Crocs® with the heel-strap, and (iii) Casual-mode (CM): Walked in Crocs® without the heel-strap. Gait events, including foot strike and toe-off, were defined by detection algorithms in the Xsens MVN Software and were used to calculate spatial and temporal parameters.

Results



Both shod conditions resulted in improved velocity and stride length compared to the control condition. The sports-mode configuration significantly improved walking velocity and stride length compared both CM and CON conditions while walking.

Discussion

The hypothesis that participants would display better walking velocity during gait assessments while walking in Crocs® with the heel-strap, compared to walking without the

heel-strap or socked (CON) was supported. Study findings suggest that adopting footwear with a heel-strap might improve walking performance compared to a strapless option. Although further study is necessary to determine clinical significance, current findings indicate that wearing Crocs® in the SM configuration might be preferable for individuals requiring longer durations on feet and walking. Additionally, older adults or others with mobility challenges, might benefit from the more secure fit.

The Influence of Sport Specialization on Movement Coordination in Female Athletes Participating in Hip-Risk Sports

Ms. Fang-Yu Syu PT, Prof. Cara Lewis PT, PhD, FAPTA

Boston University, Boston, MA, United States

Introduction

Sport specialization - intense, nearly year-round participation in a single sport - is strongly associated with lower extremity overuse injuries, particularly in female athletes participating in hip-risk sports (e.g., soccer, ice hockey, and running).

Movement coordination variability, defined as the consistency of the spatiotemporal relationship between joints, is linked to overuse injury risk. While altered knee coordination has been reported in specialized athletes during sport-specific tasks, the relationship between specialization and pelvic-thigh variability during fundamental movement tasks (e.g., walking) remains unexplored.

The purpose of this study was to investigate the relationship between levels of specialization and pelvic-thigh coordination during walking in female athletes participating in hip-risk sports.

Methods

A three-question survey was used to determine specialization level (high=3 points, low ≤ 1 point). Eight high-specialized and six low-specialized female athletes were included in this preliminary analysis. Kinematic data were collected using a motion capture system while participants walked for two minutes at a self-selected speed. Pelvic and thigh angle were processed in Visual3D.

Intersegmental coordination angles were quantified using a vector coding technique, where the coupling angle was defined as the vector orientation between adjacent points on the angle-angle plot relative to the right horizontal. Coordination variability was calculated as the circular standard deviation of the coupling angle across gait cycles. To assess phase-specific differences, coordination variability was averaged within each phase (loading response, mid-stance, terminal stance, and pre-swing).

Given the preliminary nature of the study and limited sample size, the magnitude of group differences was assessed using Cohen’s d effect sizes, interpreted as small/medium/large (0.2/0.5/0.8).

Results

High specialized athletes demonstrated substantially greater coupling angle variability in the transverse plane during loading response (d=1.01). Moderate effects (d>0.5) were also found during loading response and pre-swing (sagittal plane), mid-stance (frontal plane), and terminal stance and pre-swing (transverse plane). (Table 1)

Discussion

Greater pelvic-thigh coupling angle variability across all comparisons in the high specialized group suggests that specialization may be associated with more variable movement control during fundamental movement tasks. Thus, increased movement coordination variability may contribute to elevated overuse-injury risk in female athletes specializing in hip-risk sports.

Gait Responses to a Bout of Activity in Older Adults With and Without Knee Osteoarthritis

Ms. Fany Alvarado, Ms. Kathleen Downs, Ms. Millissia Murro, Ms. Nancy Nguyen, Ms. Mayumi Wagatsuma, Ms. Grace Kellaher, Dr. Jeremy Crenshaw, Dr. Jocelyn Hafer

University of Delaware, Newark, Delaware, United States

Introduction

Individuals with knee osteoarthritis (OA) have different gait mechanics compared to asymptomatic older adults. Adults with knee OA may also experience more fatigue than their healthy counterparts, potentially leading to additional gait changes. However, to our knowledge, the differences in gait between individuals with knee OA and healthy older adults under fatigue conditions have not been studied. The purpose of this study was to determine if changes in gait in response to a bout of activity differ between older adults with and without knee OA.

Methods

Nine older adults with (63.8±3.0 years) and ten without knee OA (63.5±3.3 years) walked on an instrumented treadmill for 34 minutes at self-selected speed (healthy: 1.5±0.2 m/s; OA: 1.4±0.1 m/s) with three one-minute challenge periods (50% speed increase), and underwent knee extensor dynamometer testing before and after the walk to assess muscle fatigue. A standard six-degree-of-freedom marker set was used for motion capture, and the first and last minute of the 34-minute walk were analyzed. Outcome measures included lower extremity peak sagittal and frontal joint moments and sagittal joint angles. A two-way ANOVA was used to compare gait mechanics between groups (with knee OA and without) and timepoints (pre and post 34-minute walk; α=0.05).

Results

Knee extensor muscle power decreased similarly after the 34-minute walk in both groups (without knee OA: -2.8±20.0%, with knee OA: -10.3±19.3%, p=0.2). The gait of older adults with and without knee OA did not change differently in response to the 34-minute walk (i.e., no significant interaction effects, p-values = 0.27-0.97;Figure 1). Additionally, there were no significant differences between groups or timepoints for any outcome variables (p-values = 0.17-0.94).

Discussion

Older adults with and without knee OA did not respond differently to a 34-minute walk. In contrast to previous (albeit limited) literature, our knee OA and no knee OA cohorts fatigued to a similar extent. The limited fatigue levels and corresponding lack of changes in gait may indicate that participants in both groups were relatively high-functioning. Future research may test whether adults with more severe knee OA would also respond similarly to their asymptomatic counterparts.

Comparison of Motion Capture and Pedobarography in Calculating Foot Progression Angle for Children Undergoing Clinical Gait Analysis

Miss Farah Azim BASc[1], Miss Scarlett Farrar[1,2], Ms Diane Wickenheiser BScPT[1], Ms Karen Davies MSc[1,3], Dr Lise Leveille MD, PhD[1,4,5], Dr Timothy Bhatnagar PhD[1,4,5]

[1]The Motion Lab at BC Children's Hospital, Vancouver, BC, Canada. [2]School of Biomedical Engineering, UBC, Vancouver, BC, Canada. [3]Dept of Physical Therapy, UBC, Vancouver, BC, Canada. [4]BC Children's Research Institute, Vancouver, BC, Canada. [5]Dept of Orthopedics, UBC, Vancouver, BC, Canada

Introduction

The Motion Lab (TML), BC Children's Hospital conducts clinical gait analysis (CGA) using motion capture (MoCap) for gait biomechanics and pedobarography to analyze foot pressure distribution. CGA informs decision-making for surgical/orthotic interventions. If a child cannot tolerate marker placement (hypersensitivity, cognitive challenges), only video and pedobarography are collected. Both marker-based MoCap and pedobarography calculate foot progression angle (FPA). TML is interested in comparing FPA between methods to ensure that for children who cannot tolerate markers, pedobarography's calculation of FPA is consistent with MoCap. This study will compare the FPA calculated using MoCap and pedobarography.

Methods

Thirteen participants were identified in this non-randomized cross-sectional study with a referral requesting assessment of rotational profile; both MoCap and pedobarography were collected. Physiotherapists completed a physical exam and placed markers according to the Helen Hayes marker set [1] and modified Shriners Hospital for Children Greenville multi-segment foot [2,3]. Participants completed five gait cycles and walked across the pedobarography platform, aiming for three foot-strikes per side. TML uses Qualisys MoCap system and novel emed platform for pedobarography. MoCap was processed in QTM and Visual3D. FPA was calculated as the angle between the vector from the heel to toe marker in relation to the lab, averaged across five trials. Pedobarography was processed in novel's software, which averaged FPA from three trials. Average FPA from both datasets were compared, alongside physical exam values (hip rotations, thigh/foot angles, transmalleolar angles). The right/left sides were combined.

Results

Mean difference in FPA between methods was 3.88° (SD=3.04°, range=0.15°-10.71°) across participants (mean=13.5y, 4 females), with pedobarography calculating lower FPA. Both methods measured FPA in the same direction (external/internal). Mean hip external rotation was 35° (SD=15°); hip internal rotation was 58° (SD=17°); thigh/foot angle was 15° external (SD=17°); and transmalleolar angle was 26° external (SD=10°).

Discussion

Findings show minimal differences in FPA calculated by both methods, as TML's standard of error is 3°. Future analysis will explore relationships between physical exam and FPA differences and include additional participants.

Hip Extensor EMG Frequency Patterns During Speed Increase in Stepping Tasks With Controlled Stride Parameters

Br Florencia Delfino[1], PhD Germán Pequera[1,2], PhD Carlo Biancardi[1]

[1]LIBiAM Biomechanics Lab, Dep. of Biological Sciences, CENUR Litoral Norte, Universidad de la República, Paysandú, Paysandú, Uruguay. [2]Departamento de Ingeniería Biológica, CENUR Litoral Norte, Universidad de la República, Paysandú, Paysandú, Uruguay

Br Florencia Delfino

PhD Germán Pequera

Introduction

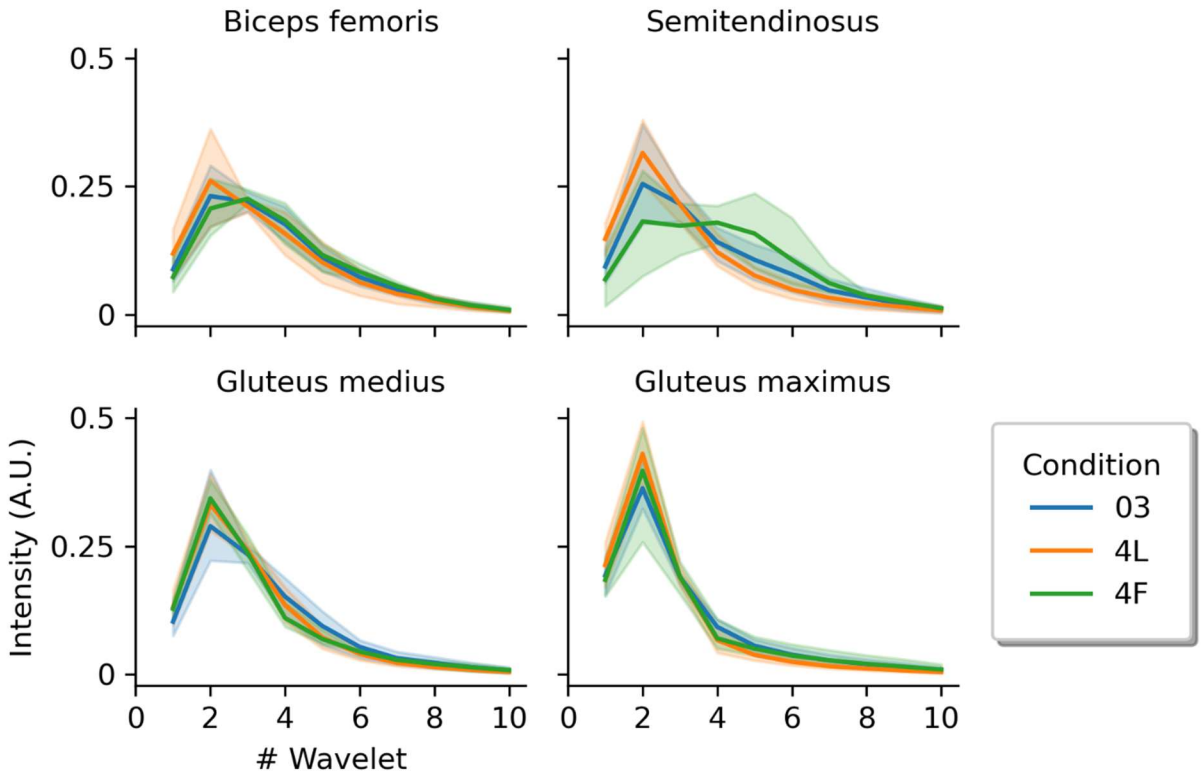
Gait speed is used to evaluate health condition [1]. When speed increases, step frequency (F) and step length (L) increase simultaneously. The impact on muscle function of modifying F or L independently during speed augmentation has yet to be studied [2]. Knowing how adaptations work in these conditions is important for numerous applications. The objective of this ongoing research is to evaluate muscle function when legs are oscillating at different speeds by controlling F and L independently, using an airwalker as a stepping device.

Methods

Five subjects participated in three trials on an airwalker combining different target step lengths (tL) and target step frequencies (tF) to achieve two target speeds (tV), since tV = tL x tF. The University Ethics Committee approved this study. The objective was to increase speed by modifying one spatiotemporal parameter at a time. Inextensible cords linked to the airwalker platforms were used to control tL, while tF was set using an audible metronome. Trials were:

- tF=1.5Hz, tL = 0.55m achieving 3 km/h (03);
- tF = 1.5Hz, tL = 0.74m achieving 4km/h (4L);
- tF = 2.05Hz, tL = 0.55m achieving 4km/h (4F);

Data from both fifth metatarsals was registered at 100Hz (10 Vicon cameras). Electromyography (EMG) of 4 hip extensor muscles (Biceps femoris, Semitendinosus, Gluteus medius and Gluteus maximus) were collected at 2000 Hz (Delsys Trigno). F, L and velocity were calculated to validate the protocol. EMG frequency distribution (FreqDist) was estimated for each trial [3].



Results

Hip extensors showed different behaviors when comparing FreqDist. The most noteworthy result was observed in Semitendinosus muscle. Speed increased by L or by F modulation caused opposite changes of FreqDist. More data is needed to confirm these trends.

Discussion

Despite sharing function, hip extensors displayed different FreqDist response. F or L driven speed changes caused FreqDist shifts towards higher or lower frequency, respectively in Semitendinosus. This could indicate changes in fiber types recruitment, positioning this muscle as an important modulator of spatiotemporal parameters.

Higher Frictional Internal Work During Limb Swing in Class III Obese Adults

Dr Gaspare Pavei[1], Dr Valentina Natalucci[1], Prof Alberto Minetti[1], Dr Luca Ruggiero[2], Prof Davide Malatesta[3]

[1]University of Milan, Milan, Italy, Italy. [2]University of Konstanz, Konstanz, Germany, Germany. [3]University of Lausanne, Lausanne, Switzerland, Switzerland

Introduction

Obese class III adults [body mass index (BMI) >40 kg/m^2] showed a higher metabolic cost than lean counterparts (BMI<25 kg/m^2) [1] when walking at all speeds. The mechanical work to move the center of mass is lower in obese class III adults than lean counterparts, with no between-group differences in the work to swing the limbs [1]. Hence, the reason for the higher metabolic cost in obese class III adults is unknown. Along with the 'classical' mechanical work approach, an additional component to overcome limb friction when swinging (frictional internal work) has been recently proposed [2]. Given the higher mass of proximal segments within limbs [1], we hypothesized that obese adults would have a higher frictional work than their lean counterparts.

Methods

The lower and upper dominant limbs of 13 obese class III adults (4 female) were swung passively from an initial position of ~30° flexion, while 2D kinematics (120 Hz) was recorded. The oscillating limb was treated as a second-order pendular system with viscous damping (linear to velocity). Five trials were recorded, each yielding a damping constant. Average values were used to calculate frictional internal work [2], using spatiotemporal parameters of obese walking adults [1], and were compared with lean adults [2].

Results

In the upper limb, the damping constant was 0.52±0.19 and 0.37±0.08 Nm·s/rad in obese and lean adults, respectively. The damping constant of the lower limb was almost twice in obese than lean adults, 4.14±2.41 vs. 2.24±0.55 Nm·s/rad. These values in obese adults yielded an average frictional internal work about 30% higher than lean adults.

Discussion

The higher frictional internal work to swing limbs in obese relative to lean adults may contribute to explaining the extra metabolic cost in walking [1]. Thus, frictional internal work represents a promising parameter to be considered in future research addressing differences in locomotion between obese class III and lean adults.

Skipping vs Running Along Circular Paths: Which Is Better?

Master student Elsa Josefa Gonzalez Heit[1], PhD Valentina Silva-Pereyra[1], Master student Vanessa Yelós Tellagorry[2], PhD Gaspare Pavei[3], PhD Germán Pequera[2,1], PhD Carlo Massimo Biancardi[1]

[1]LIBiAM Biomechanics Lab, Dep. of Biological Sciences, CENUR Litoral Norte, Universidad de la República, Paysandú, Paysandú, Uruguay. [2]Departamento de Ingeniería Biológica, CENUR Litoral norte, Universidad de la República, Paysandú, Paysandú, Uruguay. [3]Physiomechanics Lab, DFPMCT, University of Milan, Milan, Lombardy, Italy

Introduction

Skipping, or bipedal gallop, is a bouncing asymmetrical gait, which cycle begins with the trailing foot strike, followed by the leading and a final, unsupported, ballistic phase. Unlike cursorial quadrupeds, humans occasionally or in specific conditions skip. Our research aims to investigate the potential advantages of skipping during asymmetric locomotor tasks, such as moving along circular paths.

Methods

Participants were asked to perform three trials along a circular path of radius 3 m: 1) Unilateral skipping with inner leading (Sk_I); 2) same with outer leading (Sk_O); 3) running (R). Auditive feedback was provided to maintain a constant stride frequency of 1.5 Hz. Ethics Committee approved the project.

Metabolic baseline was obtained during 5' upright standing before the trials, and subtracted from the average VO2 of the last minute of each trial (K5, Cosmed, Italy). The cost of transport (CT) was computed using the RER energetic equivalent. Speed was obtained by analysing videos (60 Hz).

Vertical ground reaction forces were measured with instrumented insoles (Loadsol_pro, Novel, Germany). Data were filtered (4th order zero-lag Butterworth LPF, 15 Hz cut-off). Gait events were identified using a 20N threshold. Duty factor (DF), peak vertical force and asymmetry indices were computed.

Results

The preliminary results are shown in table 1. The CT was averaged over a range of speed from 1.7 to 2.4 ms^{-1} (N=8). We have obtained kinetic data from a single subject so far. Therefore, DF and peak forces, averaged over 300 strides per condition, represent a within-subject stride variability.

Discussion

The CT was 25% higher in circular compared to linear running. Skipping did not show a similar trend, nor differences between inner and outer leading.

Preliminary single-subject kinetic data indicate a trend toward a reduction of stance asymmetry in both skipping modes, compared to linear skipping. In running, the slightly increased DF of the outer foot, if confirmed, could underline a load-mitigating strategy that counteracts the increase of the outer peak GRF and the rise in force asymmetry during circular running.

Although the metabolic cost remains high, skipping could present pros during asymmetric tasks like circular locomotion.

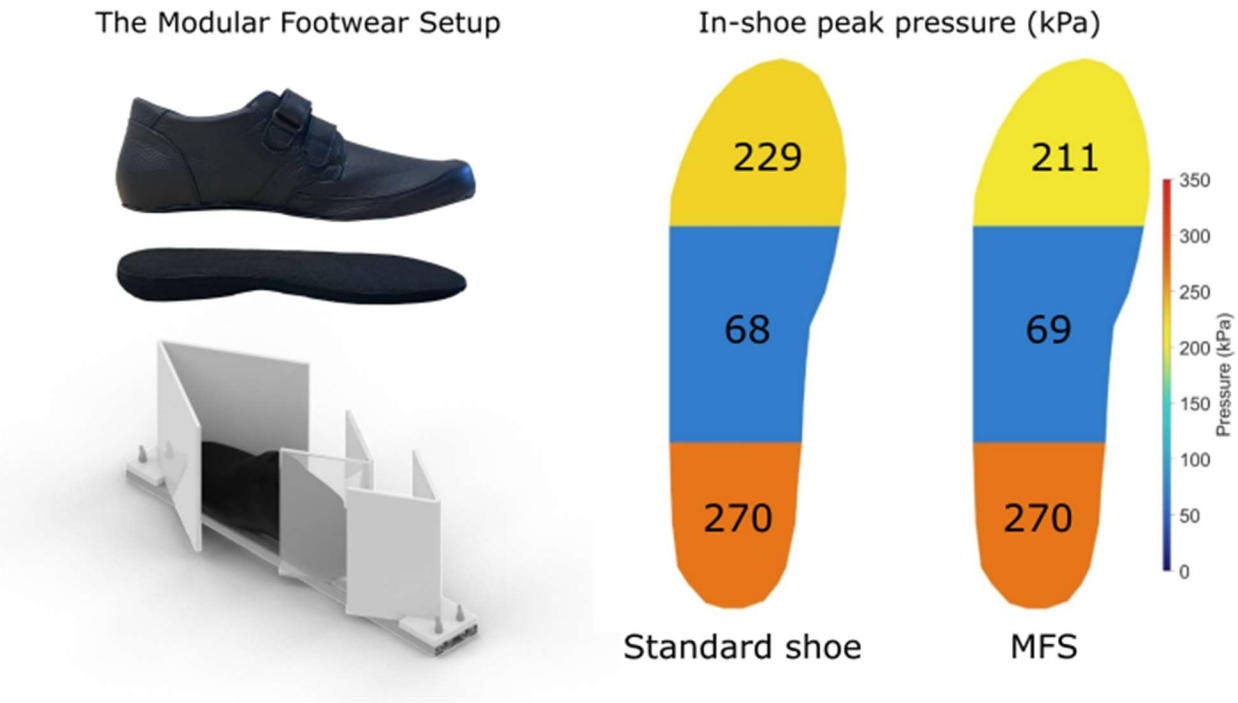
PhD Paolo Caravaggi

Introduction

Therapeutic footwear, often combined with insoles, is crucial for managing foot pathologies, particularly in preventing diabetic foot ulcers [1]. While various diabetic shoe designs exist, there is limited evidence on the isolated effects of midsole shape and material on lower limb kinematics and plantar pressure distribution. This study aimed to design and validate a novel, modular tool capable of assessing the isolated effect of different midsole designs and materials on relevant lower limb biomechanical parameters.

Methods

A Modular Footwear Setup (MFS) was developed, comprising a comfortable flexible upper (figure, top left), a micro-hook-and-loop-fastener layer and interchangeable midsoles (Vibram). A custom 3D-printed alignment device was designed for accurate and repeatable midsole attachment (figure, bottom left). The upper was manufactured in five sizes (EU 37-45) replicating those of a standard diabetic shoe (Botero, Podartis). Ten healthy subjects (5M, 5F; age=33±9 yrs) were asked to walk in two shod conditions: wearing the standard diabetic shoe and wearing the MFS fitted with an identical midsole. In-shoe plantar pressure was recorded using 99-sensor pressure insoles (Pedar, Novel) at 100 Hz. Lower limb kinematics were captured using seven IMU sensors (Ultium Motion, Noraxon) on the pelvis and lower limb segments. Five gait cycles were recorded per subject and per condition. The non-parametric paired Wilcoxon signed-rank test was used to compare pressure and kinematic data between the two conditions.



Results

Subjects maintained a consistent walking speed between the two shoe conditions ($p>0.05$). The MFS showed no significant differences in the sagittal-plane range of motion for the hip, knee, and ankle joints when compared to the standard diabetic shoe ($p>0.05$). Similarly, there were no significant differences in mean and peak plantar pressures at the forefoot, midfoot, and rearfoot regions (figure, right).

Discussion

The MFS tool appears capable of reliably replicating the kinematic and in-shoe pressure outcomes of a standard therapeutic shoe. These results suggest the MFS has the potential to be a useful and repeatable tool for testing the isolated biomechanical effects of various midsole designs and materials in large-scale clinical trials and for developing novel offloading therapeutic footwear.

Muscle Coordination Is More Complex In Older Adults When Walking In Real-World Conditions Versus Laboratory Conditions and Associated With Clinical Gait and Balance Scores

Mr. Grant Maddox, Mr. Reece Lawrence, Ms. Kaitlyn Downer, Dr. Jessica Allen PhD

University of Florida, Gainesville, Florida, United States

Introduction

Proper muscle coordination is essential to prevent falls while walking. While indoor straight-line walking is commonly used to assess muscle coordination complexity, it is not fully representative of the diverse range of tasks faced during real-world walking. We hypothesize that (1) muscle coordination complexity would be greater when walking in real-world settings (i.e., outdoors) than in indoor laboratory settings. Because muscle coordination complexity likely reflects underlying gait and balance capacity, we hypothesize (2) complexity would correlate with clinical gait and balance scores, and (3) correlations would be larger in outdoor walking due to higher demands. Such links may indicate that more complex environments are needed to reveal deficits in muscle coordination underlying impaired walking balance.

Methods

Seventeen older adults (76.59±5.4 years) walked at preferred speed under two conditions: laboratory-based 20-meter overground walk and an outdoor route incorporating ramps, stairs, and turning. Surface electromyography was recorded from twelve right-leg hip, knee, and ankle muscles. Muscle coordination complexity was quantified as variability not explained by one motor module (VNAF1)[1]. A paired t-test was used to identify if outdoor walking is more complex than indoor walking. We performed Pearson's correlation between each measure of complexity and four clinical test scores (Fig.1B). Steiger's z-tests were used to identify if there was a significant difference in outdoor vs. indoor correlations.

Results

Muscle coordination was more complex when walking outdoors versus indoors ($p=0.005$; Fig.1A). Although we found moderate to strong correlations between clinical tests and muscle coordination complexity in indoor ($r=0.30$-0.46) and outdoor walking ($r=0.24$–0.57), no significant differences between conditions were identified ($p=0.21$–0.73; Fig.1B).

Discussion

Outdoor walking elicited greater muscle coordination complexity, indicating higher coordination demands in real-world movement than in straight-line walking. This reinforces the importance of examining broader range of walking conditions when evaluating balance capacity. Both indoor walking and outdoor walking have similar correlations with clinical tests, suggesting that coordination complexity is likely related to gait and balance function. Future work will examine to what extent indoor vs. outdoor muscle coordination complexity relates to real-world falls, providing insight into its potential clinical relevance.

Images (Optional)

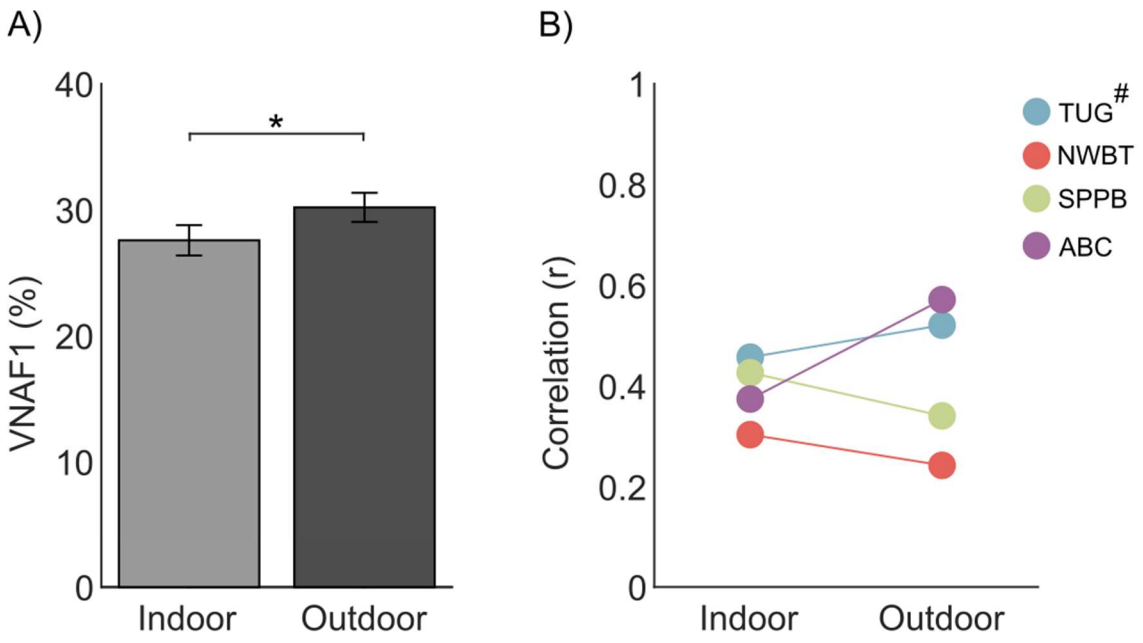

Figure 1: A) Paired t-test to evaluate the difference between indoor and outdoor muscle coordination complexity with error bars representing the standard error of the mean. B) Steigers z-test to assess differences between Pearson's correlations with clinical gait and balance tests (Timed Up and Go (TUG), Narrow Beam Walking Test (NWBT), Short Performance Physical Battery Test (SPPB), and Activity Balance Confidence (ABC) scale) and indoor and outdoor muscle coordination complexity.

Stronger Perturbations Increase the Contribution of Spinal Reflexes in Forward Dynamics Simulation of Human Walking

Mr. Gunwoo Park[1], Prof. Friedl De Groote[2], Prof. Seungbum Koo[1]

[1]KAIST, Daejeon, Daejeon, Korea, Republic of. [2]KU Leuven, Leuven, Leuven, Belgium

Introduction

Spinal reflexes are active during human walking and are widely hypothesized to enhance stability by providing rapid proprioceptive feedback [1]. Theoretical neural controller models have been proposed to explain locomotor function, yet the precise role of reflexes remains unclear, as both reflex-based and reflex-absent controllers are commonly used for walking simulations. In this study, we developed an integrated neural controller that combines supraspinal commands and spinal reflex and found that reflex-derived excitation increased if the controller is optimized under stronger pelvis force perturbation.

Methods

The neural controller comprised a reflex circuitry [2] and a multilayer perceptron (MLP) implementing a 150ms input-output delay. The MLP received the full-body state and produced both the gating variables to modulate each reflex feedback gain and the supraspinal excitation signals. Muscle excitation was the sum of the reflex-derived and supraspinal excitation from the MLP. All parameters were trained using proximal policy optimization with rewards for motion tracking and activation minimization. Training was done on a musculoskeletal model with 14 DoF and 22 Hill-type lower-limb muscles. During perturbed training episodes, anteroposterior pelvis force was applied, with its value resampled every 200ms from uniform distribution with [-Fmax, Fmax]..

Results

The neural controller achieved stable walking with a mean lower-limb joint-angle error of 1.2° relative to the reference motion when trained without perturbations. With a perturbation amplitude of 0.2BW, the controller maintained continuous walking for 20s in 88% of episodes. Reflex-derived excitation and its proportion of total excitation increased with perturbation magnitude: from 0.038 (16.6%) in the unperturbed condition to 0.073 (26.6%) with Fmax=0.1BW, and to 0.092 (29.3%) with Fmax=0.2BW.

Discussion

The increased contribution of reflex pathways observed in the perturbed training suggests that the controller adapted its policy by amplifying feedback gains to reduce falls. This

behavior indicates that spinal reflexes stabilize when the locomotor system is exposed to environmental uncertainty. Although reflex-derived excitation accounted for about 16-30% of total excitation, interpreting these quantitative values requires caution [3]. Improved models and training methods may allow more rigorous quantification of reflex contributions.

Introduction

Central pattern generators (CPGs) and reflexes are considered to contribute to the basic motor pattern of human gait at a spinal level. However, the exact mechanisms and contributions are still unclear. It is necessary to integrate such motor control mechanisms in forward dynamic gait simulations to represent healthy and pathological motor processes and to investigate the impact of various support types. The existing challenge is to map the complex motor control from supra-spinal and spinal motor functions in a physiologically plausible way.

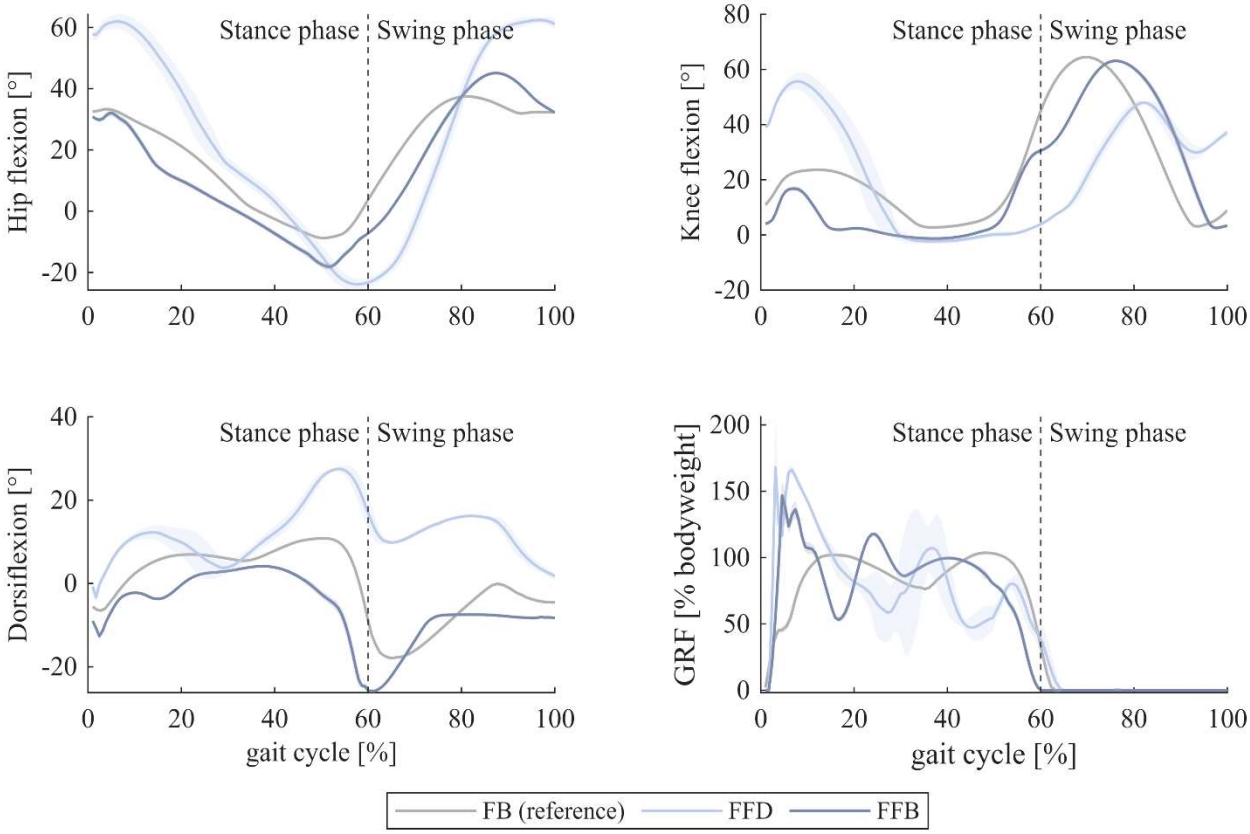
Methods

To represent CPGs and spinal reflexes simultaneously in gait simulations, two controllers with varying amounts of feedforward and feedback signals were investigated. The simulations were conducted in SCONE using Hyfydy [1]. A two-dimensional musculoskeletal human model with 18 muscles and 9 degrees of freedom was used.

CPGs were represented by feedforward signals calculated from gait-phase-dependent interpolatory cubic splines, that aimed to mimic segment positions and orientations of a previously simulated gait movement. Spinal reflexes were adapted from previously published models [1], [2], [3].

The feedforward-dominant (FFD) controller excited all muscles based on feedforward signals. Additionally, PD-feedback was used to stabilize pelvis tilt.

The second controller calculated muscle excitations based on feedforward and feedback signals (FFB) for thigh and hip muscles. Shank muscles were solely excited by proprioception.



Results

Simulation results from both new controllers were compared with results from a solely reflex-based controller [1] (FB). Highly loaded initial contacts were observed. FFD led to larger step sizes, higher knee flexion during stance phase, and increased dorsiflexion. Co-contractions and maximum muscle activations were observed. FFB produced slightly increased plantarflexion during push off and higher iliopsoas activation compared to FB.

Discussion

Feedforward signals, which aim to mimic existing gait patterns, have been demonstrated to be a promising method for representing CPGs in forward dynamic gait simulations. Nonetheless, spinal reflexes, were observed to contribute to natural gait, which is in line with physiological motor control theories. Supra-spinal motor control was simplified by automatic gait-phase-detection and should be considered in the future.

Gait Symmetry and Variability of Spatiotemporal Parameters During Treadmill Walking at the Preferred Walking Speed

Assistant Professor Haneol Kim PhD

University of Wisconsin - La Crosse, La Crosse, WI, United States

Introduction

Gait symmetry, the spatiotemporal similarity between limbs, provides a fundamental indicator of coordinated healthy neuromuscular control, while deviations are linked to pathology, injury, or musculoskeletal impairments [1]. Rhythmic auditory stimulation (RAS) has been used in rehabilitation that can induce sensorimotor entrainment and improve abnormal or pathological gait. This study aimed to examine how different RAS frequencies affect both gait symmetry and variability during treadmill walking.

Methods

Six young adults (4F/2M) voluntarily participated in this study. Each participant completed 5-minute treadmill walking trials at their preferred speed under four conditions: no auditory cueing, and three RAS frequencies set to 75, 100, and 125 beats per minute. Step length and step time asymmetry were calculated using an Asymmetry Index (AI), and variability was quantified with the Coefficient of Variation (CV) [1, 2]. A one-way repeated measures ANOVA was conducted with a significance of $\alpha = 0.05$.

Results

While AI showed no statistically significant differences across conditions, variability was significantly influenced by RAS. Young adults increased the CV of step length with RAS ($p = 0.048$). Post-hoc analysis revealed a significant difference between the no auditory cueing condition and the 125 BPM condition ($p = 0.008$). CV of step time also increased with auditory cueing ($p = 0.037$). Post-hoc analysis revealed a statistically significant difference between the no auditory cueing condition and 125 BPM ($p = 0.043$). The greatest CV was found at the metronome beats of 75 BPM, and the lowest with no auditory cueing for both parameters.

Discussion

These findings indicate healthy young adults can maintain symmetrical gait patterns even when external auditory cues disrupt likely because they can adjust to different RAS frequencies. RAS appeared to increase variability, reflecting a disruption in the consistency of their locomotor rhythm. This study contributes to understand how symmetry and

variability typically present in healthy young adults under these controlled conditions. Future research involving larger samples of young adults will be important to verify these observations and to support comparisons with children or individuals with gait impairments.

Video-Based Estimation of Subject-Specific Body Segment Parameters

Mr. Hariharan Sureshkumar Graduate Student, Dr. Seungmoon Song Ph.D.

Northeastern University, Boston, MA, United States

Introduction

Markerless motion capture systems are increasingly used in biomechanics and clinical assessment due to their lower cost and reduced setup time compared to marker-based systems. However, their accuracy varies across platforms and depends on camera configuration, task complexity, and environmental conditions. This study aims to evaluate the performance of three markerless systems Theia, OpenCap, and FreeMoCap across a range of gait and functional movement tasks. Theia is used as the reference system based on its established consistency in controlled laboratory environments using an eight-camera Qualisys setup. A secondary objective is to quantify how the number of cameras or iOS devices affects measurement accuracy, particularly for OpenCap and FreeMoCap.

Methods

We plan to recruit 20 healthy adults who will perform treadmill walking and running at multiple speeds, as well as overground tasks such as squats, sit-to-stand, range of motion tests, and obstacle negotiation. Data will be collected using Theia (8-camera setup), OpenCap (2–8 iOS devices), and FreeMoCap (3–4 cameras, with highercamera testing planned). Metrics include 3D joint angles, joint center trajectories, and spatiotemporal gait parameters (stride length, cadence, step time). Comparative analyses will evaluate both system-level differences and the effect of increasing camera count for OpenCap and FreeMoCap.

Results

Preliminary pilot recordings indicate that Theia provides stable and consistent joint angle estimates across treadmill walking and running. OpenCap shows minimal improvement in accuracy when increasing from one to eight iOS devices. Early FreeMoCap results suggest improved stability and reduced trajectory noise with additional cameras, though testing with more than four cameras is pending. Larger discrepancies across systems appear during fast movements and motions with large limb elevation, such as obstacle negotiation.

Discussion

Initial findings show distinct system behaviors: Theia remains reliable across conditions, OpenCap performance is relatively insensitive to additional cameras, and FreeMoCap benefits from increased camera count but requires further evaluation. The completed study will provide guidance for selecting markerless motion capture systems based on task demands, accuracy requirements, and available resources.

A Sensor-Based Study of Gait Challenges in Stair Walking Among Children with Intellectual Disabilities

professor Hsin-Yi Kathy Cheng -[1], professor Wann-Yun Shieh[1], professor Yan-Ying Ju Taiwan[2], Mr. Che-Kuan Lin[1]

[1]Chang Gung University, Taoyuan, -, Taiwan. [2]National Taiwan Sport University, Taoyuan, -, Taiwan

Introduction

Children with intellectual disabilities (ID) and multiple disabilities (MD) commonly present with impaired motor coordination and balance control, which significantly affect functional mobility, especially during stair negotiation. Stair walking requires greater demands on postural regulation, muscle strength, and dynamic stability than level walking. However, quantitative analyses of stair-walking performance in these populations remain limited. This study applied wearable sensor technology to objectively analyze stair-walking gait characteristics in children with ID and MD and to explore its clinical and educational applicability.

Methods

A total of 84 participants aged 15–22 years were recruited, including 32 typically developing (TD) individuals, 32 with ID, and 20 with MD. All participants wore a lower-back Xsens inertial sensor and completed a 10-m level walking test and a stair-walking task consisting of 13 steps ascending and 13 steps descending (each step 15 cm in height and depth). One ascent–descent cycle was repeated four times. Heart rate and oxygen saturation were monitored before and after testing to ensure safety. Temporal gait parameters were analyzed using one-way ANOVA with Scheffé post hoc comparisons.

Results

During stair ascent, both the ID and MD groups demonstrated longer time per step than the TD group, with the MD group showing significantly longer total ascent time and the greatest variability. Statistical analysis revealed a significant difference only between the MD and TD groups ($p < 0.05$). During stair descent, the TD and ID groups completed the task in less than 6 seconds, whereas the MD group required approximately 1.8 times longer than the TD group (TD ≈ 4.92 s; MD ≈ 8.8 s) and exhibited greater instability and gait variability.

Discussion

Stair-walking tasks were more sensitive than level walking in revealing deficits in motor control, coordination, and stability, particularly in children with MD. Wearable sensor systems effectively quantified gait impairments and provided objective evidence to support early identification of motor dysfunction and the development of individualized rehabilitation and physical training programs in both clinical and educational settings.

Lower Limb and Joint Level Differences in Mechanical Demands Between Lateral and Vertical Jumps Following a Drop Land

Mr. Hua-Bin Lin BSc, Dr. Jordan Cannon PhD

University of Waterloo, Waterloo, Ontario, Canada

Mr. Hua-Bin Lin

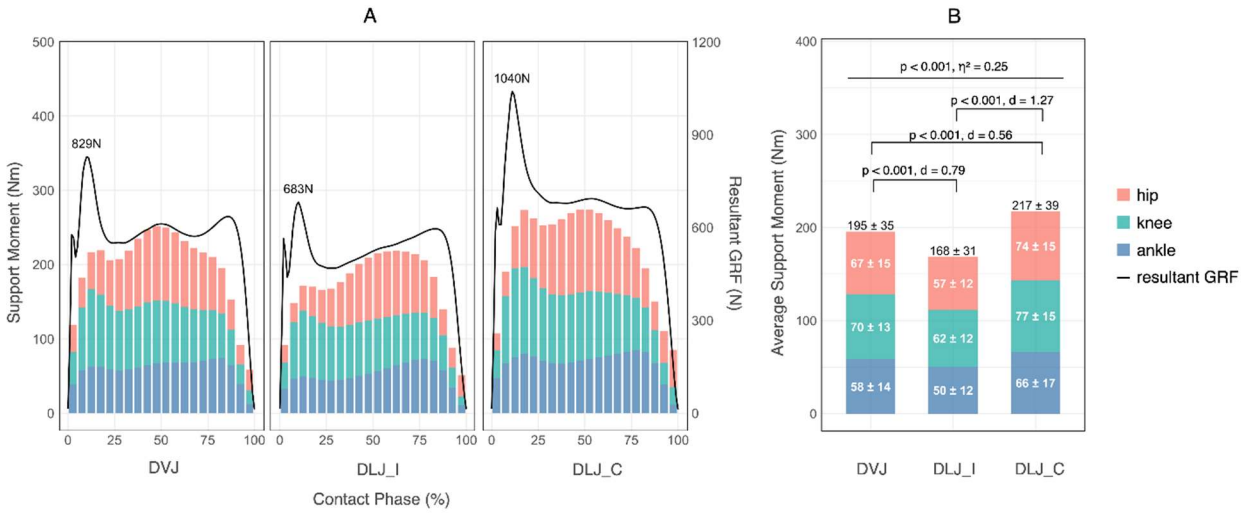
Introduction

Drop jump tasks are complex whole-body movements requiring multi-joint control to meet the mechanical demands from landing and generate propulsion for jumping. Ground reaction force (GRF) magnitude and orientation relative to the lower limb modulates net joint moment (NJM) distribution. Unlike a drop vertical jump (DVJ), with primarily sagittal plane demands, a drop lateral jump (DLJ) requires both vertical and medial-lateral GRF components for jumping. Thus, DLJs would be expected to introduce multi-planar demands across the lower limb joints and asymmetry between limbs. The purpose of this study was to compare limb- and joint-level mechanical demands between DVJ and DLJ tasks, to gain insight into differences in multi-joint control strategies.

Methods

Eighteen female athletes performed three drop jump tasks from a 30cm box landing with each foot on a force plate before maximally jumping vertically (DVJ), laterally to the right (DLJ_R), and laterally to the left (DLJ_L). Limb-level (i.e., resultant GRF and support moment) and joint-level (i.e., resultant NJMs) mechanics were analyzed during the contact phase. Variables were averaged within each task by limb condition, such that analyses compared DVJ (average of both limbs), DLJ_I (average of ipsilateral limbs to jump direction), and DLJ_C (average of contralateral limbs to jump direction). RM-ANOVA was used to compared limb and joint levels differences across conditions.

Results



At the limb-level, the resultant GRF and support moment were greatest in DLJ_C, followed by DVJ, and then DLJ_I. Thus, the contralateral limb to jump direction had the greatest demands given its role as the “push limb.” Similarly, at the hip, knee, and ankle, joint demands were greatest in DLJ_C, followed by DVJ, and lowest in DLJ_I. Within each

condition, hip and knee resultant NJMs were similar while both were greater than the ankle.

Discussion

As expected, DLJs increased limb- and joint-level demands of the contralateral limb while reducing ipsilateral demands, compared to DVJ. However, the distribution of demands among joints was unchanged (hip: 34%, knee: 36%, ankle: 30%). Therefore, consistent multi-joint control strategies were utilized, facilitated by the relative alignment of the GRF with the lower limb despite large absolute kinematic differences across conditions.

Images (Optional)

For each task by limb condition: (A) Resultant GRF and support moment (sum of hip, knee, and ankle NJMs). (B) Average support moment and average NJMs over the contact phase (mean ± SD).

Running Speed Increases Movement Variability for Key Biomechanical Variables

Dr Iain Hunter PhD, Mr. Luke VanKeersbilck, Mr. Jared Ward

Brigham Young University, Provo, Utah, United States

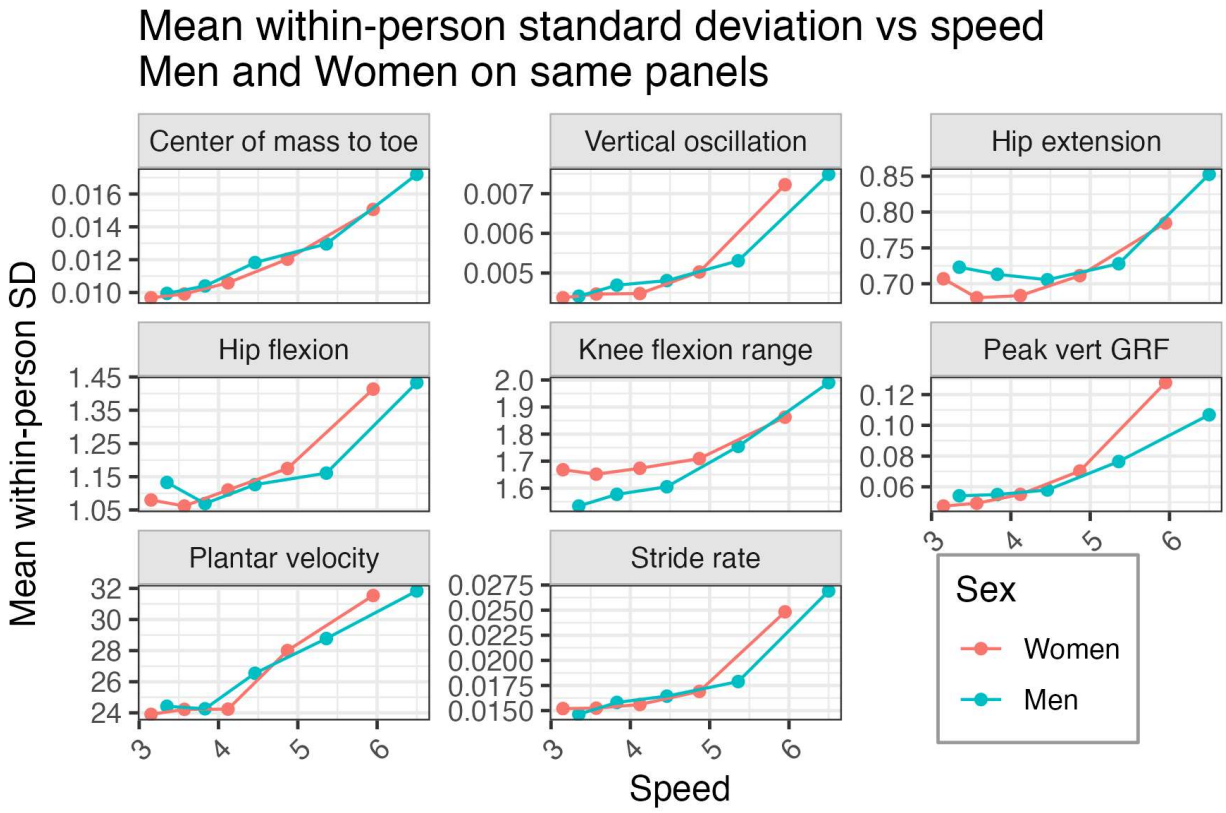
Introduction

Experienced runners tend to have lower movement variability [1,2,3]. This lower movement variability is correlated with greater mechanical efficiency [4] which may lead to improved running economy. This study investigated how variability is influenced by running speed. We expected variability of various running mechanics variables to increase as speed increased.

Methods

Sixty-seven women and 50 men ran a 3-minute warmup followed by 20-s recordings at 3.15, 3.57, 4.12, 4.87, and 5.95 m/s for women and 3.35, 3.83, 4.46, 5.37, and 6.50 m/s for men. Theia Markerless (120 Hz) and a Bertec instrumented treadmill (960 Hz) were used to record motion and forces. Visual 3d was used to calculate peak vertical ground reaction forces, stride rate, the range of knee flexion during stance, maximum hip flexion, maximum hip extension, maximum plantar flexion velocity during stance, and center of mass vertical oscillation. The 20-s recordings allowed for at least 25 strides for each speed. Standard deviations were calculated for each speed. A mixed-model was fit predicting these movements from speed, speed^2 (for non-linear relationships), sex, and subject.

Results



All variables showed a positive trend of standard deviations increasing with speed ($p<0.05$) and speed^2 ($p<0.001$). The only significant variable for sexes was peak force ($p=0.020$).

Discussion

Less movement variability is desirable for reducing mechanical efficiency. Variability of all running mechanics measures in this study increased with running speed. The question now becomes, what can we do to reduce movement variability when running at higher speeds to keep mechanical efficiency as low as possible. The lower variability demonstrated in trained runners suggests a likelihood that training at faster speeds could decrease variability at those speeds. Future research will investigate whether running variability

decreases as running experiences increases and correlate these changes with running economy.

Evaluating Accuracy and Confidence Intervals of a Probabilistic Multiview Markerless Motion Capture System

Ms Irina Djuraskovic BS[1,2], Dr Seth Donahue PhD[3,4]

[1]Shirley Ryan AbilityLab, Chicago, IL, United States. [2]Northwestern University, Chicago, IL, United States. [3]Shriners Hospitals for Children, Lexington, KY, United States. [4]University of Kentucky, Lexington, KY, United States

Ms Irina Djuraskovic

Introduction

Validation studies of biomechanical reconstruction from video using markerless motion capture typically report accuracy aggregated over a cohort. However, in practice, it is essential to know if markerless motion capture is accurate for an individual. While biomechanical reconstructions have been shown to perform well, they lack a measure of noise or confidence in the outputs. To be calibrated, the model's estimated 95th percentile confidence interval must contain the gold-standard data 95% of the time, and similarly for other percentiles. This study provides multi-site and validation of our probabilistic Markerless Motion Capture (MMC) model using external gold standard systems for multiple clinical populations.

Methods

Video data from 68 participants with varying diagnoses from 2 different sites, N = 41, Shirley Ryan AbilityLab (SRALab), N = 27 Shriners Children's (SC) were collected and processed as described in [1]. Clinical ground truth was obtained using the GaitRite Walkway at SRALab, and marker-based motion capture at SC. We evaluated the model's calibration using the Expected Calibration Error (ECE) metric, which is a global goodness-of-fit metric for statistical calibration. Kinematic bias was removed prior to ECE calculations. We also present the estimated uncertainty and absolute errors between the gold standard and our model.

Results

Our model showed that it is well calibrated with ECE values generally falling < 0.1. We also show that the model is fairly accurate, with the median absolute step length error of 16.22mm while joint angle errors were < 4° across all the SC participants (Table 1).

Discussion

We validate the probabilistic MMC against standard clinical tools to show we can accurately quantify body positions and joint angles and associated uncertainties with well-calibrated confidence intervals. We show that the median step length error falls within the expected bounds found in previous work [1]. Bias-removed kinematic values showed excellent calibration, and reasonable uncertainty and errors, except for pelvis rotation ECE, which showed moderate miscalibration. Future work will correct model specification differences that lead to biases and will evaluate reasons for lower confidence scores to ultimately use the confidence intervals to ensure high-quality data for its implementation in clinical analyses.

Does Preferred Running Speed Minimize Cost of Transport or Maintain Exercise Intensity?

Miss Isabella Shih[1], Dr. Rodger Kram[2], Dr. Jessica C. Selinger[1]

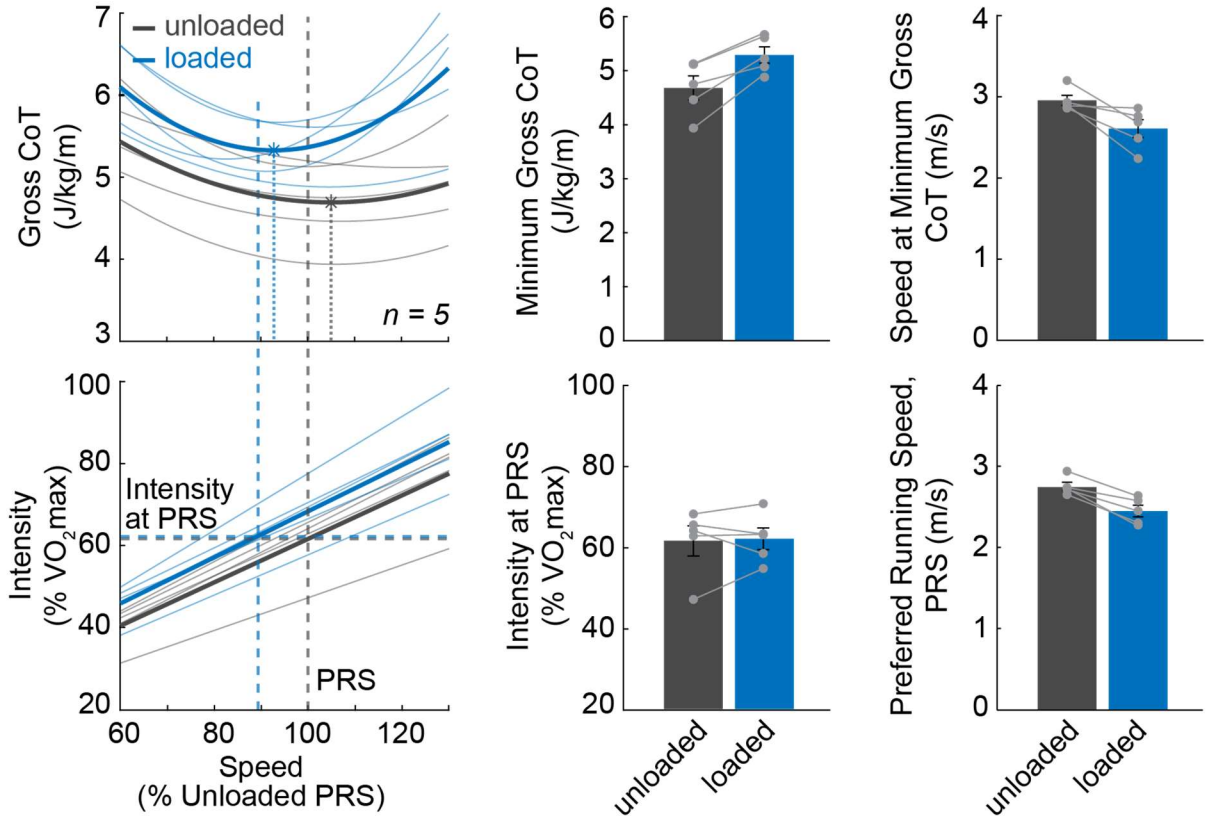
[1]School of Kinesiology and Health Studies, Queen's University, Kingston, Ontario, Canada. [2]Department of Integrative Physiology, University of Colorado, Boulder, Colorado, United States

Introduction

In humans and other animals, locomotor speed preferences tend to align with the speed that minimizes cost of transport (CoT, the *amount* of energy expended per unit distance travelled) [1, 2]. However, maintaining a given exercise intensity (*rate* of energy per unit time) is arguably more physiologically intuitive. A simple, yet untested, way to distinguish between these two objectives is to add load to the body. The speed that minimizes CoT is expected to remain largely unchanged from unloaded to loaded running [3], but exercise intensity naturally increases, allowing us to directly test which better explains PRS. The purpose of this study is to test if human PRS minimizes CoT or, instead, maintains exercise intensity using unloaded and loaded running.

Methods

Participants (n=5 of 12 planned) ran on a treadmill while metabolic expenditure and heart rate were recorded. Across three visits, runners completed a VO_2max test, PRS tests under unloaded and loaded (20% bodyweight) conditions, and ran at six speeds ranging from 70% to 120% of their PRS under both conditions. We compared runners' minimum gross CoT (J/kg/m), speed at their minimum gross CoT (m/s), PRS (m/s) and PRS exercise intensity (% VO_2max) between the unloaded and loaded conditions using paired t-tests (alpha = 0.05).



Results

PRS decreased under loaded compared to unloaded running (-11.1% ± 4.0%, p=0.0015). Unexpectedly, the speed that minimized gross CoT also decreased by a similar amount (-11.7% ± 8.5% p=0.037), although the absolute PRS tended to be slightly lower than the speed that minimized gross CoT in both conditions. PRS under unloaded and loaded conditions also resulted in very similar exercise intensities (61.7% ± 8.3% vs. 62.2% ± 6.0%, respectively; p=0.829).

Discussion

Our preliminary results suggest that human PRS may both minimize CoT and maintain exercise intensity, raising important questions about whether they are coupled or coincident objectives. The full results of this study may shed light on what fundamental objectives drive human locomotor preferences.

Influence of Race and Motion Capture Method on Knee and Hip Kinematics during Gait

Miss Iwi Eghobamien BSc[1,2], Mr. Neil Wills MSc[1], Miss Vital Nwaokoro BSc[1], Dr. Derek Pamukoff PhD[1]

[1]University of Western Ontario, London, Ontario, Canada. [2]McMaster University, Hamilton, Ontario, Canada

Miss Iwi Eghobamien

Mr. Neil Wills

Miss Vital Nwaokoro

Introduction

Motion capture method may influence comparisons between racial groups due to differences in skin tone. This study examined the influence of race and motion capture method on knee and hip kinematics during overground gait.

Methods

Forty participants were grouped into Black (10 females, 10 males) or White (10 females, 10 males) based on self-identified race and matched on sex and body size. Two overground gait assessments along a 10m walkway were completed 2-7 days apart. Five trials were completed per session at a self-selected speed that was maintained between days using the same footwear and clothing. 14 Qualisys cameras (8 for ML and 6 for MB) recorded simultaneously (60Hz), and data were averaged between sessions. Model construction was completed using Theia 3D (ML only) and Visual 3D software. Hip and knee kinematics were time-normalized from 0-100% of the gait cycle. Kinematic waveforms were compared with statistical parametric mapping (SPM) using a 2 (race) by 2 (method) repeated ANOVA (α=0.05). Post hoc evaluations used SPM using independent samples t-tests and Bonferroni correction.

Results

There were main effects of motion capture method showing higher amplitude kinematics for MB than ML in all joints and planes of motion (all $p<0.05$). There were significant interaction effects of race and method for sagittal ($p=0.035$) and frontal ($p<0.001$) plane knee angle, and frontal ($p=0.003$) and transverse ($p=0.002$) plane hip angle. Post hoc analyses indicated larger differences in kinematic waveforms between methods in Black participants compared with White participants from ~65-90% of gait cycle. MB showed more knee adduction and hip abduction compared with ML in Black participants, and greater knee adduction in Black participants compared with White participants when evaluated with MB (Figure 1).

Discussion

Race and motion capture method influence hip and knee kinematics during swing phase, which may influence interpretations from Black participants. Findings may have stemmed from ML camera placement. Ceiling-mounted cameras may have an obstructed view of lower limb segments during swing phase, or had poor contrast between dark flooring and darker skin tones. ML methods need further evaluation to understand contributors to validity and reliability on diverse samples.

Images (Optional)

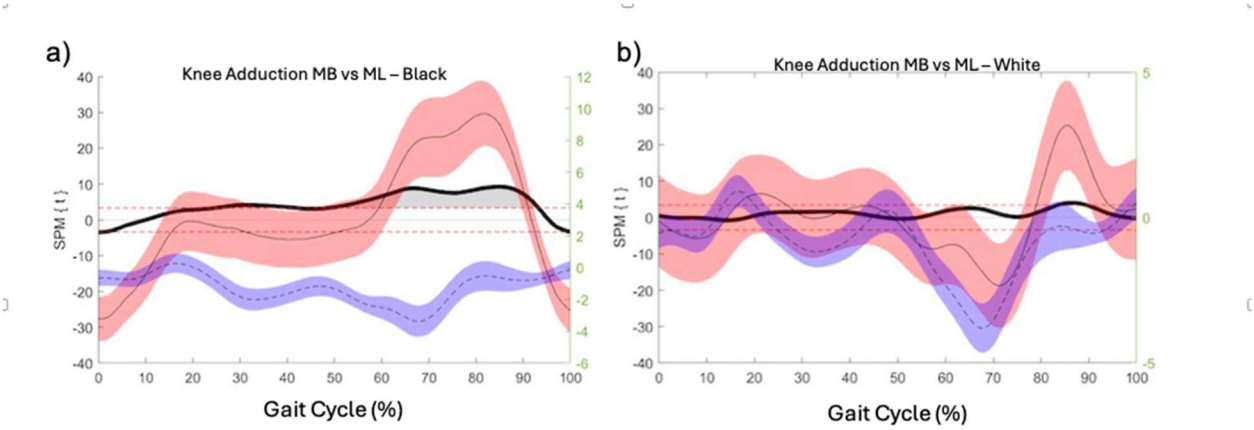

Figure 1. Post hoc comparisons of knee adduction waveforms throughout the gait cycle in Black (a) and White (b) participants. Marker-based is red, markerless is blue. Blue and red shaded regions indicate standard deviation. Gray shaded regions indicate significance.

Rapid Phenotyping of Unilateral Osteoarthritis via a 6-Minute Markerless Gait Stress Test

Mr Jack Clarke BEng[1], Dr Peter Ellison[1], Dr Matthew Bowes[2], Dr Nicholas Shenker[3], Mr Zijie Ren[1], Professor Adar Pelah[1,4]

[1]University Of York, York, North Yorkshire, United Kingdom. [2]York And Scarborough Teaching Hospitals NHS Foundation Trust, York, North Yorkshire, United Kingdom. [3]Cambridge University Hospitals NHS Foundation Trust University Hospitals, Cambridge, Cambridgeshire, United Kingdom. [4]Florida Atlantic University, Boca Raton, Florida, United States

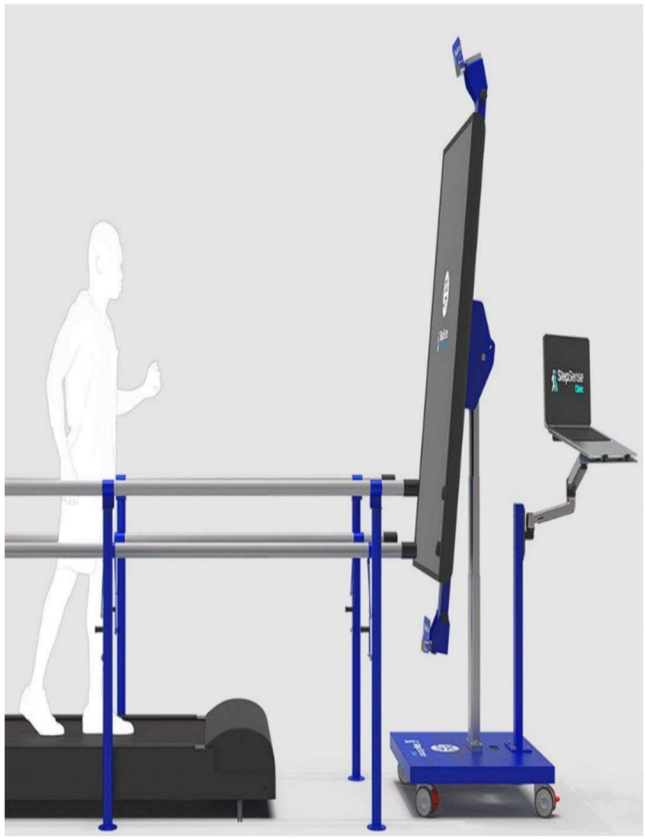
Introduction

Traditional gait analysis remains confined to specialized laboratories due to high costs and complex protocols, limiting its utility for routine Osteoarthritis (OA) screening. While low-cost Time-of-Flight (ToF) cameras offer a scalable alternative, their ability to detect subtle, phenotype-specific deficits in short clinical windows remains unproven. This study aimed to validate a rapid, markerless "gait stress test" workflow for classifying Unilateral OA. We hypothesised that a 6-minute variable-velocity protocol could successfully extract robust dynamic kinematic biomarkers, unmasking the latent temporal asymmetry and maladaptive response profiles described in marker-based literature.

Methods

Gait kinematics were captured from 16 participants (9 Unilateral OA, 7 Controls) using a single Azure Kinect camera. Participants completed a 6-minute treadmill protocol (1.5–4.5 km/h staircase). Post-processing then extracted relevant spatiotemporal metrics. A Repeated Measures ANOVA was then employed to analyse the dynamic response of the left versus right limbs across velocity phases. We assessed whether the markerless data could reproduce the Speed * Group interaction (dynamic failure) and Laterality (asymmetry) patterns previously established as clinical markers of unilateral pathology.

Results



the system extracted biomarkers consistent with clinical expectations. Notably, the main effect of Group classification only approached significance ($p = 0.051$, Effect Size = 0.261), suggesting that static averages may lack diagnostic sensitivity. However, the dynamic analysis proved robust: the markerless data revealed a significant Speed * Group interaction for stride time ($p = 0.015$, Effect Size = 0.191), mirroring maladaptive responses described in marker-based studies such as Bejek et al. [1]. Furthermore, the system

reliably quantified Laterality (Left vs. Right) (p = 0.016, Effect Size = 0.373), distinguishing unilateral OA asymmetry from control symmetry.

Discussion

This study establishes the feasibility of a rapid, markerless workflow for OA phenotyping that requires no patient preparation. The successful detection of dynamic deficits (p=0.015) validates that low cost ToF Cameras can capture non-linear gait adaptations to a suitable degree of accuracy. By demonstrating that a 6-minute stress test yields asymmetry metrics consistent with established clinical pathology, this method offers a viable pathway for high-throughput screening and "functional Classification" of OA in outpatient clinics.

Standing From Seat Heights Below the Popliteal Increase Muscular Demands More Than Joint Torques

Dr. Jacob Banks PhD, Dr. Neal Wiggermann PhD

Baxter Int., Batesville, Indiana, United States

Introduction

Standing from a seated posture is a common daily activity. Muscular strength and seat height can influence the success of standing[1]. While seat heights below popliteal height are more difficult to rise from; kinetic analysis has not identified differences in lower limb peak joint moment demands[2]. The aim of this work is to better understand low seat height kinetic demands.

Methods

To date, data from twelve healthy adults has been recorded and analyzed. Kinematic and kinetic data were recorded while participants stood from up to 20 seated heights ranging 18cm to 79cm. OpenSim musculoskeletal models[3] were used to estimate peak lower limb sagittal plane joint range of motion, torques, and muscle group activation levels from standing. Dependent variables were plotted relative to seat height normalized to individual popliteal height, for qualitative interpretation (Fig. 1).

Results

Hip, knee, and ankle joint ranges of motion were inversely influenced by seat height. Joint torques were also inversely related to normalized seat height, particularly for the hip and knee, however peak demands tended to plateau at heights below the popliteal. Muscle group activations resembled joint moments, though they appear more sensitive to seat height. A secondary analysis of 90-110% versus 40-60% normalized seat height indicates roughly a 15% and 22% increase for peak joint moments at the hip and knee, respectively, but a 49% and 52% increase in group muscle activation at the hip and knee, respectively.

Discussion

The phenomenon of how below popliteal level seat heights exhibiting similar kinetic demands despite more perceived effort and difficulty of standing have previously not been fully quantified. Here we applied a musculoskeletal model to demonstrate that muscle activations increase at a higher rate than joint moment demands. This discrepancy may represent reduced force-length properties of muscle and muscle moments about the joint[4]. Those with difficulty standing from low seat heights may benefit from a kinematic

strategy that optimizes muscular potential. These preliminary results will benefit from additional data and quantitative analyses.

Attentional Adaptation and Gait Stabilization during Interactive Metronome Gait Training in Middle-Aged Adults

Jae-Won Kang M.S.[1,2], Dr. Soo-Ji Han Ph.D.[2,3], Yun-Bae Jeong M.S.[1,2], Jung-Min Yoon M.S.[1,2], Prof. Sang-Kyoon Park Ph.D.[1,2]

[1]Korea National Sport University, Seoul, Seoul, Korea, Republic of. [2]Motion Innovation Center, Seoul, Seoul, Korea, Republic of. [3]Pukyong National University, Pusan, Pusan, Korea, Republic of

Introduction

Middle-aged adults may experience age-related cognitive decline, which can lead to weakened gait ability and an increased risk of falls[1]. Interactive Metronome(IM)-based training has been proposed as an effective intervention to enhance gait stability by modulating temporal processing and attentional control in the brain through metronome beats and real-time auditory feedback. However, this dual-task condition can induce selective attentional overload and compromise gait performance, which can be resolved through sensory integration achieved by sufficient training duration[2]. Therefore, the purpose of this study was to identify the certain time interval at which selective attention adaptation occurs during IM-based treadmill gait training in middle-aged adults and to provide recommendations for a minimum training duration.

Methods

Thirteen middle-aged males (Age:57.7±3.9years; Height:170.3±5.1cm; Weight:73.8±8.1kg; K-MoCA:26.2±2.0points) without musculoskeletal disorders in the past six months participated. Treadmill walking data were collected using eight infrared cameras (Qualisys, SWE) and a treadmill (Bertec, USA), while auditory feedback was provided through an IM device (Interactive Metronome, USA). Participants walked at their preferred speeds to determine the individual cadence(109.9±6.3bpm), which was applied to the IM during a 10-minute treadmill walking session. Gait data divided into three intervals (initial:1:00–1:30 min; middle:5:00–5:30 min, final:9:00–9:30 min) were analyzed using a one-way repeated measures ANOVA followed by Bonferroni correction(α=.05).

Results

There were no significant differences in cadence and step time across intervals(Table 1). However, significant differences were shown in the ankle joint range of motion (AROM) and the coefficient of variation (CV) of AROM during the stance phase.

Discussion

Gait training using rhythmic auditory stimulation increased ankle movement and decreases variability, which improved gait consistency and stability[3]. In this study, the decrease in the CV of AROM during final suggests that the attentional control mechanisms induced by dual-task condition stabilized during the final contributing to enhanced gait stability. Therefore, it is recommended that IM-based gait training for middle-aged adults be conducted for approximately 9 minutes to achieve optimal effectiveness.

RPE-Based Identification of Fatigue-Related Changes in Running Spatiotemporal Variability

Ms Jaewoo Cho, Ms Hyunji Kim, Prof Jooeun Ahn

Seoul National University, Gwanak-gu, Seoul, Korea, Republic of

Introduction

Running-induced fatigue is known to increase spatiotemporal variability [1], yet conventional time-based analyses often obscure meaningful individual differences in fatigue progression [2]. The rating of perceived exertion (RPE) offers an individualized scale of internal load that may better capture fatigue-related changes in motor control [3]. This study examined how spatiotemporal variability evolves across successive RPE levels during prolonged running and explored whether specific “hard” intensity points (RPE 14–16) exhibit abrupt transitions in variability.

Methods

Seven recreationally active adults (4 males and 3 female) completed a running trial on an instrumented treadmill at a self-selected speed targeting volitional exhaustion (2.95 ± 0.32 m/s). On average, they stopped at 24.7 ± 7.0 min with a terminal RPE of 18.4 ± 1.6. 3D kinematics (120 Hz), ground reaction forces (1200 Hz) and RPE were collected. Heel-strike and toe-off were identified using a 20 N threshold, and 100 consecutive right-leg steps at each RPE level were analyzed. Cadence, contact time, flight time, stride length, and vertical oscillation were computed, and their variability was quantified using the coefficient of variation (CV).

Results

Across RPE levels, most spatiotemporal metrics showed their largest increases in variability at RPE 15. Paired t-test results comparing the absolute CV values at each RPE level with those at the preceding level indicated a significant rise in cadence variability at this point ($p < 0.05$). Vertical oscillation exhibited a significant increase at RPE 16 ($p < 0.001$), whereas other metrics showed smaller or inconsistent changes.

Discussion

RPE-based alignment accurately identified the RPE levels at which variability sharply increased, effectively reflecting individual fatigue responses. The pronounced rise in cadence variability at RPE 15 suggests a mid-fatigue transition point where step-to-step timing becomes unstable. In contrast, the significant increase in vertical oscillation at RPE

16 indicates a later-stage breakdown in whole-body motion control under higher fatigue. Together, these findings highlight that gait parameters exhibit distinct sensitivity to fatigue and that RPE-based segmentation can reveal consistent trends in spatiotemporal variability

Images (Optional)

Are Surgical Limb Knee Dynamics Altered Across the Gait Cycle Post-ACL Reconstruction

Ms. Janelle Baker, Dr. Susan Sigward PhD, PT, ATC

University of Southern California, Los Angeles, CA, United States

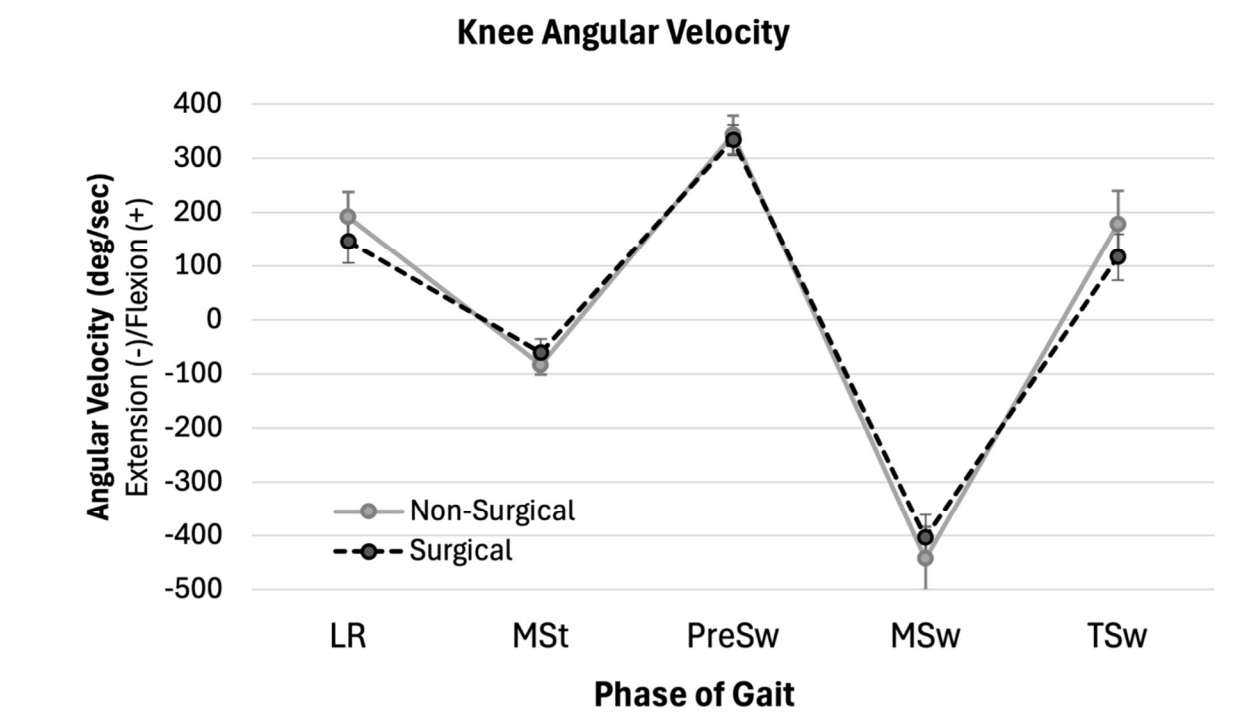
Introduction

Reduced knee flexion and extension excursion across stance is a prominent characteristic of altered knee gait mechanics in the surgical (Sx) limb following ACLr [1,2,3]. This, along with reduced Sx limb shank angular velocity during loading response, suggests individuals adopt less dynamic or stiffer strategies during stance. However, it is unknown if these strategies carry over to the swing phase when rapid flexion and extension are required without the demands of weight bearing.

Methods

15 individuals 113.6 ± 18.5 days post-ACLr participated. Three-dimensional kinematics (250 Hz; Qualisys, Inc. Sweden) were collected while they walked across a 10m walkway at self-selected speed. Sagittal plane knee angular velocity (extension (-) and flexion (+)) was calculated from marker trajectories using a 6 DOF kinematic model across the stance and swing phase of the gait cycle (defined as the period between subsequent heel strikes) for both limbs. Peak angular velocities were identified during loading response (LR; +), mid stance (MSt; -) and pre-swing (PreSw; +) of the stance phase and mid (MSw; -) and terminal swing (TSw; +) of the swing phase [4]. Repeated measures (limb x phase) ANOVA was used to determine whether differences exist between limbs and phases (significance $\alpha \leq 0.05$).

Results



Significant main effects (limb $p=0.004$, phase $p \leq 0.001$) and interactions ($p \leq .001$) were found (Figure 1). Sx limb angular velocity was lower for LR 27.01% ($p=.001$), MSt 32.32% ($p=.001$), MSw 9.27% ($p=.032$) and TSw 41.82% ($p=.001$) but not PreSw. Extension angular velocity was greatest in MSw.

Discussion

Consistent with the characterization of less dynamic kinematics, the surgical knee exhibited reduced angular velocity across phases of stance and swing. The largest percent difference between limbs was observed in flexion velocity prior to initial contact of stance and the smallest during MSw when the angular velocity demands were the greatest. Despite the absence of weight bearing demands, it is not clear if reductions during swing

reflect an inability to achieve faster velocities or an adjustment to prepare for the demands of weight bearing.

Effects of a Body Weight Support System on Lower Extremity Joint Kinematics During Running

Dr. Jeff Mettler Ph.D., Ms. Sasha Botsul, Ms. Josephine Cooley, Mr. Connor Rockford, Mr. Jay Clark M.Ed., ATC

Augustana College, Rock Island, IL, United States

Introduction

Body weight support (BWS) systems, which reduce the impacts experienced by a runner, have become increasingly common for both training and rehabilitation. Runners exhibit reduced hip flexion [1], knee flexion [1-2], and ankle dorsiflexion [2] when using a BWS system, although it is unknown whether a BWS system influences frontal and transverse plane kinematics. Therefore, the purpose is to investigate the effects of a BWS system on the sagittal, frontal, and transverse plane kinematics of the hip, knee, and ankle while running.

Methods

To date, pilot data from 2 adults have been analyzed. After a warmup, each participant was fitted with inertial measurement unit sensors on their pelvis and lower extremities before running at 100%, 90%, 80%, and 70% of their body weight on a BWS system (LightSpeed Lift; Duluth, MN, USA). Participants ran at a constant self-selected speed for 3 minutes during each condition with 2 minutes of walking between each condition. 30 seconds of data were collected for each condition, and peak stance phase kinematics of the right hip, knee, and ankle were analyzed for each BWS condition.

Results

Results are reported in Table 1. Participant 1 demonstrated reduced hip adduction with an increase in BWS, although participant 2 did not demonstrate the same trend. Both participants demonstrated reduced knee internal rotation and ankle dorsiflexion with increased BWS. Finally, both participants demonstrated increased ankle adduction, and participant 2 demonstrated reduced ankle eversion with increased BWS.

Discussion

Preliminary results revealed that an increase in BWS caused a reduction in ankle dorsiflexion, which is supported by previous research [2]. Furthermore, increased BWS appears to have effects on frontal and transverse plane kinematics, although the study is ongoing. An *a priori* power analysis revealed that data must be collected on at least 16

participants for the study to detect a meaningful result if it exists, and it is anticipated that sufficient statistical power will elucidate any potential effects of BWS on sagittal, frontal, and transverse plane kinematics of the lower extremity joints during running.

Evaluation and Comparison of Multiple Gait Stability Metrics for the Upper Body and Lower Body When Applied to Healthy Walking Under Graded Lateral Perturbations

Dr. Jeongin Moon Ph.D, Dr. Richard Nuckols Ph.D

University of Massachusetts Lowell, Lowell, MA, United States

Introduction

Gait stability is essential for safe locomotion and important for older adults who desire independent living. Dynamic gait stability metrics such as the margin of stability (MoS), short-term Lyapunov exponent (LE), and maximum Floquet multipliers (FM) have been used to quantify the body's ability to respond to internal or external perturbations during walking. These stability metrics have been applied to different body segments in various studies but frequently yield different interpretations of the same gait pattern. A problem may be that studies rarely analyze the various stability metrics for both the upper extremity (UB) and lower body (LB) within the same study which may lead to discrepancies and confusion. This study aimed to concurrently measure multiple dynamic stability metrics (MoS, LE, and FM) from both UB and LB during walking with progressively graded lateral perturbations.

Methods

Fifteen healthy young male adults participated in the IRB approved study (#20-057-YAN-XPD). Participants completed four 5-minute walking trials under 4 intensities of lateral perturbation on a CAREN instrumented treadmill capable of lateral translation. Marker data was recorded, and UB (trunk) and LB (limbs) kinematics were calculated. C7 marker mediolateral position was used for the UB state representation and LB joint kinematics were used for LB state representation. Dynamic stability metrics of LE, FM, and MOS were calculated from these data. We used a one-way repeated-measure ANOVA to test the effect of perturbation on stability metrics.

Results

With increasing lateral perturbation intensity, the LE significantly increased for the UB and LB which suggest reduced local stability (Figure 1). Likewise, the FM significantly increased for the UB with increasing perturbation suggesting reduced orbital stability. However, the FM decreased for the LB suggesting increasing orbital stability. The MoS had a significant correlation with the LE of the UB and LB and the FM of the LB.

Discussion

Dynamic stability metrics exhibit distinct intensity and segment dependent response patterns. By performing a systematic comparison of multiple stability metrics within a single experimental paradigm, this within-study comparison helps clarify the relationships among these measures. Future work will aim at applying this approach to better understanding clinical gait.

Adaptive Observation of Gait Disturbances using Central Pattern Generator Models

Mr Jesse Macht MASc, P.Eng.[1], Dr Fae Azhari PhD, P.Eng.[1], Dr Joshua Taylor PhD[2]

[1]University of Toronto, Toronto, Ontario, Canada. [2]New Jersey Institute of Technology, Newark, New Jersey, United States

Introduction

Minor gait disturbances (for example those caused by asymmetric muscle atrophy, misalignment in lower limb prosthetic systems, and pain induced adaptation) are often difficult to detect and require experienced clinical intervention to identify and correct. If left undetected, these disturbances may lead to long term health issues such as osteoarthritis. In this work, we implement an adaptive state observer that simultaneously provides estimates of state variables (joint angles) and physical parameters (muscle activity gains, limb lengths, body mass) associated with gait using a simple wearable sensor package. By providing estimates of the physical parameters as they vary over time, we present this observer as a quantitative analytical tool that can be used to measure and diagnose some physical causes of gait disturbances.

Methods

The key to rendering the musculoskeletal system as a linear time varying (LTV) state space model amenable to adaptive observation is the inclusion of a central pattern generator (CPG) model for the gait control signals originating from the central nervous system (CNS), inspired by the control model presented by Ryu and Kuo [1]. An adaptive Kalman filter is implemented to learn the LTV musculoskeletal model, thus illuminating any disturbances that may impact the gait system.

Results

We demonstrate that the gait control signal, driven in part by acceleration impulses from the motor cortex via the CPG, provides persistent excitation to the musculoskeletal system. We also provide an analysis of the observability Grammian for the LTV musculoskeletal model and the output relationship implicit in our sensor package design. To validate the proposed observer, a standard gait model in OpenSim is utilized to simulate different walking patterns with disturbances introduced in the musculoskeletal system. Simulated sensor readings (acceleration and ground reaction force) are generated from the walking simulation and passed to the adaptive observer.

Discussion

The resulting estimated states and model parameters produced by the observer are compared against the values used in simulation to discuss the effectiveness of the approach for detecting mechanical issues that lead to abnormal gait.

Single-Camera Markerless Gait Analysis for Clinical Sagittal-Plane Assessment in Children with Cerebral Palsy

Ms. Jingwen Hu[1], Dr. Michelle Spirtos[1], Dr. Damien Kiernan[2], Prof. Ciaran Simms[1]

[1]Trinity College Dublin, Dublin, Dublin, Ireland. [2]Central Remedial Clinic, Dublin, Dublin, Ireland

Introduction

Gait analysis is critical for evaluating movement difficulties and guiding treatment in children with cerebral palsy (CP). Conventional multi-camera, marker-based motion-capture systems require dedicated infrastructure which are difficult to use in home environments. Single-camera markerless approaches that convert 2D-video into 3D-keypoints offer a more accessible alternative. However, most existing methods do not provide sufficient meaningful 3D-keypoints to define and compute clinically interpretable sagittal-plane joint angles for children with CP. This study investigates whether a transformer-based 2D-to-3D model using single-camera input can estimate 3D gait kinematics and derive sagittal-plane joint angles for children with CP.

Methods

We applied a transformer-based model to predict 3D gait motion from 2D-keypoints detected from a single-camera. The model was trained on 2000 anonymized 3D gait traces of children with CP. Using 11 input 2D-keypoints, we reconstructed 17 3D-keypoints, enabling computation of clinically relevant sagittal-plane joint angles based on the coordinate-system definitions of standard marker-set gait analysis protocols. Because real single-camera video was not yet available in the dataset, input was generated by virtual camera projection of the 3D gait data.

Results

Model performance was preliminarily examined in an independent evaluation sample of 10 children with CP, each contributing at least three gait cycles across two sessions. This evaluation indicated a substantial reduction in lower-limb joint-angle errors compared with a baseline open-source transformer pretrained on standard datasets. Mean hip-angle error decreased from 18.3° to 8.5° (left) and from 15.0° to 9.2° (right), while knee-angle error decreased from 17.7° to 4.5° (left) and from 14.2° to 5.8° (right). Using the 17 predicted 3D keypoints, sagittal-plane mean joint-angle errors were approximately 8.5°/9.7° (hip),

3.3°/3.9° (knee), and 5.5°/5.4° (ankle) for the left/right limbs, respectively. Additional offset-correction strategies are expected to further reduce hip and ankle-angle errors.

Discussion

These preliminary findings suggest that a suitably trained transformer-based, single-camera markerless approach with expanded keypoints can achieve clinically promising sagittal-plane gait accuracy in children with CP. Such a low-cost and accessible method has the potential to support gait assessment in home environments. Future work will validate this method using real mobile-device video and assess both repeatability and clinical agreement.

Swing-Leg Inertia Enhances the Explanation of Ankle Contribution and Propulsive Mechanisms in Running

Dr. Jinsung Jung Ph.D[1], Prof. Hyerim Lim Ph.D[2], Prof. Sukyung Park Ph.D[1]

[1]KAIST, Yuseong-gu, Daejeon, Korea, Republic of. [2]Kumoh National Institute of Technology, Gumi-si, Gyeongsangbuk-do, Korea, Republic of

Dr. Jinsung Jung

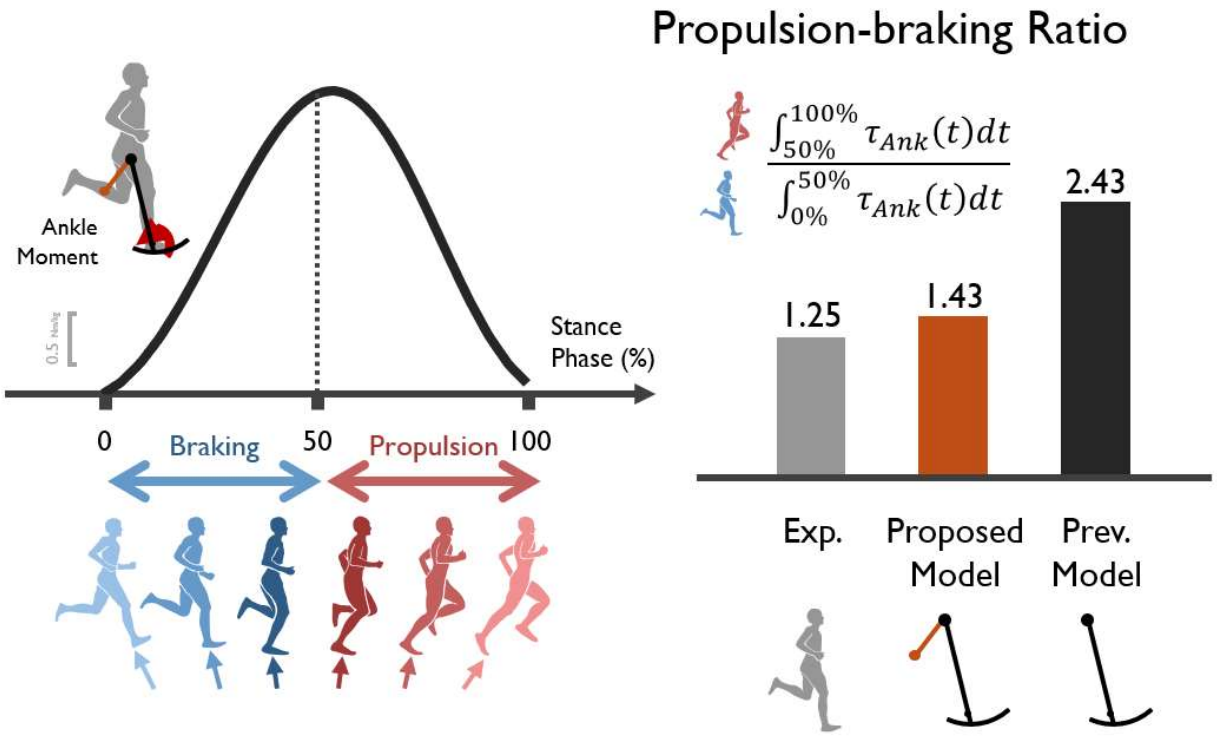
Prof. Hyerim Lim

Introduction

The spring loaded inverted pendulum (SLIP) model has served as a fundamental representation of human gait dynamics, and extended formulations can reproduce joint level patterns. While these extensions capture ankle behavior well during walking, they diverge substantially during running [1]. Because the ankle produces the largest moment and power and governs braking and propulsion, misrepresenting its behavior leads to incorrect interpretations of stance phase mechanics. To address this, we incorporated swing leg mass to represent its inertial influence during running and its interaction with the stance leg. This addition enables more accurate representation of ankle contributions and propulsive mechanisms within a simplified framework.

Methods

The model separates the body center of mass into two point masses: one for the swing leg and one for the remainder of the body including the stance leg. These masses are connected through a pivot and a linear spring, allowing interaction between swing and stance leg dynamics. A torsional spring between the virtual torso and the swing leg generates swing related torque. Stance leg parameters such as stiffness, initial conditions, and foot geometry were adopted from prior work, while swing leg parameters were assigned based on experimental observations. To represent the flight phase required for a steady state limit cycle, the two masses were merged into one at takeoff and then allowed to follow free fall motion with appropriate initial conditions.



Results

The proposed model resolves the characteristic underestimation of ankle contribution in early stance and overestimation in late stance seen in previous models. It more accurately matches the ratio of the integrated ankle moment between braking and propulsion, reducing errors by over seventy percent. The model further shows that the additional kinetic energy needed at the flight transition is on the order of several tens of joules, similar to the elastic energy released from the Achilles tendon. This establishes clearer physiological relevance for the simplified propulsive mechanism.

Discussion

By more faithfully reproducing ankle dynamics in running, the model corrects major limitations of prior SLIP based approaches and provides improved insight into propulsion and stance phase mechanics.

Integrated Analysis of Lower Limb Kinematics, Muscle Activation, and Plantar Pressure During Stair Ambulation in Individuals With Chronic Ankle Instability: A Pilot Study

Mr. Jongsu Kim PT, BPT, Mr. Sanghyun Cho MD, PhD, Mr. Jongwon Choi

Yonsei University, Wonju, Gangwon-do, Korea, Republic of

Introduction

Chronic ankle instability (CAI) is associated with recurrent ankle sprains and altered lower-limb biomechanics, which may contribute to secondary impairments and reduced quality of life. Nevertheless, prior studies of stair ambulation in individuals with CAI have typically been conducted under controlled laboratory settings and relied on discrete analysis, limiting their ability to characterize continuous biomechanical patterns. To address these limitations and provide more practical and clinical insights, this study conducted an integrated continuous analysis of 3D joint kinematics, muscle activation, and plantar pressure during stair ambulation outside the laboratory.

Methods

Nine young adults (4 with CAI and 5 healthy controls) participated in the study and were screened according to the recommendations of the International Ankle Consortium. Each trial consisted of 3 meters of level walking before and after a 10-step staircase. All participants completed five repetitions of stair ascent and descent at a self-selected comfortable speed. IMU-based 3D joint kinematics (pelvis, hip, knee, ankle), surface EMG (TA, PL, GCM, RF, BF, GMed), and plantar pressure were collected and synchronized using a multi-sensor system. After data processing, continuous signals were analyzed using Statistical Parametric Mapping (SPM), which enables time-series comparisons across the entire gait cycle. Hotelling's T^2 tests were used to evaluate multivariate patterns of 3D joint kinematics and muscle-coordination, followed by post hoc analyses when significant effects were detected. Independent t-tests were applied to assess differences in plantar-pressure distribution.

Results

Hotelling's T^2 tests revealed no significant group differences in 3D joint kinematics or in distal and proximal muscle-coordination patterns. Independent t-tests indicated that plantar-pressure distribution showed no clear differences between groups.

Discussion

Although no statistically significant differences were observed, differences in hip and ankle kinematics reflected characteristics in individuals with CAI, while the distal-coordination peaks suggested increased ankle strategy variability, and the proximal-coordination changes implied the use of compensatory strategies. These tendencies aligned with findings from previous SPM studies on level walking. Observed trends therefore suggest that meaningful group differences may emerge with an adequately powered sample during stair ambulation. Based on the preliminary data analysis, the main study aims to recruit at least 26 participants per group to ensure adequate statistical power.

Images (Optional)

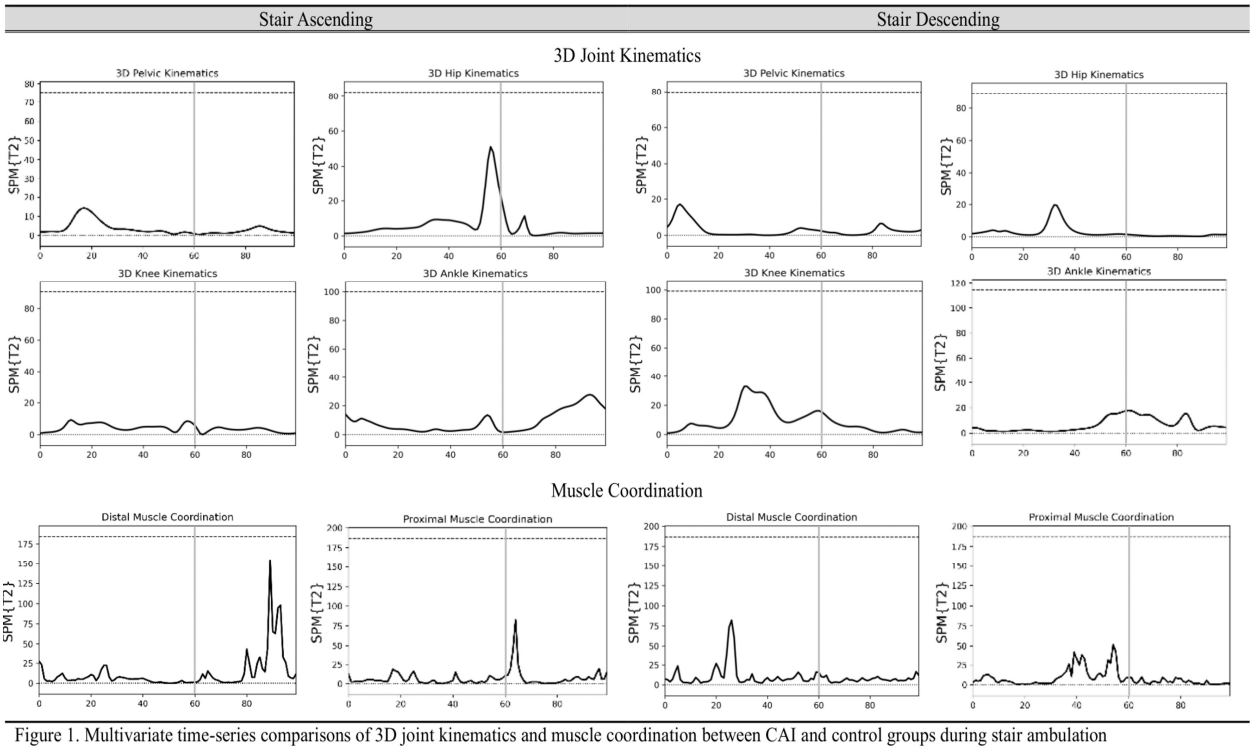

Figure 1. Multivariate time-series comparisons of 3D joint kinematics and muscle coordination between CAI and control groups during stair ambulation

Reduction of Cross-Talk in Lower Limb Secondary Joint Angles With Motion Capture Based on Dynamic 3D Scanning

Dr. Helios De Rosario[1], Dr. Juan López-Pascual[1], Dr. Mario Lamas[1], Dr. Brian Horsak[2]

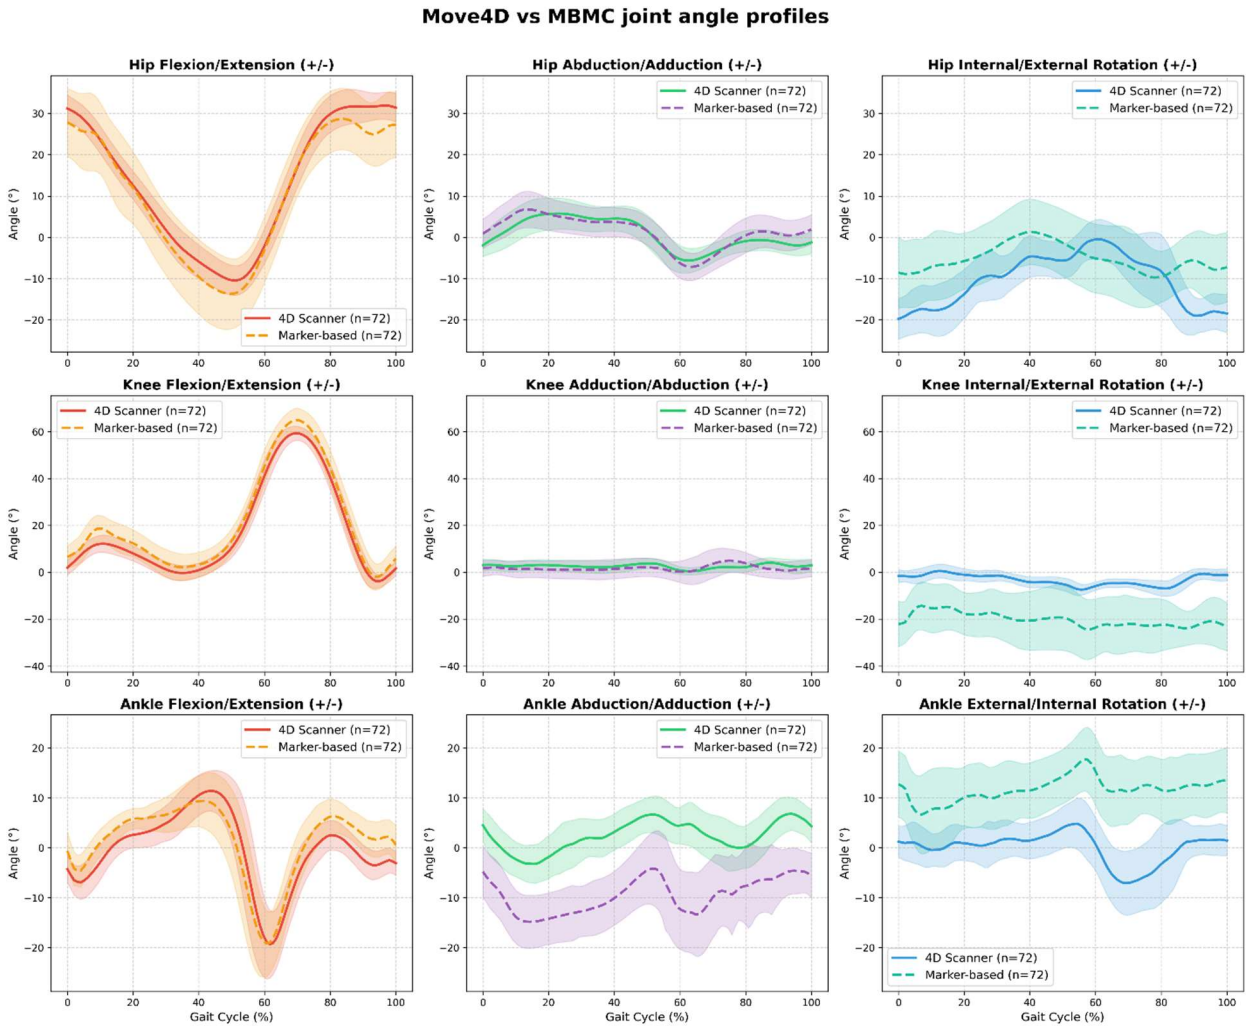
[1]Instituto de Biomecánica de Valencia. Universitat Politècnica de València, Valencia, Valencia, Spain. [2]Center for Digital Health & Social Innovation, University of Applied Sciences, St. Pölten, Mostviertel, Austria

Introduction

Gait analysis with marker-based motion capture (MBMC) is the clinical standard but is time-consuming and invasive. Markerless motion capture based on RGB videos (MMC) is a convenient alternative, but often suffers from high errors, especially for secondary angles outside the sagittal plane. Alternative MMC systems based on dynamic scans measuring human shape rather than estimate poses from RGB videos may mitigate these errors. This study compared lower limb joint angles derived simultaneously from the Move4D dynamic body scanner [1] and MBMC, against true bone motion observed in previous studies with fluoroscopy.

Methods

Twelve healthy subjects underwent standard gait analysis with three repetitions. 3D kinematic data were collected simultaneously using the pose model of Move4D and with a modified Cleveland Clinic Marker Set. Hip, knee and ankle joint angles (flexion/extension, abduction/adduction, internal/external rotation) were calculated following ISB recommendations. The resulting ranges of motion (ROM) and angle profiles were compared to published in vivo fluoroscopic data, which served as the gold standard reference for actual bone motion.



Results

The ROM of hip and ankle were consistent between both systems. The profiles of all hip angles and flexion-extension of knee and ankle were consistent, while differences emerged in secondary angles. The ROM of knee abduction/adduction was smaller in the Move4D data than for MBMC (5.1º vs 10.8º on average). While no differences were found in the ankle ROM, an offset between Move4D and MBMC was found in the secondary angles, possibly associated to the marker instrumentation error. The Move4D-derived secondary angles were closer to the published fluoroscopy values.

Discussion

The Move4D system provided convenient, non-invasive kinematic data for gait that is comparable with the results of MBMC in the main angles, and closer to the results of studies with fluoroscopy in secondary angles. The pose model derived from 3D body scans with precision < 1 mm [1] may overcome the error of soft tissue artifacts observed during standard marker-based motion capture. Therefore body scanning-based MMC seems to offer greater fidelity to true skeletal motion while providing a convenient analysis without markers or invasive methods.

Introduction

Runners risk developing metatarsal bone stress injuries (BSIs) due to the high impact, repetitive nature of the sport. Foot muscle strength has been identified as a modifiable risk factor for metatarsal BSI [1], but it remains unclear how strength influences arch biomechanics during running. We hypothesized that runners with stronger feet have higher arches that deflect less during loading.

Methods

Thirty-two runners (age:21.3±1.6, 16 male) who ran ≥24km/week participated in this institutionally approved study and provided written consent. Arch doming and lesser toe strengths were measured using a dynamometer and participants were divided into high and low foot strength groups. Barefoot running biomechanics data were collected to measure dynamic arch height index (dAHI), arch height deflection, and angular displacement of the midtarsal joint during stance. Maximum and minimum values and their timing were compared between groups using two-tailed t-tests. Statistical parametric mapping was used to compare dAHI throughout stance.

Results

Runners in the high strength group had flatter feet but their arches collapsed less. High strength runners had 2.9 times less negative arch deflection (Figure 1; p=0.04). They began increasing AHI earlier, so they achieved maximum dAHI and positive arch deflection 16.9% earlier in stance (p<0.01). The high strength group had 2.5º less midtarsal joint extension (p=0.04) which further suggests less arch collapse. These results suggest that the high strength group had more active muscle involvement that aided resistance to arch collapse and windlass mechanism engagement to maintain and increase dAHI.

Discussion

Our results align with the understanding that intrinsic foot muscles help regulate arch mechanics [2] and alter metatarsal loads [3]. This work offers possible explanations for

reduced injury risk seen in higher strength and lower arched athletes [1,4]. Foot strength training in runners can positively impact arch biomechanics. Decreased arch collapse may help reduce metatarsal strain and thereby reduce BSI risk. While exploratory, these results could be further substantiated in clinical trials evaluating the role of foot strengthening to modify risk for metatarsal BSI.

Images (Optional)

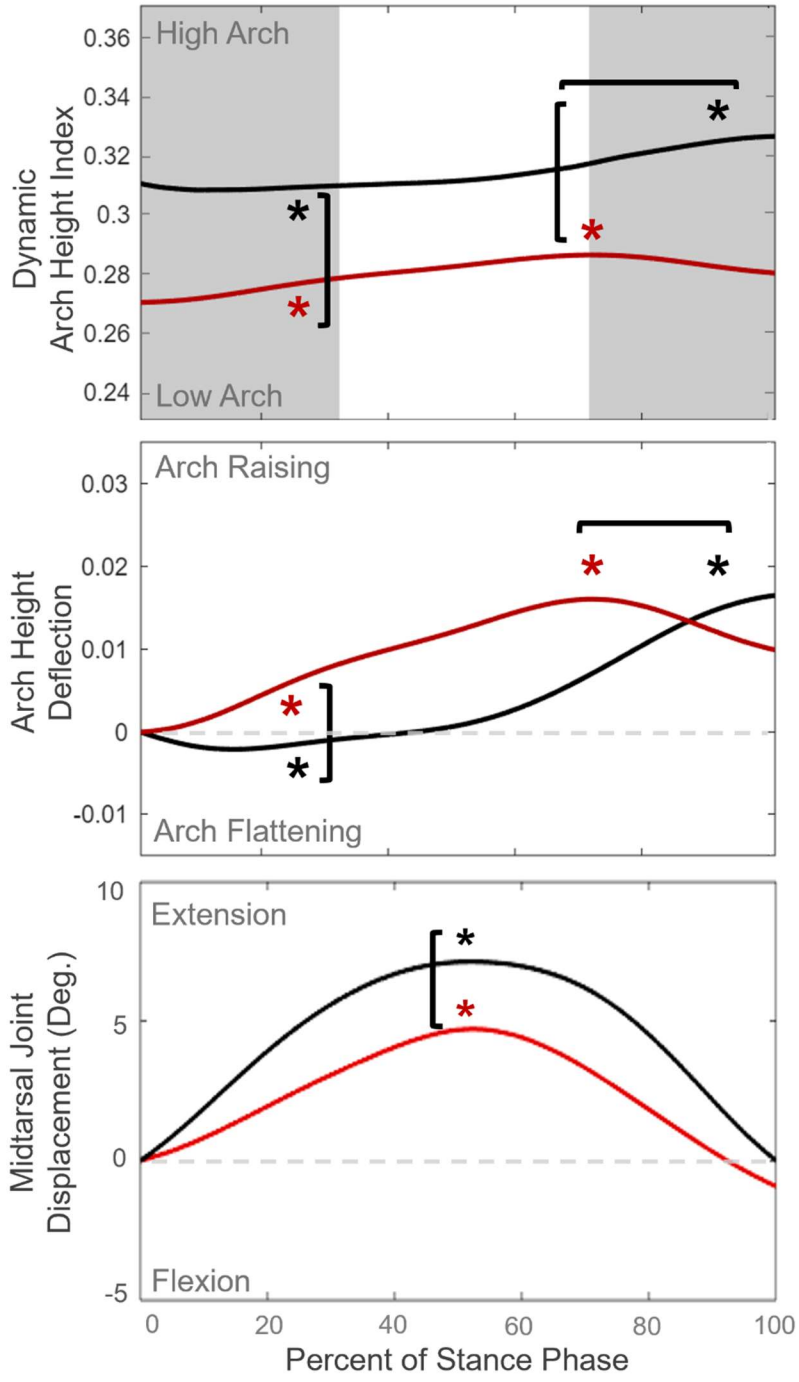

Figure 1. Dynamic arch height index, arch height deflection, and midtarsal joint displacement during running stance. High foot strength group is shown in **red**. Low foot strength group is shown in **black**. Grey-shaded regions indicate statistically significant differences between groups based on SPM analysis. Stars indicate significant differences. Vertical brackets reflect significant differences in min./max. magnitudes while horizontal brackets reflect differences in timing of those events.

Comparison of Two Heel-Strike Perturbation Intensities on Lower Limb Kinematics in Healthy Adults

Dr. Juliane Mueller Researcher (Post-doc), B.Sc. Anne Lotte Schneider Graduate, M.Sc. Nikolai Hepke PhD Student, Prof. Dr. Jörg Lohscheller Professor, Prof. Dr. Steffen Mueller Professor

Trier University of Applied Sciences, Trier, Rhineland-Palatinate, Germany

Introduction

Understanding the biomechanical response to gait perturbations is essential for advancing sensitive diagnostic approaches and enhancing fall-prevention strategies. This study analyzed the kinematic responses of healthy adults to two perturbation intensities applied during initial heel contact, aiming to determine the minimal perturbation strength required to elicit a meaningful kinematic response.

Methods

Fifteen healthy adults (8f/7m;30±9years;174±11cm;72±17kg) walked (1m/s) on an instrumented split-belt treadmill with two separately selectable belts, while two stimuli were randomly applied five times each during initial heel contact of the right leg (S_{Strong}: acceleration/duration: -11m/s^2/0.09sec; $S_{weak:}$ acceleration/duration: -6,7m/s^2/0.055sec). Kinematics of the lower extremity were recorded during normal gait (N) and stumbling ($S_{(Strong/Weak)}$) using a 3D motion analysis system (10 cameras (Vicon),200Hz;model: HBM2). Maximal joint flexion angles (°) and their timing within the gait cycle (%GC) were extracted for the ankle and knee joint of perturbed (PL,right) and contralateral leg (CL, left). Additionally, spatiotemporal gait parameters were extracted. Multiple one-way ANOVAs for dependent samples (post-hoc Tukey-Kramer; α=0.05) were used to compare outcomes between N, S_{Strong} and S_{Weak}.

Results

The PL showed a significant increase in maximum flexion of the ankle joint ($p<0.0001$) during S (compared to N) with significant differences between stimuli ($S_{Strong} > S_{Weak}$). The timing of maximum knee flexion in the gait cycle of PL shifted significantly ($p<0.0001$) during S without differences between both stimuli. The step width ($p=0.0001$) of the PL increased significantly during S without differences between stimuli. The CL showed a significant increase of maximum flexion for both joints (ankle:$p=0.0005$;knee: $p=0.0037$) as well as a significant shift of timing of maximum flexion for both joints (ankle: $p<0.0001$;knee: $p=0.0051$) with significant differences between stimuli only for the ankle.

The stride duration of the CL increased significantly (p=0.0005) during S with significant differences between stimuli (S_{Strong}> S_{Weak}). (Tab.1)

Discussion

Both artificially induced perturbations significantly altered lower-limb kinematics and spatiotemporal gait adaptations, indicating a progressive bilateral compensation strategy. Moreover, the strong perturbation induced earlier and more pronounced compensatory responses. However, these findings validate the perturbation protocol and highlight that both stimulus levels are suitable for population-specific applications (e.g. patients, athletes, elderly).

Evaluation of Learnable Triangulation for Lower-Limb Kinematics in Osteoarthritis Patients Using a Four-Camera Markerless System

Dr. Junqing Wang, Dr. Wei Xu, Prof. Yong Nie, Prof. Kang Li

West China Hospital, Sichuan University, Chengdu, Sichuan Province, China

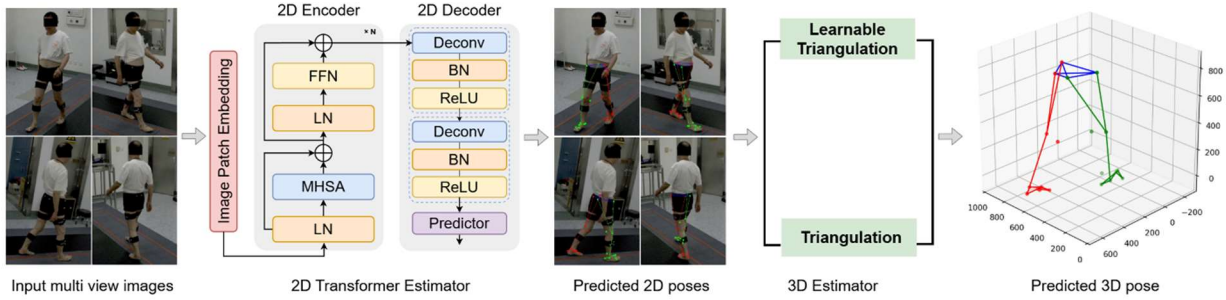
Introduction

Triangulation is a commonly used method for multi-view 3D pose estimation. However, when the number of cameras is limited, estimation accuracy may be compromised due to issues such as occlusion. Learnable triangulation can achieve superior estimation accuracy with fewer cameras. Nevertheless, whether this method can improve the estimation of lower-limb joint angles in patient populations remains unknown. Therefore, this study evaluated whether learnable triangulation could enhance the estimation accuracy of lower-limb joint angles compared to conventional triangulation in a dataset of patients with osteoarthritis (OA) using a four-camera system.

Methods

A total of 150 patients with end-stage hip or knee osteoarthritis were allocated to a training set (n=120) and a testing set (n=30). Kinematic data were synchronously collected at a frequency of 150 Hz as participants walked at a self-selected speed, using both a four-camera markerless system and a ten-camera marker-based system. The markerless algorithm was developed on the training set, including data preprocessing, 2D pose estimation, and 3D pose estimation (using learnable triangulation and conventional triangulation, respectively). On the testing set, the differences between the markerless and marker-based systems in terms of keypoints and lower-limb joint angles were evaluated using root mean square error (RMSE) and intraclass correlation coefficients (ICC).

Results



The grand mean RMSE for all keypoints predicted by learnable triangulation and conventional triangulation were 6.4 mm and 10.4 mm, respectively. The average RMSE for all joint angles using learnable triangulation and conventional triangulation were 3.79° and 4.23°, respectively. ICC values were higher in the sagittal plane (learnable triangulation: 0.96; conventional triangulation: 0.93), but lower in the frontal plane (learnable triangulation: 0.60; conventional triangulation: 0.56) and transverse plane (learnable triangulation: 0.32; conventional triangulation: 0.27).

Discussion

In a four-camera markerless system, learnable triangulation can improve keypoint prediction accuracy and subsequently enhance the accuracy of lower-limb joint angles in the sagittal plane; however, it does not improve the accuracy of lower-limb joint angles in the frontal and transverse planes. Since marker-based systems are also subject to errors due to soft tissue artifact, future studies could compare markerless results with more accurate methods such as biplane radiograph to evaluate their accuracy.

Classifying Possible Sarcopenia With a Single IMU Sensor While Walking in Older Adults

Mr. Junwoo Park PT, MSc, Dr. Kitaek Lim PT, PhD, Dr. Seyoung Lee PT, PhD, Mr. Jongwon Choi PT, MSc, Prof. Woochol Joseph Choi PT, PhD

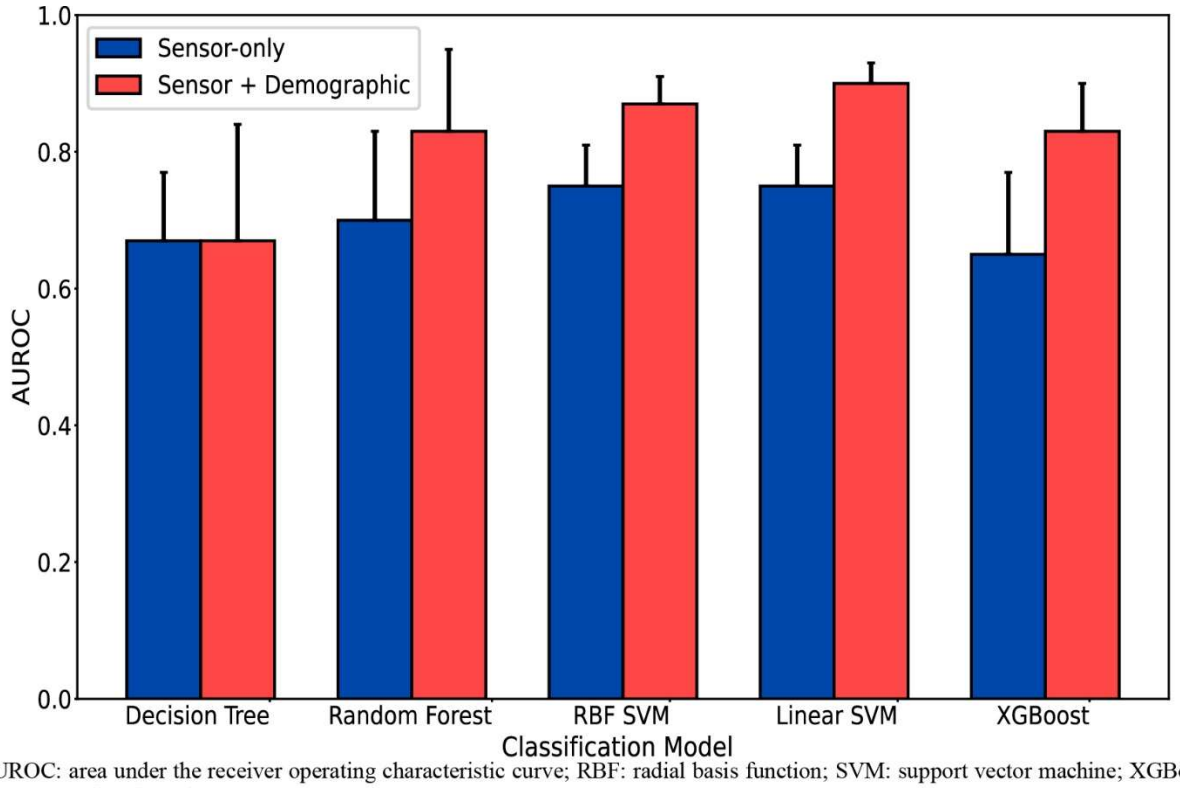
Injury Prevention and Biomechanics Laboratory, Department of Physical Therapy, Yonsei University, Wonju, Gangwon-do, Korea, Republic of

Introduction

Sarcopenia is a condition of aging-related skeletal muscle loss, and the Asian Working Group for Sarcopenia (AWGS) has suggested the clinical guidelines for identification of sarcopenia with calf circumference, muscle strength, physical performance, and skeletal muscle mass [1]. However, these are impractical for community or clinics use. We used machine learning algorithms to easily screen the possible sarcopenia with a single inertial measurement unit (IMU) sensor data collected while walking.

Methods

We recruited 57 older adults (13 males, 44 females; mean age = 78.7 years). Possible sarcopenia was defined when both of the following conditions were met based on AWGS guidelines: (1) at least one calf circumference smaller than 34 cm for men or 33 cm for women; and (2) either handgrip strength <28 kg for men or <18 kg for women, or a five-times sit-to-stand time ≥12 seconds. Twenty participants (2 males, 18 females) were classified as having possible sarcopenia. For the classification model input, IMU sensors were attached to 10 body segments, collecting kinematic data during 10 m walking. Input features included the mean and variance of IMU data per gait cycle, along with demographic information (height, weight, age, gender). Five machine learning models were developed to compare classification performance: linear/radial basis function (RBF) kernel support vector machine (SVM), decision tree, random forest, and extreme gradient boosting. Model performance was evaluated using 5-fold cross-validation.



Results

The RBF-kernel SVM model using IMU data from the left lower leg demonstrated the best performance, achieving an accuracy of 0.73 (0.06) and an area under the receiver operating characteristic curve (AUROC) of 0.75 (0.06). Furthermore, the linear SVM model that incorporated both left lower leg IMU data and demographic features yielded improved classification performance, with an accuracy of 0.80 (0.04) and an AUROC of 0.90 (0.03) (Figure 1).

Discussion

Our results indicate that a single IMU sensor can classify possible sarcopenia with moderate accuracy, and that performance improves by approximately 10% when demographic information is included. These findings support the integration of wearable sensor data with clinical characteristics to enhance the detection of possible sarcopenia in older adults.

Lower Extremity Joint Work Redistribution After A 30-Minute Treadmill Walk Is Not Explained By Baseline Walking Mechanics, Knee Extensor Strength, Or Physical Activity In Older Adults

Mr. Justin R. Matties MS, Dr. Ross J. Brancati PhD, Ms. Zoe H. Smith PhD, Dr. Jane A. Kent PhD, Dr. Katherine A. Boyer PhD

University of Massachusetts, Amherst, MA, United States

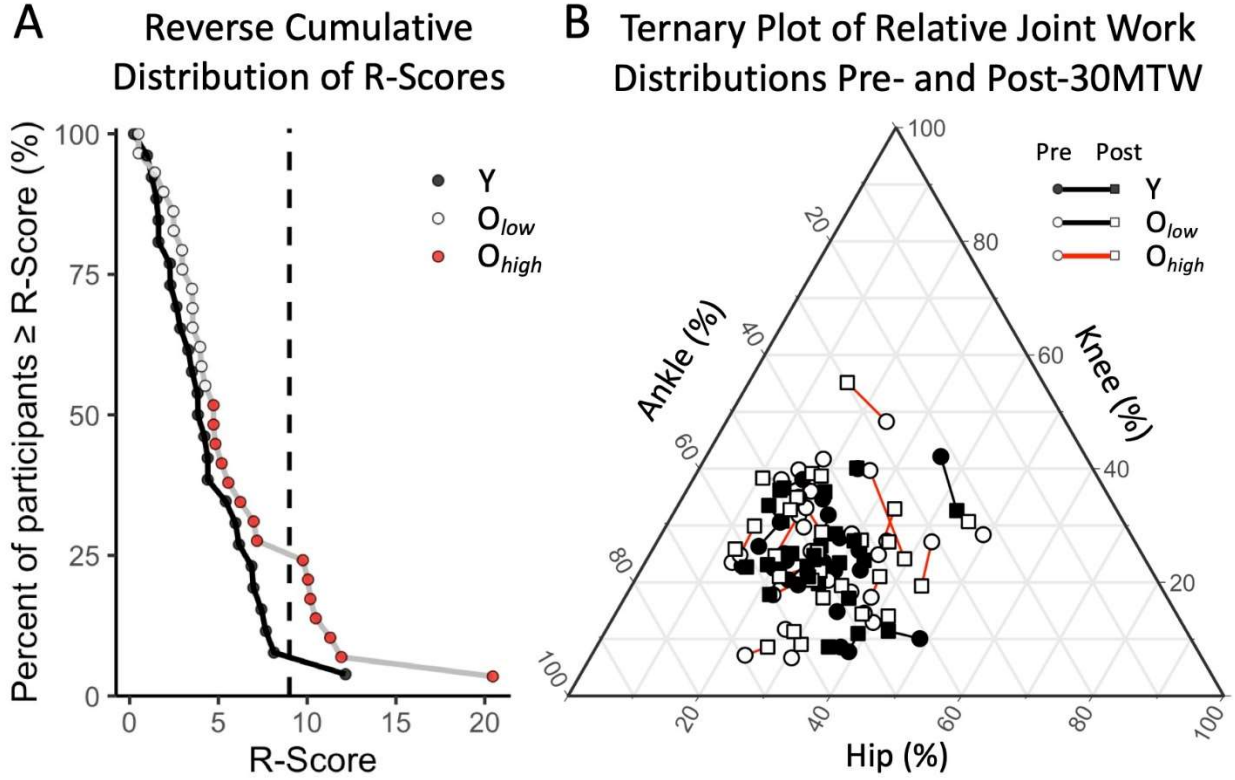
Introduction

Older adults (O) may experience greater changes in performance in response to standardized bouts of activity (i.e., higher fatigability) than younger adults (Y) [1]. The potential interactions between altered gait mechanics, low habitual physical activity and muscle weakness in this fatigability have not been determined. Thus, we compared baseline characteristics and the responses to a 30-minute treadmill walk (30MTW) at preferred walking speed (PWS) in Y and O.

Methods

Twenty-six Y (34.7±3.2 yr, n=15 female, BMI: 24.5±3.5 $kg \cdot m^{-2}$, PWS: 1.13±0.14 $m \cdot s^{-1}$) and 29 O (73.0±2.6, n=19 female, BMI: 26.4±3.8, PWS: 1.14±0.14) wore an accelerometer (ActiGraph) to quantify minutes of weekly moderate-to-vigorous physical activity (MVPA). Overground sagittal plane joint kinematics and kinetics at PWS were calculated pre- and post-30MTW. Isometric knee extensor (KE) torque and isokinetic KE power were measured at $120° \cdot s^{-1}$ and $240° \cdot s^{-1}$ (Biodex). Changes in the relative distribution of ankle, knee and hip positive joint work were quantified as an overall redistribution score (R-score): the Euclidean distance between relative joint work distribution pre- and post-30MTW. O were bisected into high (O_{high}) and low (O_{low}) R-score groups. Group differences in baseline MVPA, KE peak torque, and gait kinematics and kinetics were assessed with ANOVAs, with Tukey HSD comparisons reported when a significant main effect was observed ($p < 0.05$).

Results



R-score >9 was observed in 24.1% of O and 3.8% of Y (Figure 1A). O_{high} exhibited a greater R-Score compared to O_{low} and Y ($p<0.001$) (Figure 1B). R-scores did not differ between O_{low} and Y ($p=0.255$). Peak isometric KE torque and power were lower in O_{low} and O_{high} than Y ($p<0.001$), but not different between O_{low} and O_{high} ($p>0.883$). MVPA ($p=0.364$), and pre-30MTW gait mechanics were not different between groups ($p\geq0.400$).

Discussion

A greater proportion of O had an altered gait strategy post 30MTW, though a common direction of change was not observed (Figure 1b). These data indicate that exercise induces gait changes independent of baseline characteristics. Future work should investigate these gait changes, captured by R-score, as contributors to fatiguability in O.

How Residual Limb Length in Individuals with Unilateral Transfemoral AmputationAffects Body Weight Transfer

Mr. Kai Kobayshi B.Sc., Mr. Shunta Kobayashi B.Sc., Assoc.Prof. Hiroaki Hobara Ph.D.

Tokyo University of Science, Toyko, Tokyo, Japan

Introduction

Weight transfer during double-limb stance is fundamental for forward progression and the maintenance of gait stability [1]. In this phase, effective weight acceptance by the leading limb is particularly critical. Among individuals with unilateral transfemoral amputation (uTFA), shorter residual limbs possess reduced musculature and leverage, potentially limiting their capacity to support body weight [2]. Although weight-transfer strategies in prosthesis users are influenced by loading/unloading responses at push-off and walking speed [3], the contribution of residual limb length to weight-transfer mechanics remains unclear. Therefore, we investigated how residual limb length influences weight transfer in individuals with uTFA.

Methods

Twenty-six individuals with uTFA and four individuals with knee disarticulation (KD) were recruited. Participants with uTFA were classified into Short, Middle and Long groups using tertile segmentation of the residual to intact femur length ratio. All participants walked on an instrumented treadmill at eight speeds (2.0-5.5 km/h), and ground reaction forces (GRFs) were collected at 1 kHz. From the vertical GRF, the first (Fz1) and second (Fz2) peaks were extracted for each step. Loading rate (LR) was calculated as Fz1 divided by the time from initial contact to Fz1, and unloading rate (uLR) as Fz2 divided by the time from Fz2 to toe-off. A three-way mixed-effects ANOVA compared prosthetic- and intact-leading conditions across limb-length groups and speeds ($P < 0.05$).

Results

No significant differences among residual limb length groups were found at any speed or leading limb condition for either parameter.

Discussion

The present findings indicate that residual limb length does not meaningfully influence body-weight transfer during gait, as neither LR nor uLR differed across limb-length groups

at any walking speed or under either leading-limb condition. These results suggest that weight acceptance on the prosthetic side may rely not on residual musculature but on compensatory hip extensor activation.

Introduction

Post-menopausal estrogen loss and age-related sarcopenia reduce collagen synthesis in middle-aged and older women, increasing soft-tissue laxity and weakening the foot arch [1]. These morphological changes impair the foot's ability to store and return energy during locomotion, raising the metabolic cost of walking. This decline is particularly common among older women working long hours in weight-bearing occupations. Although foot-strengthening exercises can be beneficial, adherence is often low due to the time and effort required for women who are actively working. Considering that custom insoles (CIs) can redistribute plantar pressure and enhance sensory input to support more efficient gait [2], we evaluated the effectiveness of CIs in improving walking efficiency in middle-aged women in prolonged weight-bearing occupations.

Methods

15 women over the age of 55 working in jobs that require more than 4 hours of standing per day were recruited for this study. We used a three-dimensional (3D) foot morphology

captured using a foot scanner (MediACE Scan: MS320F) to print CIs made up of thermoplastic polyurethane (TPU) that support the medial longitudinal arch and stabilize the rearfoot to improve shock absorption and energy storage for propulsion. We compared the effectiveness of the CIs with commercially available prefabricated insoles (PIs) without medial arch support in reducing O_2 cost recorded with a portable metabolic analyzer (VO_2 Master) during 5 minutes of treadmill walking. The O_2 cost was calculated as the difference in the O_2 consumption between the last 1 minute of walking and 2 minutes of resting before walking, divided by the walking speed. We compared the O_2 cost between CIs and PIs using paired t-test ($p<0.05$).

Results

We found that wearing CIs significantly reduced the O2 cost, on average by 18.4% (Fig.1), during walking in 15 participants than PIs ($t_{[14]}=3.585$, $p=0.003$).

Discussion

In this study, CIs that are practical for use with everyday shoes effectively reduce oxygen consumption in middle-aged and older women working in prolonged weight-bearing occupations. Future studies may consider evaluating the long-term effects of using CIs on walking efficiency and muscular function.

Energy Expenditure-Based Simulations Reveal Neural Contributions to Modular Control of Walking Biomechanics

Ms Kaitlyn Downer, Dr. Jessica Allen PhD

University of Florida, Gainesville, Florida, United States

Introduction

Motor modules have been proposed as a neural control strategy for complex movement, though some argue they arise purely from biomechanics [1]. We used subject-specific simulations to test whether motor modules reflect a control strategy by varying the cost function while keeping biomechanics constant. If motor modules represent an underlying control strategy, changing cost function components would influence motor module complexity and structure.

Methods

Kinematics and kinetics from seven older adults (5F; 62.7±6.3 years) walking at their self-selected speeds were used in OpenSim Moco tracking simulations. Ten gait cycles per subject were simulated to capture variability. Simulations minimized either sum of squared activations (effort) or metabolic cost of transport (CoT), with varying weights to capture different prioritization of energy expenditure. Effort weights spanned 4 orders of magnitude, while CoT simulations were dynamically weighted to achieve low (3-5 J/kg/m) and high (6-8 J/kg/m) CoT. To ensure consistent biomechanics, simulated gait cycles with solutions with RMSE >5 degrees were removed. Motor modules were extracted from simulated muscle activity and compared across simulations. Complexity was quantified as variability not explained by one module (VNAFby1). To quantify structure, four modules were extracted from each simulation [2] and compared using Pearson's correlations.

Results

All subjects had 6-10 valid gait cycles for analysis. Both motor module complexity and structure were influenced by the cost function. Increasing priority on energy expenditure generally increased complexity (higher VNAFby1; Fig. 1A). Module structure also varied across cost functions (Fig. 1B). Within model comparisons (Effort vs Effort, CoT vs CoT) were more correlated than between model comparisons (Effort vs CoT), indicating that the choice of expenditure model impacts motor modules. Variability in structure was also present within the same expenditure model, showing that the weight on the term influences module structure.

Discussion

These results support the result that motor modules reflect not only biomechanical constraints but also neural control strategies. Since clinical populations often show altered modules, rehabilitation should target neural control (e.g. EMG-guided protocols) in addition to biomechanics.

Introduction

Knee osteoarthritis (OA) is a leading cause of disability in older adults [1]. Understanding gait and mobility in individuals with knee OA can inform interventions. Past work has shown that healthy individuals adapt their lower-extremity coordination in response to different walking surfaces [2]; however, the effects of surface on clinical populations remain unclear. This study aims to compare walking coordination biomechanics in knee OA on flat and irregular surfaces.

Methods

Ten adults with knee OA (40–75 years) were recruited. Kinematic data were collected using eight Xsens Awinda (Movella Inc., The Netherlands) Inertial Measurement Units attached to the pelvis, bilateral thighs, shanks, and feet. Participants completed ten 4-m walking trials on flat (hospital hallway) and irregular (polyurethane floor panels; Terrasensa, Germany) surfaces. Coordination amplitude and variability were quantified using Mean Absolute Relative Phase (MARP) and Deviation Phase (DP), respectively, computed from Continuous Relative Phase analysis [3] based on knee and hip sagittal-plane joint angles. Differences between surfaces were evaluated using Statistical Parametric Mapping (SPM) paired t-tests ($\alpha = 0.05$).

Results

Results from five of the participants were analyzed. Knee–hip MARP was consistently lower on the irregular surface, indicating more in-phase coordination compared with the flat surface, during the initial–mid swing phase (~70–80% of the gait cycle) (Fig. 1a, b). Knee–hip DP values appear increased on the irregular surface across the gait cycle, suggesting

greater coordination variability; however, this difference was not statistically significant (Fig. 1c, d).

Discussion

Our preliminary data indicate that irregular terrain elicits greater knee-hip in-phase coordination (lower MARP), suggesting a stability-oriented strategy. The irregular surface challenges the neuromuscular system, and this coordination pattern may help maintain upright stability and reduce fall risk. The absence of significant DP differences may reflect the small sample size. The ongoing study will recruit more participants, with future analyses examining additional kinematic measures (e.g., joint angles, range of motion) and other joint pairs (e.g., ankle–knee coordination).

Images (Optional)

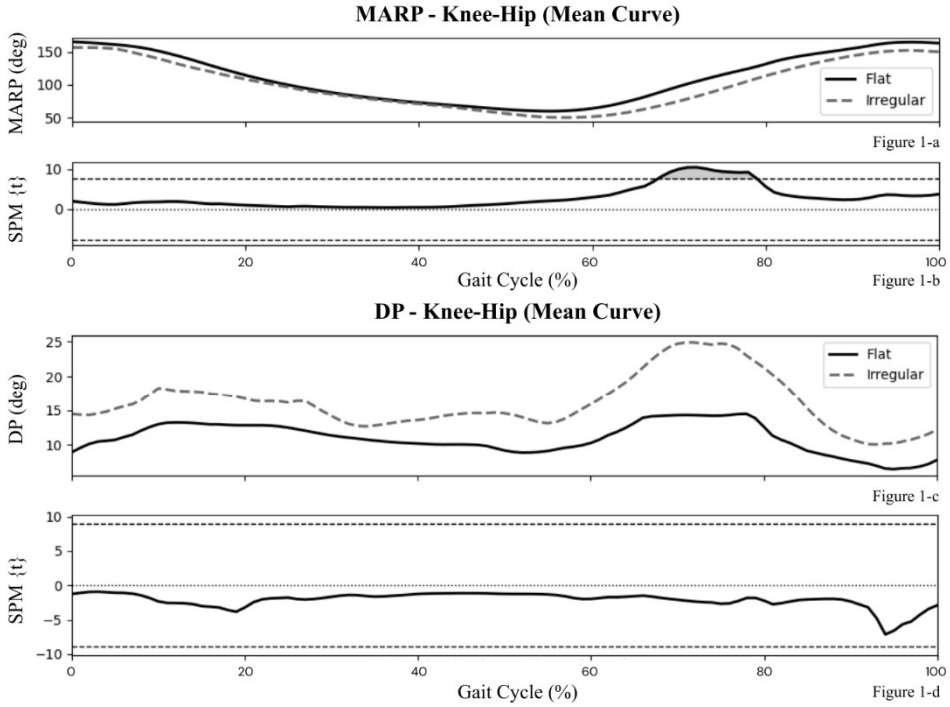

Fig. 1. Panels a and c show the mean knee–hip MARP and DP curves on different surfaces across the entire gait cycle. Panels b and d present the corresponding SPM t-tests for MARP and DP. Grey-shaded regions in the panel b indicate periods of significant difference. A positive significant region in panel c indicates that the flat surface elicited higher values.

Effect of Emotional Expression on Upper Body Kinematics in Novel Movements

Ms. Katherine Elder MS, Dr. Melissa Gross PhD

University of Michigan, Ann Arbor, MI, United States

Ms. Katherine Elder

Introduction

Emotion expressed during ordinary movements like gait and sit-to-stand can be recognized by others and affects the movement kinematics. Similarly, emotion can be recognized in novel movements without a functional goal like arm gestures or dance, but little is known about the effect of emotion on the kinematics of these movements. In a study of a simple arm gesture comprising shoulder adduction from vertical to horizontal position with free movement of elbow and wrist joints, investigators found that maximum linear velocity and acceleration of the fingertips were significantly greater for anger than for sadness. The purpose of this study was to investigate the effect of emotional expression on the kinematics of a complex novel movement of the upper body.

Methods

A professional-level dancer was asked to create a short movement phrase using their upper body. The phrase was split into six gestures for analysis: gather, tilt, sweep, curl, press, and drop. Three trials were performed while expressing each of four emotions: neutral, sadness, anger, and joy, and motion capture data were collected. Visual3D was used to calculate resultant velocity and acceleration of the hands and custom Matlab code was used to extract maximum values. Significant differences were detected using ANOVA with Bonferroni post hoc comparisons.

Results

Velocity of the right and left hands was significantly affected by emotion in 3 of 6 gestures (Table 1). In general, across gestures, hand velocities decreased with sadness compared to the high arousal emotions (anger and joy). Hand acceleration was less affected by emotion, with sadness decreasing hand acceleration compared to anger in two gestures.

Discussion

We found that hand velocities and accelerations can be used to discriminate among emotions, particularly anger and sadness, consistent with previous findings for simple movements. With complex movements, however, we found that more emotions could be discriminated with analysis of only hand kinematic data, i.e., anger and joy, possibly because complex movements encode more information about emotion. Since human movement is inherently complex and often novel, future studies of emotion expression should be based on complex movement and include even more kinematic variables.

Images (Optional)

Table 1. Maximum resultant linear velocities and accelerations

Gesture	Kinematic Variable	Anger	Joy	Neutral	Sadness
Gather	Right Hand Velocity (m/s)	7.38 ± 0.98^{S}	7.35 ± 1.38^{S}	4.92 ± 0.47	$3.06 \pm 0.08^{A, J}$
	Left Hand Velocity (m/s)	$4.76 \pm 0.25^{J, N, S}$	3.69 ± 0.27^{N}	2.75 ± 0.45^{J}	$1.42 \pm 0.25^{A, J, N}$
	Left Hand Acceleration (m/s^2)	130.32 ± 50.58^{S}	67.06 ± 2.87	60.89 ± 5.21	37.28 ± 4.34^{A}
Sweep	Right Hand Velocity (m/s)	3.38 ± 1.21^{S}	3.23 ± 0.44^{S}	3.07 ± 0.38	$1.14 \pm 0.32^{A, J}$
	Left Hand Acceleration (m/s^2)	13.27 ± 5.61^{S}	5.74 ± 2.23	8.89 ± 3.43	2.51 ± 0.87^{A}
Press	Right Hand Velocity (m/s)	0.19 ± 0.06^{N}	0.22 ± 0.06^{N}	$0.04 \pm 0.02^{A, J}$	0.07 ± 0.03

All $p < .05$. Superscripts indicate values are significantly different from anger (A), joy (J), neutral (N), sadness (S).

A Simple Resync Method for Wearable Inertial Sensors to Track Knee Flexion for 5 Days With High Fidelity

Dr. Ke Song, Dr. Josh Baxter

University of Pennsylvania, Philadelphia, Pennsylvania, United States

Introduction

Knee motion is critical for joint health, yet its real-world impact is not captured by in-lab motion analysis. While inertial measurement unit (IMU) provides a new way to track real-world knee motion, few confirmed the validity of week-long IMU data where sensor sync may be inaccurate due to device clock drift. A reliable post-hoc resync method is warranted.

Methods

5 healthy individuals (3M/2F) wore 4 IMUs on their thighs and shanks using medical tapes (**Fig. 1A**), for 5 continuous weekdays (Mon-Fri) that also included 3 in-lab markerless motion capture sessions (Mon, Wed, Fri) on walking, squat, step up/down, and sit-to-stand. Before attaching IMUs Monday and after detaching Friday, we inserted all IMUs in a custom-made "resync tool" (**Fig. 1B**) and swung it to produce a sync signal. We cross-correlated thigh/shank IMU sync signals to identify their time offsets on Mon and Fri, thereby relative clock drift over the week. We removed this drift by linearly "dilating" the faster IMU clock to match the other. After resyncing, we applied sensor-to-segment realignment to define the knee anatomical frame, then accelerometer-gyroscope fusion to calculate flexion. We compared IMU-estimated dominant-leg knee flexion to motion capture on all 3 days (Mon, Wed, Fri) using Pearson correlation and root-mean-square difference (RMSD).

Results

IMU clock drifts varied among participants (0.005–0.041 sec/hour). Our resync tool successfully removed this drift, and our IMU-estimated knee flexion strongly agreed with motion capture on all 3 days with high correlations (Mon: ≥0.948, Wed: ≥0.941, Fri: ≥0.906) and small RMSDs (Mon: ≤5.2°, Wed: ≤5.8°, Fri: ≤5.5°) (**Fig. 1C**).

Discussion

We demonstrate that leg-worn IMUs reliably track knee motion over a 5-day span, including mid-experiment (Wed) where linear drift rate was correctly assumed. This is a major advancement over single-session validations and is enabled by our simple resync method

that IMU wearers can perform at home. Our cost-friendly paradigm captures week-long data with minimal wearer interaction, which will help accelerate the translation of IMU technologies to larger clinical studies. We will leverage our novel approach to track multi-day knee mobility in osteoarthritic knees and determine how it relates to chronic disease progression.

Functional Electrical Stimulation of the Biceps Femoris Long Head Reduces Knee Internal Rotation Moment During Gait

PhD Candidate Koen Jongbloed MSc (Mechanical Engineering), Graduate Researcher Jacob Kok MSc (Mechanical Engineering), Professor Frans Van der Helm PhD, Associate Professor Eline Van der Kruk PhD

Delft University of Technology, Delft, Zuid-Holland, Netherlands

Introduction

Anterior cruciate ligament (ACL) injuries frequently lead to persistent gait alterations and increased risk of reinjury and osteoarthritis [1] [2]. Functional electrical stimulation (FES) applied to the biceps femoris long head (BFLH) during early stance may help reduce ACL-relevant knee loading in gait by counteracting anterior tibial translation and internal tibial rotation [3][4]**.** Repeated use may improve neuromuscular control, contributing positively to both the rehabilitation process and overall clinical outcomes. The aim of this study was to evaluate the reduction in knee joint loading during BFLH-targeted FES and to assess the after-effects of repeated FES on neuromuscular control following removal of the stimulation in healthy controls.

Methods

Nine healthy participants (24.4±1.08 years, 5M 4F) each completed two treadmill sessions after warm-up comprising 3 conditions: 4 min control, 4 min FES, and 4 min post-stimulation. FES (40 Hz, 350 µs pulse duration, 300 ms stimulation duration, Odstock FSR, intensity: max tolerable) was delivered via surface electrodes to the dominant BFLH at heel strike. Kinematic and kinetic data were collected on an instrumented treadmill (1000Hz, Motek, Vicon 100 Hz). and processed using a full-body gait model (Vicon Nexus, CGM2.5, 3-DOF joints). Statistical parametric mapping (SPM1D) identified significant differences over the gait cycle, and linear mixed-effects models evaluated changes across repeated exposure, after-effect, and retention phases.

Results

In the stimulated leg, FES significantly reduced the internal knee rotation moment (KRM) by 9.4% during 42–48% of the gait cycle compared to control ($p=0.0002$; $d=0.42$). Knee adduction moment (KAM) showed no reduction. No significant after-effects were observed.

Discussion

BFLH stimulation reduced internal rotational knee loading during gait in healthy adults. We did not observe changes in knee kinematics or kinetics after stimulation, indicating no clear evidence of lasting motor adaptation. These findings support the use of BFLH-targeted FES as an assistive strategy to modulate ACL-relevant knee loading in healthy adults. Future studies should refine stimulation protocols, and investigate effects in ACL-deficient populations.

Images (Optional)

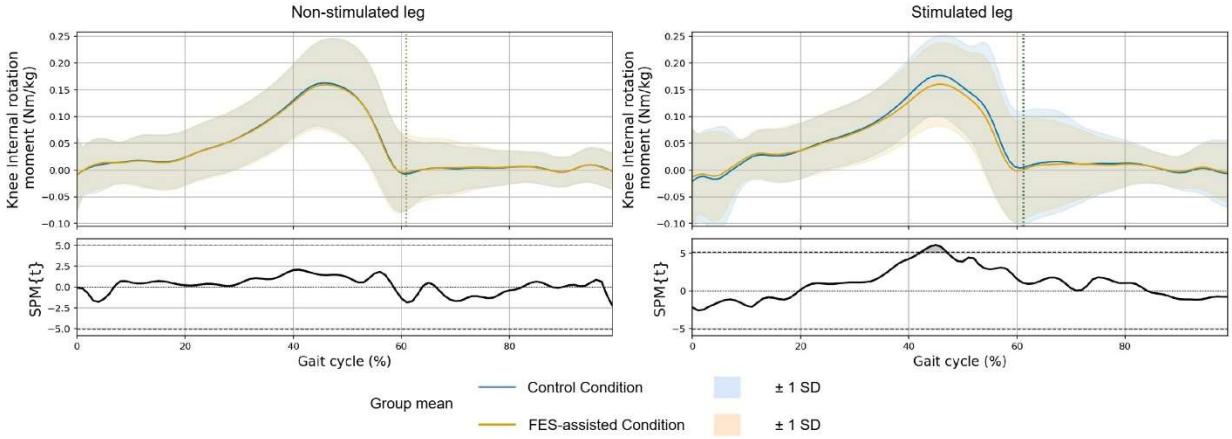

Figure 1: Mean KRM across the gait cycle for all participants during control (blue) and FES-assisted (orange) walking. Data are shown for the non-stimulated and stimulated legs, normalized to 0–100% of the gait cycle.

Event-Specific Characteristics of Mediolateral Margin of Stability During Walking

Mr. Kouichi Suzuki B.Sc., Mr. Kai Kobayashi B.Sc., Mr. Shunta Kobayashi B.Sc., Assoc. Prof. Hiroaki Hobara Ph.D.

Tokyo University of Science, Tokyo, Tokyo, Japan

Introduction

Margin of stability (MoS) is widely used to quantify dynamic stability during walking [1]. Although the MoS was originally evaluated as the minimum value within a gait cycle, recent studies have evaluated the MoS at Heel Contact (HC) and Toe-Off (TO) [1, 2]. Event-based MoS values reflect the stability characteristics of each phase; however, the differences in the MoS between gait events have not been systematically examined. Therefore, the aim of the present study was to clarify the characteristics of MoS at multiple gait events.

Methods

Six healthy individuals were recruited. All participants walked at six speeds (2.0-7.0 km/h) on an instrumented treadmill, and ground reaction forces and moments were collected at 1 kHz. Mediolateral (ML)_Center of Pressure (CoP) position, ML_Center of Mass (CoM) position and ML_CoM velocity were calculated from these data [3]. MoS was defined as the distance between CoP and XCoM where

MoS=CoP-XCoM

$XCoM=CoM+v_{CoM}/(\sqrt{g/l})$

in which g is gravitational acceleration and l is leg length. ML_MoS at HC and TO were extracted for each gait cycle and compared across all walking speeds. Normality was assessed using the Shapiro–Wilk test. When the assumption of normality was met, a two-way repeated-measures ANOVA was performed ($p < 0.05$).

Results

There were significant main effects of speed ($p < .001$) and gait event ($p < .001$) on ML_MoS. ML_MoS at TO were significantly smaller than at HC across all walking speeds ($p < .001$). We also found a significant interaction effect on ML_MoS ($p = 0.025$).

Discussion

ML_MoS magnitude is not the same between HC and TO, indicating that these two events represent different aspects of mediolateral dynamic stability within the gait cycle. Moreover, the magnitude of the difference in ML MoS between the two events varies with walking speed.

A Young Mind vs. the Aging Brain: Age-Based Differences in a Virtual Reality Dual-Task Paradigm

Ms. Kristen De Melo MSc., PhD Candidate, Ms. Emily Marino BSc. Candidate, Dr. Lori Ann Vallis PhD

University of Guelph, Guelph, Ontario, Canada

Ms. Kristen De Melo

Ms. Emily Marino

Introduction

Maintaining the ability to dual-task (DT) is critical for functional independence; however, this ability begins to decline as early as age 40 and accelerates after age 65 [1,2]. These declines in motor-cognitive performance mirror early neurological changes, increases in fall risk, and highlight vulnerability in shared neural resources [2,3]. This study aims to explore DT interference and the role of cognition in movement control, with the long-term goal of identifying early markers and targets for non-invasive intervention.

Methods

Gait and cognitive performance were recorded (OptiTrack, 120 Hz; Corvallis, USA) as participants (18-35yrs and 60-80yrs) completed an adapted Simon effect task in virtual reality (Vive Pro 2 Headset). While walking, an arrow appeared (location: top left, right, or middle of virtual world) to indicate navigation direction around a “sinkhole” in two virtual environments (forest, hallway). This produced congruent (e.g., right-pointing arrow on the right), incongruent (e.g., right-pointing arrow on the left), and neutral trials (middle of screen). We hypothesized greater DT interference (e.g., slower gait, diminished step patterns) in older adults (OA) compared to younger adults (YA), highlighting reduced motor-cognitive integration capacity. ANOVA statistical analyses were conducted with significance set at $p<0.05$.

Results

Preliminary analyses (YA: N=3; 22.3±4.9yrs, OA: N=3; 61.7±1.2yrs) revealed variations in arrow congruency and virtual environment did not produce significant changes ($p>0.05$). However, when OA were required to transiently adapt their gait (e.g., sinkhole avoidance), they demonstrated reduced velocity and an increased time to approach the sinkhole and complete the trial compared to YA ($p<0.05$). Additionally, OA transitioned from narrow, long steps during straight walking to wider, shorter steps during gait adaptation trials, mimicking typical YA patterns ($p<0.05$). Data collection and processing are still ongoing.

Discussion

These findings highlight age-related vulnerabilities in DT and indicate that both cognitive control and movement coordination are promising targets for training. Ongoing work in this cohort will explore whether targeted cognitive and motor-cognitive training can reduce DT costs and improve functional performance, particularly in OA.

Compensatory Muscle Activation Patterns of Lower Limb Muscles During Walking

Ms. Kyubin Chun, Prof. Seungbum Koo

KAIST, Daejeon, Daejeon, Korea, Republic of

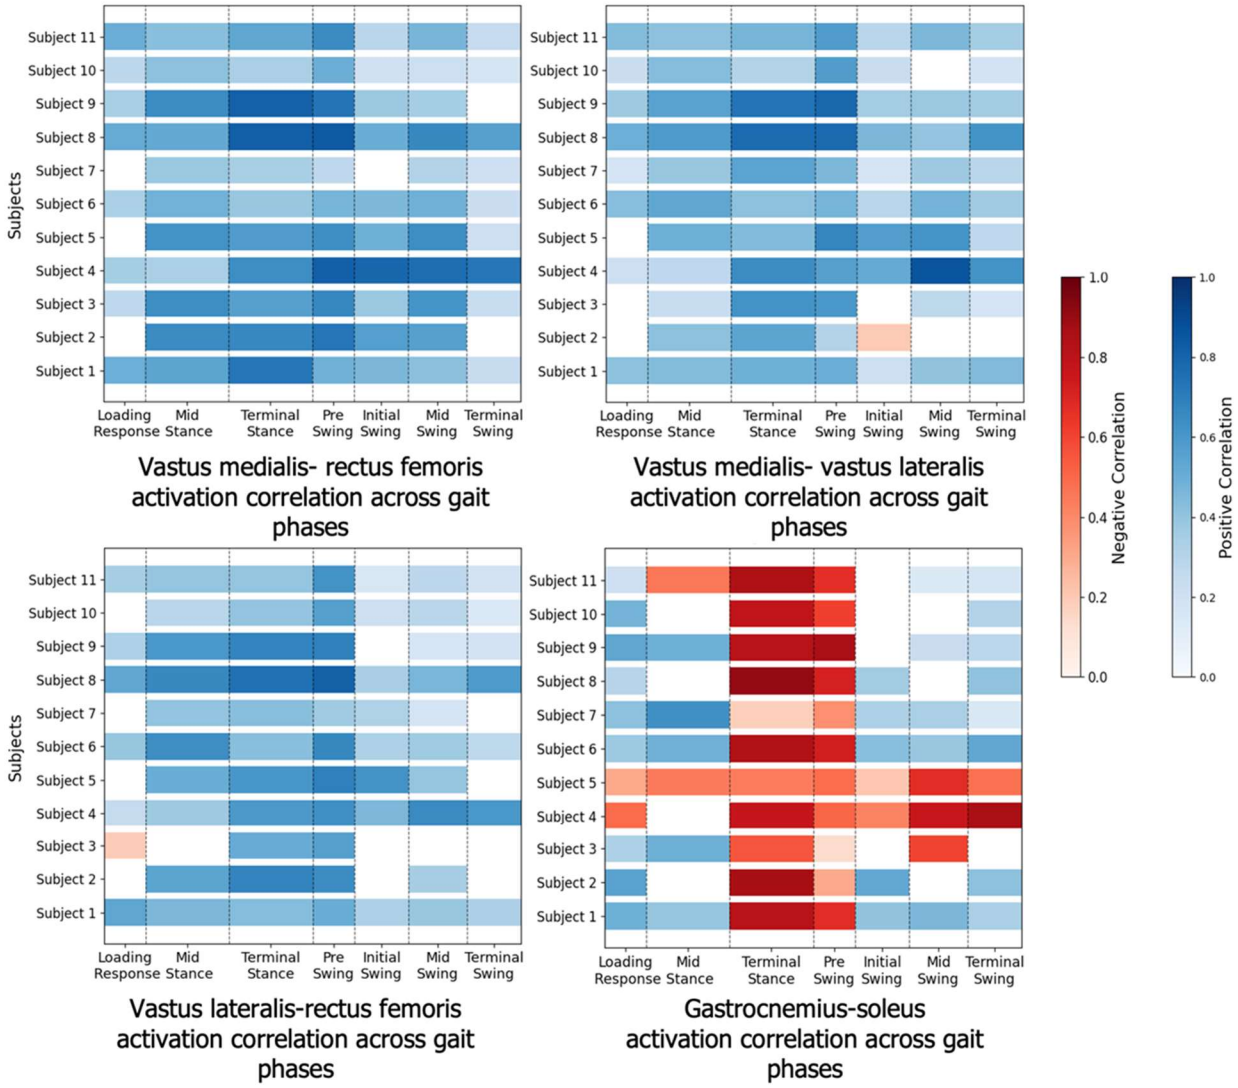
Introduction

Human gait can be reproduced consistently across strides. Although joint angle variability during walking remains low [1], lower-limb muscle activation shows high variability [2]. This shows that similar gait kinematics do not necessarily result in consistent muscle activity. Motor redundancy has been reported as a potential explanation for this variability [3]. This study proposes that the ability to sustain consistent walking despite variability in muscle activation can be attributed to coordinated interactions among muscles. We hypothesize that within a muscle group with similar functions, a decrease in the activation of one muscle will be accompanied by an increase in the activation of another.

Methods

IRB approval and informed consent were obtained prior to testing. Eleven male participants walked on a treadmill for five minutes. Muscle activity was recorded from the quadriceps (vastus medialis, vastus lateralis, rectus femoris) and the plantar flexors (gastrocnemius, soleus) to investigate compensatory mechanisms. Gait cycle was divided into seven distinct phases. Mean activation values were computed for each phase. Since muscle activity may be influenced by the muscles from other functional groups, activation values were normalized using the muscle set reported in [4]. Pearson correlation coefficient was calculated between muscles within the same functional group ($p < 0.05$).

Results



For plantar flexors, all subjects exhibited negative correlations during terminal stance and pre-swing phases. In contrast, correlations in quadriceps muscles were consistently positive. The vastus medialis–rectus femoris pair showed positive correlations across all gait phases with significant correlation. Similarly, the vastus medialis–vastus lateralis and vastus lateralis–rectus femoris pairs demonstrated positive correlations in most gait phases with significant correlation.

Discussion

Negative correlations in the plantar flexors during push-off support the presence of compensatory mechanisms. Conversely, quadriceps muscles exhibited consistently positive correlations. This demonstrates an opposite inter-muscular relationship. These

findings contradict the compensatory hypothesis for the quadriceps and instead suggest that they function as a unified group.

Comparison of Optical and IMU-Based Gait Classification in Ankle Arthrodesis Using Machine Learning

Dr. Leandra Bauer[1,2], Dr. Andreas Brand[3,4], Prof. David Rügamer[5,6], Prof. Sebastian Baumbach[2,7]

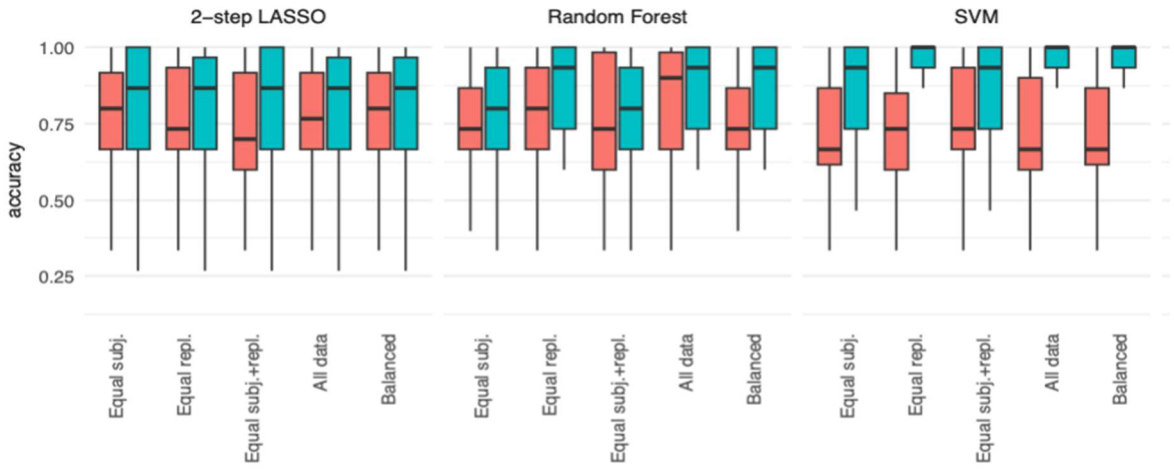
[1]Experimental Orthopaedics, University Hospital Jena, Campus Eisenberg, Waldkliniken Eisenberg, Friedrich-Schiller-University Jena, Jena, Thuringia, Germany. [2]Department of Orthopaedics and Trauma Surgery, Musculoskeletal University Center Munich (MUM), University Hospital Munich, LMU Munich, Munich, Bavaria, Germany. [5]Department of Statistics, LMU Munich, Munich, Bavaria, Germany. [6]Munich Center for Machine Learning (MCML), Munich, Bavaria, Germany. [7]OrthoPlus, Munich, Bavaria, Germany

Introduction

Optical motion capture (OMC) systems remain the gold standard in clinical motion analysis. Inertial measurement units (IMUs) offer a cost-effective and practical alternative. Recent developments enable multi-segmental modeling of the foot even in IMU applications, thereby expanding their clinical significance [1,2]. The aim of this study was to compare the ability of IMU and OMC systems to perform automated classification based on different ankle arthrodesis using machine learning (ML) methods.

Methods

In a prospective, bicentric study, 70 patients with tibiotalar (n = 34) or subtalar arthrodesis (n = 36) were compared. Motion analysis was performed using an IMU-based 2-segment foot model (Ultium Motion, Noraxon) and the marker-based Oxford Foot Model (Vicon). For both systems, kinematic data of the tibia–hindfoot, tibia–forefoot, and hindfoot–forefoot segments were collected over the gait cycle and processed using functional principal component analysis. Based on this, various ML algorithms (LASSO, Random Forest, SVM) were used to classify the arthrodesis (tibiotalar vs. subtalar). In addition, different input variables (such as number of steps) were compared. Model performance was evaluated based on accuracy, AUC, and F1 score; in addition, segment- and plane-specific influences on model performance were analyzed.



Results

All ML models achieved high classification quality with mean accuracies of 0.75–0.90 and AUC values > 0.90 (Fig. 1, IMU - red, OMC - green). The comparison showed similar results across all datasets, with IMU-based models achieving slightly lower performance values. For IMU data, sagittal movement between the rearfoot and forefoot had a significant influence on classification. For OMC data, transverse movement between the tibia and rearfoot had the strongest influence.

Discussion

The IMU-based 2-segment foot model achieved diagnostic accuracy comparable to that of the OMC system. IMU systems therefore have great potential for clinical use, particularly for objective functional assessment and follow-up after ankle arthrodesis. Future work should examine their applicability to other pathological gait patterns.

A Case Study Comparing Biomechanical Variables in New Versus Old Running Prostheses Across Velocities up to Maximum Velocity

Ms. Lina Jaafar B.S.[1], Ms. Claudia Barattini M.E.[2], Dr. Alena Grabowski Ph.D[3]

[1]University of Colorado at Boulder, Boulder, CO, United States. [2]Turin Polytechnic University, Turin, Piedmont, Italy. [3]University of Colorado, Boulder, CO, United States

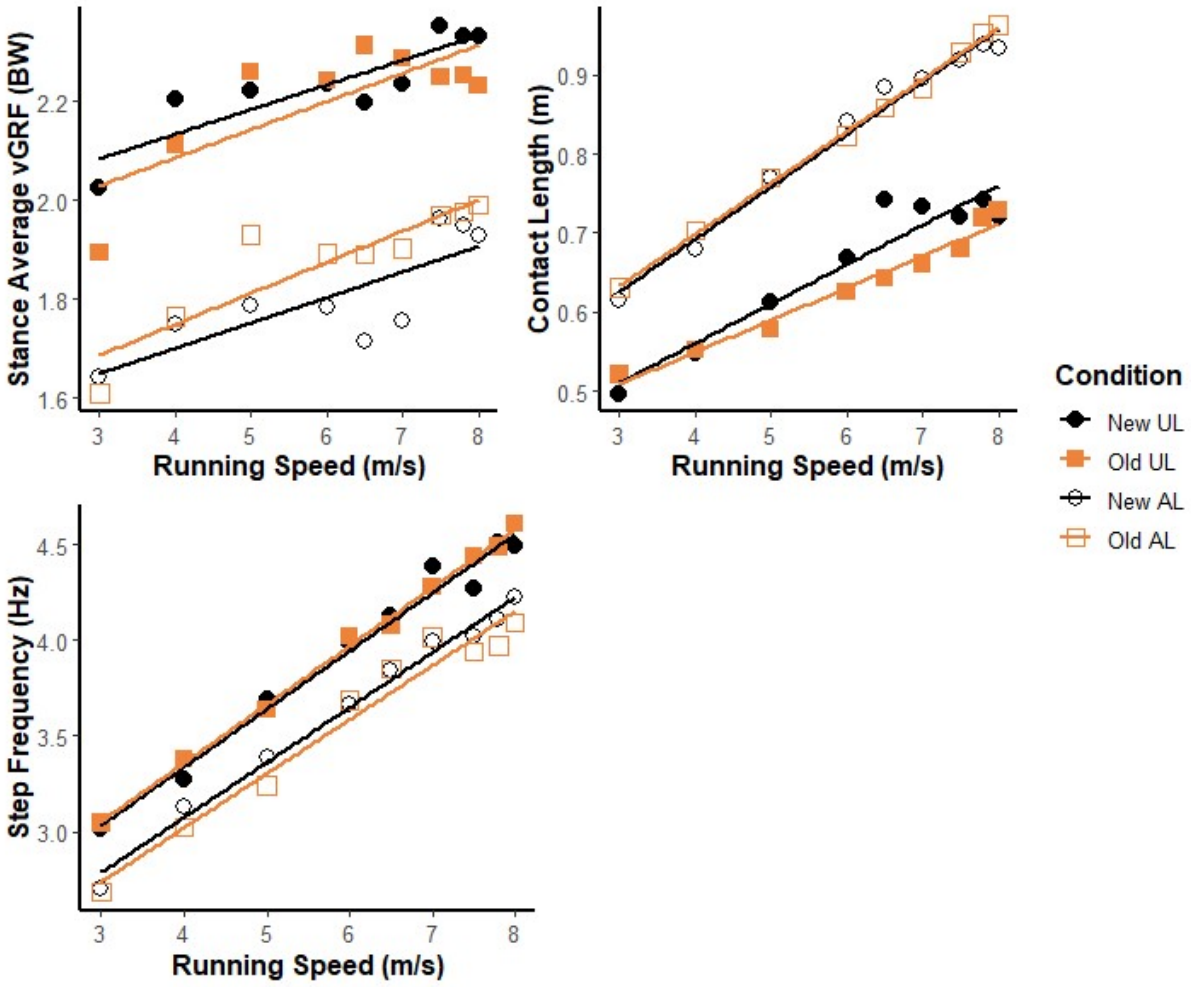
Introduction

Running-specific prostheses (RSPs) are passive-elastic carbon fiber devices that enable people with transtibial amputation (TTA) to run. The stiffness and energy-return of RSPs likely change with use, potentially affecting athletes' maximum velocity (vmax) and biomechanics across velocities. This case study examined an elite female athlete with a unilateral TTA using identical new and old RSPs to evaluate differences in v_{max} and biomechanics at steady running speeds.

Velocity is the product of contact length (Lc), step frequency (StepF), and stance average vertical Ground Reaction Force ($vGRF_{avg}$) [1]. Because the new RSP is likely stiffer and exhibits greater energy return versus old, we hypothesized that the new versus old RSP would result in faster v_{max}, longer Lc, higher StepF, and higher $vGRF_{avg}$ in the affected leg (AL) across velocities [1]. We further hypothesized that velocity would not have an interaction effect with RSP condition.

Methods

The athlete completed 20-step trials on a force-measuring treadmill beginning at 3 m/s and increasing by 1 m/s, with increments shrinking as she approached v_{max}: the fastest trial completed without drifting back on the treadmill. We collected GRFs for each trial and processed data in Visual3D, MATLAB, and RStudio.



Results

The athlete achieved a v_{max} of 8.15 m/s versus 8.0 m/s wearing the new versus old RSP. Use of the new versus old RSP resulted in similar AL Lc, higher AL StepF, and lower AL $vGRF_{avg}$ across speeds. Linear regression models indicated similar AL StepF slopes for new and old RSPs across velocities (0.288 vs. 0.283), suggesting no interaction with velocity. In contrast, AL $vGRF_{avg}$ increased less with speed in the new vs. old RSP (slope 0.050 vs. 0.057).

Discussion

Our findings suggest the new RSP enabled a faster v_{max} and higher StepF, but lower $vGRF_{avg}$, potentially reflecting increased RSP stiffness that limited compression. Though limited to one participant, this study highlights the potential influence of RSP wear on sprint mechanics and performance. Future studies with larger samples and motion-capture analyses are planned to characterize human–prosthesis interactions and to evaluate UL biomechanics across speeds.

Dual-task Interference and Practice Related Improvements in Locomotion Among Children and Young Adults

Ms. Julia De Oliveira B.Sc. M.Sc. Candidate, Dr. Lori Ann Vallis Ph.D.

University of Guelph, Guelph, Ontario, Canada

Introduction

Adaptive locomotor behaviours permit successful navigation of the environment; however, dual-tasking (DT) can impact performance. When walking and simultaneously performing a cognitively demanding task, performance of one or both tasks can be reduced [1]. DT costs seem to be inherent across the lifespan and are observed in children and adults [2]. Past research has postulated the decline is due to interfering neural resources and has shown that practice over many sessions can mitigate DT costs [3]. The objective of the current study is to determine if *short-term practice* can also reduce DT cost in adults and children.

Methods

Participants (young adults, YA: 18-25yrs; Children, Ch: 7-9yrs) were instrumented with retroreflective markers; gait parameters were captured (Optitrack; 100Hz; Corvallis, USA) as participants stepped over an obstacle simultaneously completing an auditory Stroop task. Participants were then assigned to one of three groups: No-practice, Single task (ST) practice (single obstacle crossing followed by single auditory Stroop) or DT practice (concurrent obstacle crossing with auditory Stroop). A retest was conducted 1 hour after practice to explore consolidation effects.

Results

Preliminary statistical results for YA participants (N=3; T-test; SPSS, version 30.0) revealed reduced average antero-posterior (AP) velocity between ST (obstacle crossing) and DT (obstacle crossing + auditory Stroop; $p=0.028$) and a significant increase in standard deviation (StD) for step length, lead toe/heel and trail heel crossing distance ($p<0.001$) under DT conditions. Following short-term practice, significant reductions in StD of AP velocity ($p=0.002$) and lead heel obstacle crossing distance ($p=0.003$) were observed.

Discussion

Preliminary findings indicate that short-term practice can mitigate DT costs in YA. Previous research demonstrated similar reduction in gait variability following single locomotor

practice sessions [4]. Ongoing work includes practice with child participants; we expect that short-term DT practice will mitigate DT costs, although children may need additional practice. This research will expand our knowledge on typical locomotor and cognitive development and identify optimal practice strategies across the lifespan.

Minimalist and Cushioned Footwear Interactions with Backpack Load on Children's Gait Mechanics

Prof Adriane Muniz[1,2], MSc MD Ana Silva[2], Dr Luciana Angélica Jesus[2], MSc Ana Paula Xavier[2], PT Maria Clara Gomes[2], PT Tainá Medeiros[2], Prof Luciano Menegaldo[2]

[1]Escola de Educação Física do Exército, Rio de Janeiro, RJ, Brazil. [2]Universidade Federal do Rio de Janeiro, Rio de Janeiro, RJ, Brazil

Introduction

Footwear characteristics can influence children´s gait. Minimalist shoes have been proposed as an alternative to promote foot functionality. Moreover, improper use of backpacks and inadequate footwear may impose excessive loads on the pediatric musculoskeletal system. However, few studies have investigated their combined effects on gait, particularly across different footwear types. Here, we compare gait parameters in children wearing minimalist footwear versus cushioned tennis shoes, both with and without a backpack.

Methods

Seventeen children (9.2 ± 0.8 years; 58.8% boys; 36.0 ± 4.4 kg; 1.4 ± 0.05 m) walked at 4.5 ± 0.5 km/h while their gait was recorded using a three-dimensional motion capture system (Vicon). Each participant was assessed under four conditions: cushioned tennis shoes and minimalist footwear, each with and without a backpack loaded with 10% of body mass. Pelvis, hip, knee and ankle kinematic and force plate peak parameters were compared using a two-way repeated-measures MANOVA. Significance level was set at $p<0.05$. Post hoc analyses were performed using a univariate two-way repeated-measures ANOVA with Bonferroni correction. All statistical analyses were conducted in R (R Core Team, 2025).

Results

The MANOVA revealed significant main effects of footwear ($F= 7.17$, $p=0.02$), load ($F= 42.445$, $p=0.0003$), but no footwear-load interaction ($F= 1.708$, $p=0.289$). Walking with 10% of body mass backpack increased pelvic anteversion ($p<0.001$), hip flexion ($p<0.001$), hip flexion moment ($p=0.003$), knee flexion moment ($p=0.008$), plantarflexion moment ($p<0.001$) and hip ($p=0.007$) and ankle ($p=0.005$) power generation, while reducing hip extension angle ($p<0.001$) (Figure 1). Minimalist footwear reduced ankle dorsiflexion during

stance (p<0.001) and knee abduction moment (p=0.0001) at weight acceptance. It also increased ankle plantarflexion angle (p<0.001) and propulsion power (p=0.007) (Figure 1).

Discussion

Carrying a backpack equivalent to 10% of body mass increased mechanical demands on the lower limbs during walking. Minimalist footwear reduced knee abduction moment while increasing ankle plantarflexion angle, moment, and power during propulsion, regardless of backpack use. These adaptations suggest that minimalist footwear may reduce knee load, promote the development of distal musculature, and, over time, support enhanced foot development in children.

Neuromechanical Responses to Perturbations Delivered by Bilateral Ankle Exoskeletons During Human Vertical Hopping

Dr Luke Jessup, Dr Alexandra Voloshina, Dr Monica Daley

University of California, Irvine, Irvine, California, United States

Dr Luke Jessup

Dr Alexandra Voloshina

Introduction

Terrestrial locomotion is robust, even in unpredictable environments that impose frequent perturbations. Yet little is known about how mechanics across scales integrate to rapidly stabilize limb function during perturbations and how these responses may adapt. In a novel approach, we leveraged the precise, covert control of ankle exoskeletons to deliver perturbations during human hopping while measuring *in vivo* muscle and joint mechanics.

Methods

Two healthy participants hopped in place wearing bilateral cable-driven ankle exoskeletons, performing ten 45-second trials: initial unperturbed, surprise perturbation (SP; ×4), expected perturbation (EP; ×4), and final unperturbed. Hop height was prescribed; hop frequency was unconstrained. SP trials involved a single perturbation delivered at a random hop, whereas in EP trials participants were cued 5 seconds beforehand. The exoskeletons followed users' natural ankle motion throughout, except during the perturbation, when they imposed a plantarflexion motion from mid-flight through until body-weight acceptance – a phase that normally exclusively involves dorsiflexion. Kinematic, ground reaction force, lower-limb electromyographic (EMG), and soleus ultrasonographic data were collected. Data were compared between the unperturbed trials and the first SP and EP trial.

Results

There were no clear differences between the SP and EP trials. Hops immediately following the perturbation exhibited increased variability in frequency, height, and peak vertical

force. During the perturbed hop, ankle plantarflexion (-38%) and dorsiflexion (-34%) decreased, as did knee (-12%) and hip (-15%) extension, while knee (+8%) and hip (+19%) flexion increased. Consequently, joint work – particularly negative work – shifted proximally. During the same hop, peak EMG decreased for soleus (-11%) and medial gastrocnemius (-19%) but increased for all other recorded muscles, most prominently tibialis anterior (+78%), biceps femoris (+61%), and erector spinae (+42%). During the perturbation, soleus fascicles shortened 5.1 mm instead of lengthening 1.6 mm as in unperturbed hops, and in the subsequent stance phase, fascicles lengthened 5.5 mm more and shortened 1.3 mm less than during unperturbed hopping.

Discussion

Participants shifted joint work proximally and increased energy dissipation, aided by antagonist muscle activation and agonist fascicle lengthening, to recover from an exoskeleton perturbation. A larger sample will enable clearer interpretation of between-trial and between-participant differences in response timing and recovery strategy.

Images (Optional)

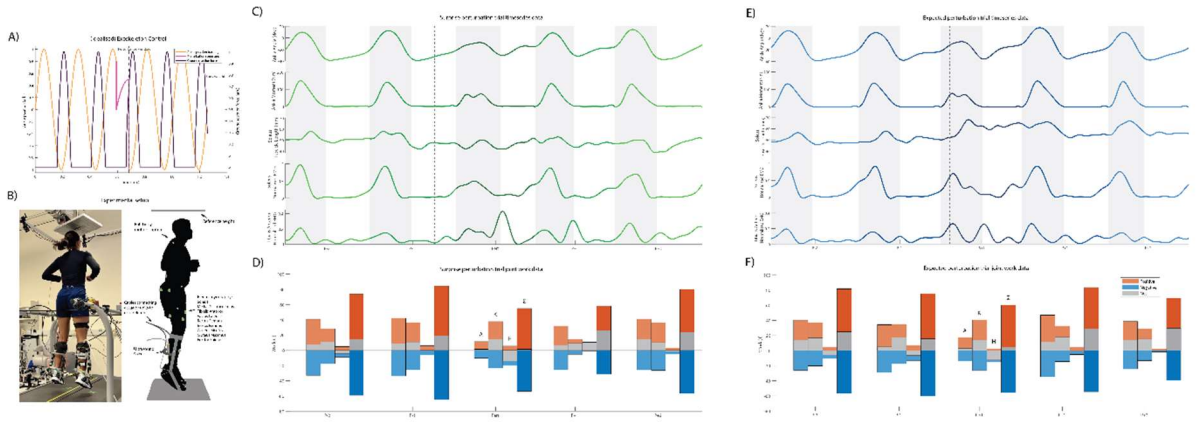

Figure. A) (Idealised) ankle exoskeleton control. In the unperturbed state, the actuators of the exoskeletons are commanded to follow ankle position. In the perturbed state, the actuators are commanded to plantarflex the ankle, from mid-flight of the hop through until the ground reaction force equals body weight during ground contact. **B) Image and illustration of the data collection.** Participants hop in bilateral ankle exoskeletons, with hop frequency unconstrained and hop height prescribed by a block suspended above their head. Motion capture, force plate, electromyography (EMG), and ultrasound data are collected simultaneously. **C) Timeseries data from the first surprise perturbation trial from participant one.** Ankle angle (positive direction = dorsiflexion), ankle moment, soleus fascicle length, soleus normalised EMG, and tibialis anterior normalised EMG. Shaded regions correspond to the ground contact phase of each hop, light regions to each aerial phase. Dashed vertical lines indicate the time over which the perturbation was applied. **D) Joint work data from the first surprise perturbation trial from participant one.** Ankle (A), knee (K), hip (H), and summed (sigma) joint work of each hop. Positive work = orange, negative work = blue, net work = grey. **E) Timeseries data from the first expected perturbation trial from participant one.** As in C. **F) Joint work data from the first expected perturbation trial from participant one.** As in D.

Gait on the 'GO': A Proof-of-Concept Study on Wearable Sensory Insoles for Gait Assessments

Miss Maahika Mehta[1], Mr. Adam Bradshaw[1], Mr. Sandro Nigg[1], Dr. Benno Nigg[1], Dr. Emily Matijevich[2], Dr. Maryam Hajizadeh[2]

[1]Human Performance Laboratory, Calgary, Alberta, Canada. [2]Orpyx Medical Technologies, Calgary, Alberta, Canada

Introduction

Chronic diseases like diabetes significantly impact gait characteristics, increasing risk of balance impairments and falls. Gait assessments provide a quantitative approach for characterizing these patterns. Traditionally, these utilize specialized technology or qualitative screening, reducing clinical transferability. Wearables offer accessible, objective, gait and mobility monitoring. The aim of this project is to develop a proof of concept individualized multi-task gait report, using Orpyx Motion Insight sensory insoles, providing a novel framework for quantifying motion characteristics across a diverse set of functional tasks.

Methods

This project utilized data from a previously collected dataset (REB23-0561) on individuals with diabetes and healthy controls. Plantar pressure and inertial measurement unit (IMU) data was collected during a variety of walking, stairs and standing tasks using the Orpyx Motion Insight sensory insoles. Four movement metrics were computed through custom developed algorithms: Walking Toe Clearance (cm), Stairs Stride Time Asymmetry (%), Standing Postural Sway Area (mm/s) and Standing Anterior-Posterior Peak Velocity (mm^2). Subsets of 4 individuals with diabetes and 3 healthy were selected for initial analysis; statistical group differences were not calculated at this stage. Individual data was combined into a gait report. Values were classified as healthy (green), abnormal (yellow) and at-risk (red) through a heuristic threshold method. Thresholds were determined from normative literature data if available, or from healthy participant ranges.

Results

Individuals with diabetes trended towards lower toe clearance especially in fast and cognitive walking tasks, and higher stairs stride time asymmetry (+ 5%). Postural sway area and peak velocity (anterior-posterior axis) were greater in *some* individuals with diabetes, though these metrics were subject to high variability. Comprehensive movement metric

reports revealed distinctive gait profiles, emphasizing the need for personalized, longitudinal monitoring.

Discussion

This exploratory analysis suggests that individuals with diabetes may exhibit early gait and balance changes, detectable through the Orpyx Motion Insight sensory insole metrics. By assessing multiple mobility tasks, this project aimed to capture a broad picture of functional motor performance. Future work will apply the described methodologies to a larger, generalized dataset, statistically differentiating clinical and healthy populations.

Metabolic Costs of Rhythmic Arm Swing

Ms Yilin Fu, Dr Manoj Srinivasan

The Ohio State University, Columbus, OH, United States

Introduction

Arm swing is an important part of human movement, usually studied during walking and running, where it may improve stability and reduce metabolic costs [1,2,3]. However, the energetics of independent arm swing (without being coupled to locomotion) has not been characterized. Here, we quantify the metabolic cost of rhythmic arm swing, investigating the effect of arm swing amplitude and frequency.

Methods

Participants were seated in a stable, supported position with their feet flat on the ground, performing single-arm rhythmic swings with metronome-guided frequencies from 0.25 to 1.0 Hz, amplitudes of 15° to 90°, and mean arm angles of 7.5° to 45°, totaling up to 30 trials each. Metabolic costs were measured using COSMED-K5 device and upper limb kinematics using marker-based motion capture.

Results

The data was used to quantify changes in metabolic costs across swing amplitudes and frequencies and model the relationship between upper-limb movement and metabolic costs through power-law regression. Net metabolic rate for arm swing was obtained by subtracting the mean value from a resting trial. Across all arm-swing conditions, gross metabolic rate ranged from approximately 1.014 to 1.425$W \cdot kg^{-1}$, yielding net metabolic rates from 0.054 to 0.465$W \cdot kg^{-1}$ above rest, much lower than leg swing metabolic costs at analogous amplitudes and frequencies [4,5]. Mechanical work over these frequencies ranged from 0.073 to 1.214 $J \cdot kg^{-1}$ per cycle. Fitting a power-law model to the data showed that larger amplitude and frequency movements have greater energy expenditure, with power law exponent greater than 1.

Discussion

In future work, we will seek to transform this rich data using inverse dynamics to fit a model of metabolic cost from shoulder-torque and mechanical work. This will allow us to quantify the cost of arm swing during walking. Arm swing energetics are modified by being coupled to the walking dynamics, and this modification can be understood by estimating the arm torques and mechanical work, and the consequent energy cost of such exertion.

Using Haptic Feedback to Increase or Decrease Trunk Sway

Dr. Margo Donlin PhD

Bucknell University, Lewisburg, PA, United States

Introduction

Individuals with chronic stroke often experience increased trunk sway (~10°) compared to unimpaired individuals (~5°), which can contribute to altered loading and muscle activity. Alternatively, increasing trunk sway may reduce knee adduction moments and redistribute knee cartilage load. Regardless of direction, promoting desired trunk sway may be beneficial. Previous research has used biofeedback to modulate trunk sway, but haptic feedback has rarely been used during walking.

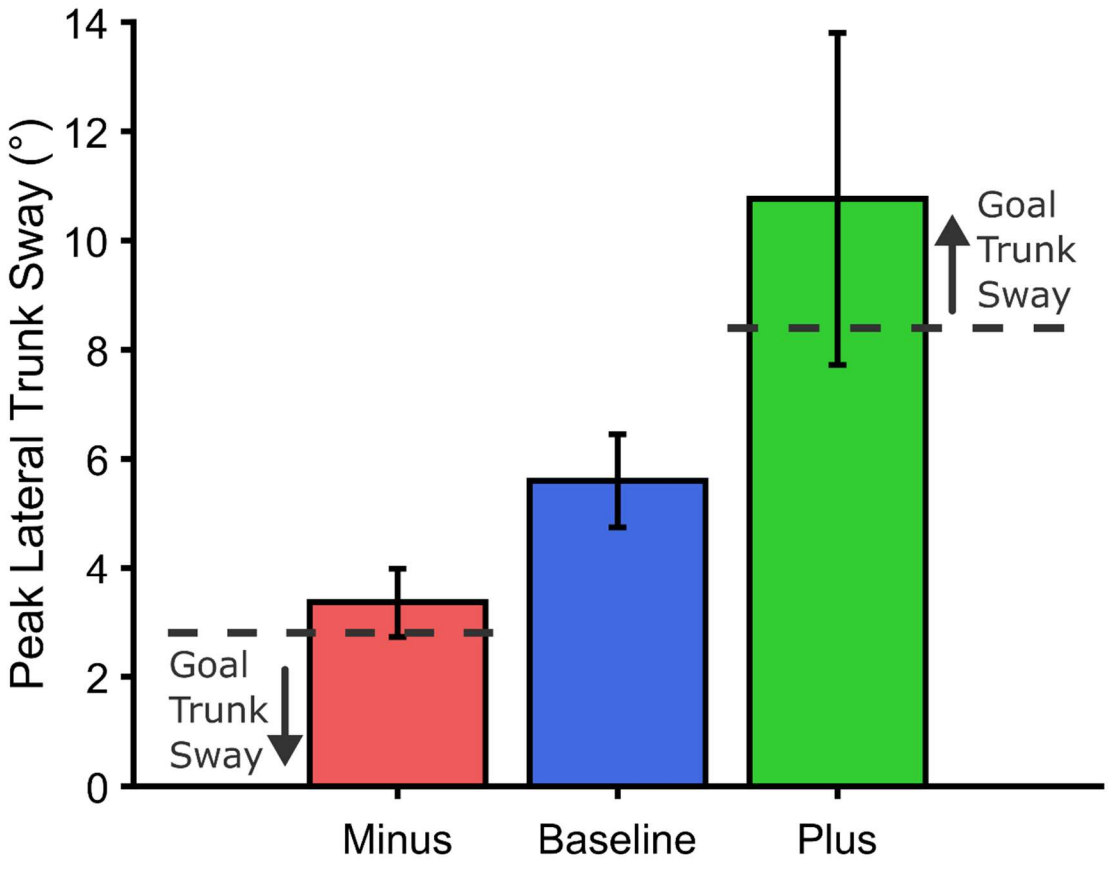
The purpose of this study was to determine if haptic feedback can be used to modulate trunk sway during walking in unimpaired individuals. Specifically, we hypothesized that haptic feedback would result in desired increases or decreases in trunk sway.

Methods

To date, four unimpaired subjects (29±1 years; 1.60±0.04 m; 76.78±19.39 kg; 4 F) with no lower-body musculoskeletal injury in the last six months were outfitted with five inertial measurement units (SageMotion, Kalispell, MT, USA; 100 Hz) on one leg to measure real-time sagittal plane joint angles.

Subjects completed three overground walking trials at their comfortable speed. In the baseline trial, subjects walked with no feedback to measure their natural trunk sway. The two feedback trials were (1) 50% increase in trunk sway (“plus”) and (2) 50% decrease in trunk sway (“minus”). In both feedback trials, haptic feedback was provided at the upper extremity of the side that exceeded the threshold. Due to the small sample size, only visual comparisons were performed.

Results



Trunk sway was smaller in the minus trial (3.4±0.6°) than baseline (5.6±0.9°) and larger in the plus trial (10.8±3.0°, Figure 1).

Discussion

Subjects were able to understand the haptic feedback and substantially alter their trunk sway in both the minus and plus trials. Therefore, haptic feedback may be a useful mechanism to promote desirable changes in trunk sway during walking, whether the goal is to decrease trunk sway in rehabilitation or increase trunk sway to reduce knee adduction moments.

This pilot study did not measure knee adduction moment, but the full-scale version will calculate this outcome measure. Future studies will include individuals with chronic stroke to determine if haptic feedback can decrease trunk sway in a clinical population.

Musical, Visual, and Auditory Pacing Cues Produce Distinct Scaling Dynamics in Gait Entrainment

Ms. Marilena Kalaitzi Manifrenti, Mr. Vasileios Mylonas, Mr. Seung Kyeom Kim, Mr. Aaron Likens

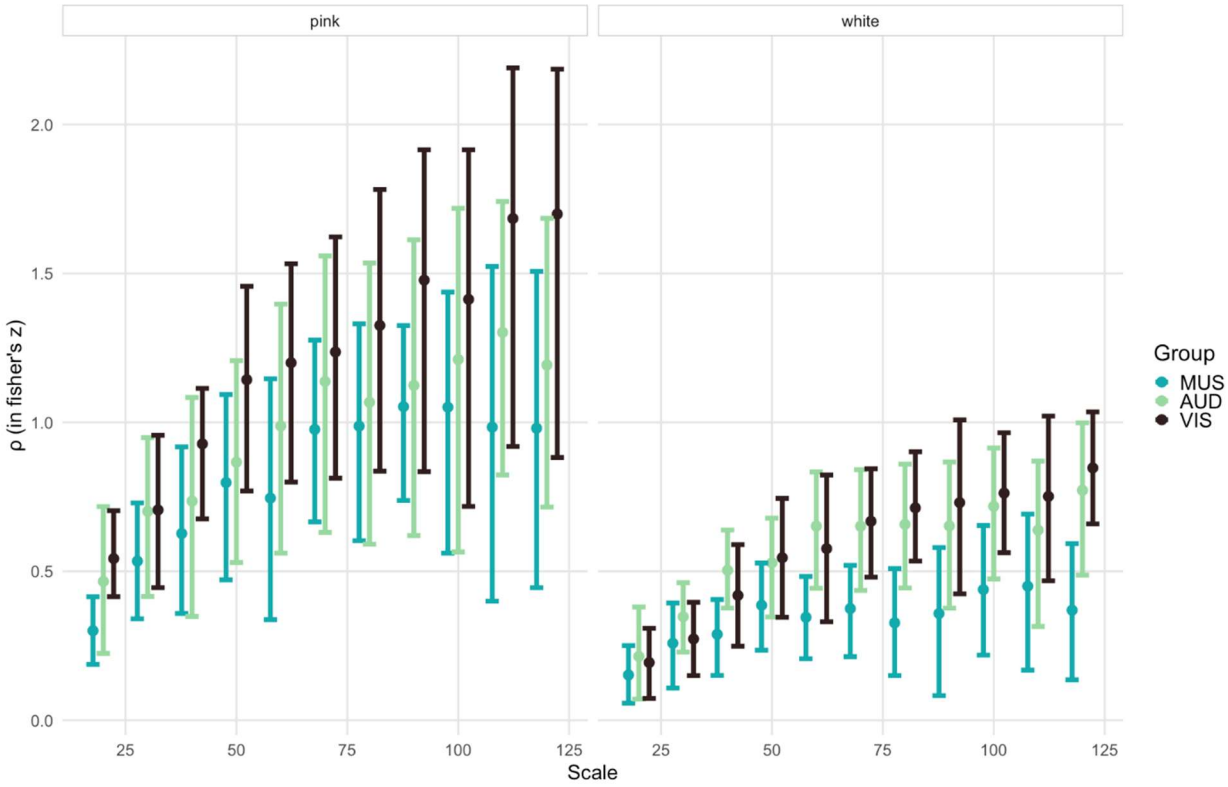
Department of Biomechanics and Center for Research in Human Movement Variability, University of Nebraska at Omaha, Omaha, Nebraska, United States

Introduction

Human gait exhibits complex temporal dynamics that reflect interactions within the sensorimotor system. One hallmark of healthy gait is the presence of fractal patterns in step timing (pink noise), where gait features are related over time. With aging, those patterns degrade and become random (white noise). Cues are external timing signals used to influence gait timing and have been used to restore natural fractal patterns. Cueing-modalities (visual, auditory) influence gait differently; we test how cueing-modality and noise influence step-to-cue coupling (STCC) across time scales.

Methods

Eighteen healthy young adults were assigned to one of three cueing modalities: music (MUS), non-musical auditory beeps (NMA), a vertical visually oscillating bar (VIS). Participants performed 12-min walking trials pacing to pink and white noise cues, randomized. Multiscale-correlations, ρ(s), between cue and step timing were quantified using detrended cross-correlation analysis and converted to Fisher-Z (20–120 scales). A multilevel model evaluated the effects of cue-modality, noise, scale, scale^2, and their interactions, on ρ, with random participant effects.



Results

Noise and scale interacted, so we don't interpret any main effects other than scale^2 which was not involved in an interaction. The model explained 80.1% of variance, with 67.2% due to individual differences. Pink noise produced steeper increases in ρ across scales compared to white noise (Fig.1), indicating stronger STCC ($\beta=2.56, t(368)=4.98, p<0.01$). Another interaction between cueing-modality and scale showed that VIS has the greatest rate of change in ρ ($\beta=5.34$, CL=(4.39,6.29)), followed by NMA ($\beta=3.69$, CL=(2.83,4.56)), and MUS ($\beta=2.70$, CL=(1.90,3.51)). Pairwise, VIS demonstrated a greater rate of change in ρ than NMA ($\beta=1.65, t(368)=2.52, p=0.033$) and MUS ($\beta=2.64, t(368)=4.17, p<0.01$).

Discussion

Findings show a quadratic relationship between ρ and scales, suggesting an STCC asymptote. Pink noise produced stronger growth in ρ across scales because its prominent low-frequency fluctuations lead to STCC. Conversely, white noise contains only unpredictable fluctuations, hence entrainment is limited to short-term corrections. Modality-wise, VIS demonstrated the strongest scale-dependent coupling putatively due to its continuous nature and vision's dominant role in locomotion. Overall, sensorimotor integration, measured through STCC, seems to improve with visual information and to be compromised when fractal dynamics are suppressed.

Day-to-day Similarity in Muscle Fatigability and the Change in Gait Kinematics in Response to 30-minutes of Walking

Ms. Mayumi Wagatsuma[1], Mr. Julien Mihy[1], Dr. Stephen Cain[2], Dr. Jeremy Crenshaw[1], Dr. Christopher Knight[1], Dr. Jocelyn Hafer[1]

[1]University of Delaware, Newark, DE, United States. [2]West Virginia University, Morgantown, West Virginia, United States

Introduction

Older adults are susceptible to muscle fatigue in response to activity, which leads to changes in gait. Most muscle fatigue studies are conducted in lab settings with a single visit; however, self-reported fatigue in older adults fluctuates throughout and across days. A single day of muscle fatigability data might be insufficient to understand how muscle fatigue affects gait in response to activity in the real-world. It is essential to determine whether muscle fatigability and fatigue-induced gait changes vary day-to-day. Therefore, the purpose of this study was to determine whether the same bout of exercise induces similar muscle fatigue and changes in gait kinematics on different days.

Methods

Eleven adults (age 73±7yrs) completed the same protocol at two lab visits, separated by at least 9 days. The time of day was matched between visits. Participants wore five inertial measurement units and completed: (1) 10-meter walking at preferred speed (speed matched pre/post and between visits), (2) self-reported lower extremity muscle fatigue on 0-10 scales, and (3) isokinetic ($270°\cdot s^{-1}$) knee extensor dynamometer testing before and after an established 30-minute treadmill walking protocol. Stride length and knee and ankle ranges of motion (ROM) were calculated from the 10-meter walks. Dynamometer and self-reported muscle fatigability were the change in peak muscle power and the change in self-reported muscle fatigue level, respectively. Intraclass Correlation Coefficients (ICC) were used to examine the similarity of changes in gait kinematics and dynamometer and self-reported muscle fatigability between visits.

Results

There was moderate between-visit similarity for the change in ankle ROM (ICC=0.648). Self-reported muscle fatigability and the change in stride length had poor similarity (ICCs=0.40

and 0.24), while knee ROM and dynamometer fatigability had very poor similarity (ICCs=-0.06 and -0.08) between visits.

Discussion

These findings suggest that muscle fatigability and changes in gait kinematics in response to a bout of exercise may vary between in-lab visits even when the exercise is controlled to be exactly the same between visits. A traditional in-lab single visit exercise test may not be sufficient to understand muscle fatigability and gait changes in response to activity in older adults.

Assessing Walking Balance in Participants With Acromegaly Using Obstructed Walking

Ms Yuqi Wang MSc, Mr Gary Ohanessian MSc, Ms Michaela Title MSc, Ms Lisa Tramble RN, Dr Vicki Munro MD, FRCPC, Dr Syed Ali Imran MBBS, MRCP(UK), FRCP(Edin), FRCPC, Dr Michel Ladouceur PhD

Dalhousie University, Halifax, NS, Canada

Introduction

Acromegaly, characterized by growth hormone excess, adversely affects the patients' musculoskeletal and neural systems, consequently impairing physical function. Patients with acromegaly (PWA) experience higher rates of falls and fall-related injuries than Canadian older adults[1]. This study aims to explore the walking balance deficits in participants with acromegaly (PWA) compared to participants with non-GH-secreting pituitary adenoma (PNA), and young healthy participants (HC).

Methods

This study included two age-, sex-, BMI-matched groups (n=8 for each; PWA and PNA) and a YHC group (n=12). The kinematics of a 7 segment lower limb model was collected using an OptiTrack MoCap system and the ground reaction forces were acquired using two AMTI force plates. Participants walked without obstruction or over a 10% leg length unilateral obstacle. Inverse Dynamics were calculated using Visual 3D. A 2-way repeated ANOVA, and statistical parametric mapping was used to compare outcomes between the groups.

Results

In the crossing limb PWA's exhibited less reduction of knee extensor energy absorption in comparison to PNA and YHC participants (K3; PWA: 0.054J/kg; PNA: 0.089J/kg; YHC: 0.120J/kg; p=0.01). PWA's supporting limb generated less hip abductor energy when crossing over the obstacle in contrast to both the PNA and YHC group (PWA: -0.070J/kg; PNA: +0.122J/kg; YHC: +0.100J/kg; p=0.03).

Discussion

Our study revealed a trend of PWA adopting a different adaptation strategy during obstructed walking that is characterized by a reduction in the absorption of energy at the knee in the crossing limb and at the hip in the supporting limb. However, some of the

changes occurring with acromegaly may not be solely resulting from the GH secretion but also from the pituitary adenoma treatment as seen with the PNA group adaptations.

Kinetics Changes in Participants With Acromegaly During Walking

Ms Yugi Wang MSc, Mr Gary Ohanessian MSc, Ms Michaela Title MSc, Ms Lisa Tramble RN, Dr Vicki Munro MD, FRCPC, Dr Syed Ali Imran MBBS, MRCP(UK), FRCP(Edin), FRCPC, Dr Michel Ladouceur PhD

Dalhousie University, Halifax, NS, Canada

Introduction

Acromegaly is a multisystem disorder characterized by elevated growth hormone (GH) and insulin-like-growth factor-1 (IGF-1). Previous studies have reported a wide array of neuromuscular and skeletal abnormalities in PWA including arthropathy, bone enlargement, abnormal muscle structure and function, and central and peripheral nervous system dysfunction. In addition to the effects of elevated GH and IGF-1, mass effects of the pituitary adenoma or complications of adenoma removal surgery could potentially play a role in walking impairment. This study aims to explore the changes in the kinetics of walking in participants with acromegaly (PWA) compared to participants with non-GH-secreting pituitary adenoma (PNA), and young healthy participants (YHC).

Methods

This study included two age-, sex-, BMI-matched groups (n=8 for each; PWA and PNA) and a YHC group (n=12). The kinematics of a 7 segment lower limb model was collected using an OptiTrack MoCap system and the ground reaction forces were acquired using two AMTI force plates. Inverse Dynamics were calculated using Visual 3D. A repeated mixed linear model, and statistical parametric mapping was used to compare outcomes between the groups.

Results

Statistical parametric mapping showed that Hip and Knee moments differences during the stance phase with an increase in the hip flexor moment, a reduction in the mid-stance unloading for the hip abduction moment, the knee extension moment, and the knee abduction moment. Furthermore, the hip flexors generation of power, the knee extensors absorption of power, the ankle plantarflexors generation of power at the initiation of swing, as well as the knee flexors absorption of power at the end of swing were reduced in the PWA and PNA groups with the changes being more in the PWA group.

Discussion

Our study revealed a trend of PWA reducing their absorption of energy by muscles during walking. However, some of the changes occurring with acromegaly may not be solely resulting from the GH secretion but also from the pituitary adenoma treatment as seen with the PNA group adaptations.

Reconstructing the ground reaction force distribution among the foot bones

Prof Michele Conconi[1], Eng. Alexandre Naaim[2], Prof. Nicola Sancisi[3], Prof. Raphael Dumas[4], Dr Paul-André Deleu[5]

[1]Department of Industrial Engineering, University of Bologna,, Bologna, Italy, Italy. [2]2Laboratoire de Biomécanique et Mécanique des Chocs, Univ Eiffel, Univ Lyon 1, Lyon, France, France. [3]Department of Industrial Engineering, University of Bologna, Bologna, Italy, Italy. [4]Laboratoire de Biomécanique et Mécanique des Chocs, Univ Eiffel, Univ Lyon 1, Lyon, France, France. [5]Foot & Ankle institute, Brussels, Belgium, Belgium

Introduction

The use of foot models in musculoskeletal analysis is crucial to identify how ground reaction force (GRF) is distributed among the bones. The limitation of standard multi-segment foot models (MSFM) [1,2] was overcome using a new synergy-based 4-DOF foot model (SBFM) [3], which represents the kinematics of all bones as a combination of four foot motions, maintaining joint constraint consistency. In this paper, we extend the model by introducing a method for identifying contact regions and estimating the total ground reaction force for each bone, validated against experimental measures.

Methods

Twenty-four healthy subjects (50±13 years, 73±10 kg) performed gait analysis with a Footscan® pressure plate (0.5m × 0.4m, 4096 sensors) mounted over an AMTI-force plate (0.5 × 0.4 m), thus allowing the capture of both ground resultant force and pressure distribution [4,5]. A template foot, including a set of 29 contact spheres built to approximate bone eminences (Fig.1), was scaled anisotropically on each subject based on foot dimensions. Foot bone kinematics were reconstructed using the SBFM. A training set of twenty subjects at mid-stance was used to optimize the sphere radius so that sphere intersection with the ground optimally matches the measured pressure map, as well as the stiffness of the virtual spring associated with each sphere in the contact model to optimally replicate the total ground reaction force. The tuned contact model was applied to the remaining four subjects. Finally, the GRF was estimated for all subjects over the entire gait cycle.

Results

The mean RMSE between model and experimental measure was 270.8N and 209.9N for the training and the validation set respectively. Identification of the contact region was reasonable (fig. 1).

Discussion

The discrepancies between model predictions and experimental observations suggest the model should not only be calibrated at mid-stance but refined over the entire gait cycle. Nevertheless, results support the applicability of the model. The SBFM can be employed in both inverse and forward dynamics musculoskeletal models, allowing for the investigation of the foot dynamics.

Images (Optional)

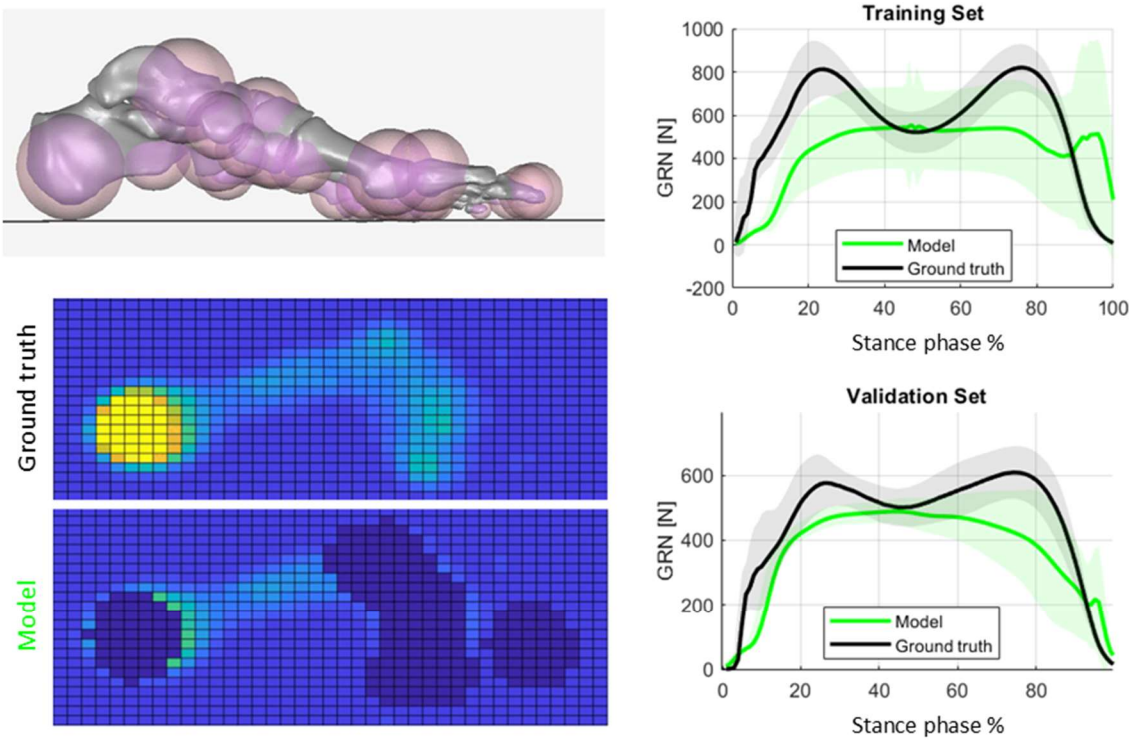

Figure 1: Distribution of the contact spheres in the model (top left); validation of the identification of the contact location (dark blue area) against pressure map (middle, bottom left). Comparison between predicted and measured GRF on the training set (top right). Comparison between predicted and measured GRF on the validation set (top right).

Standardized Upper-Body Joint Angle Estimation from Markerless Joint Centers

Dr. Milad Nazarahari

University of Alberta, Edmonton, Alberta, Canada

Introduction

Markerless motion capture systems provide an accessible tool to quantify upper-body kinematics. However, current non-commercial systems either lack standardized ISB-compliant joint definitions or rely on complex inverse kinematics with limited upper-limb validity. In this work, we have developed and validated a joint-center-based framework that computes standardized upper-body joint angles from the estimated joint centers using an open-source multi-view markerless system.

Methods

Six adults performed joint-focused tasks, involving single-axis movements that isolated primary upper-limb and trunk joint rotations, and a functional Pasta Box task, while an ISB-compliant marker-based system and eight smartphones recorded movements. The MediaPipe Holistic model provided 2D markerless joint centers, which were subsequently triangulated to obtain 3D joint-center positions. Thorax, humerus, forearm, and metacarpal coordinate systems were built using estimated JCs. Subsequently, shoulder angles were computed using a tilt–torsion representation with decomposition to flexion/extension (FE) and abduction/adduction (AA), and other joint angles were computed using the Grood–Suntay convention. An ISB-compliant marker-based configuration served as the gold standard. Figure 1 illustrates the segment coordinate systems for the markerless and marker-based gold standard.

Results

Markerless estimated shoulder FE, AA, and internal/external (IE) showed good-to-excellent ($r = 0.89–0.99$; RMSE = 3.0–13.3°), and elbow FE showed excellent ($r = 0.98–1.00$; RMSE = 2.7–4.0°) agreement with the gold-standard measurements. Elbow IE and wrist FE showed good-to-excellent agreement during joint-focused tasks (elbow IE $r = 0.95$, RMSE = 12.87°; wrist FE $r = 0.80$, RMSE = 12.08°); however, their accuracy decreased in the occlusion-heavy Pasta Box task (elbow IE $r = 0.56$, RMSE = 22.4°; wrist FE $r = 0.45$, RMSE = 18.2°).

Discussion

Our joint-center-based pipeline enables standardized, clinically interpretable upper-body kinematics using 3D markerless systems, with shoulder and elbow flexion/abduction

achieving accuracy that closely approaches that of the marker-based gold standard. Performance reductions were primarily limited to wrist and axial rotations during occlusion-heavy scenarios, reflecting challenges in joint-center estimation rather than limitations of the proposed approach. These findings highlight the potential of markerless systems for clinical upper-body joint angle tracking.

Muscle Latency as a Mechanism for Activity-Related Changes in Gait Mechanics

Ms. Millissia Murro, Ms. Fany Alvarado, Ms. Kathleen Downs, Ms. Nancy Nguyen, Ms. Mayumi Wagatsuma, Ms. Grace Kellaher, Dr. Jeremy Crenshaw, Dr. Jocelyn Hafer

University of Delaware, Newark, DE, United States

Introduction

Muscle fatigue (i.e., decreased muscle power following activity) can alter gait mechanics. However, the relationships between muscle fatigue and other aspects of muscle function and gait are unclear, as traditional measures such as strength and electromyography (EMG) activation do not correlate well with changes in gait. Recently, we identified that the temporal coordination between muscle activation and mechanics, *muscle latency*, changes in response to fatigue. Because latency is potentially modifiable, understanding its relationship to fatigue-induced changes in gait and muscle activation parameters may provide novel targets for intervention. The purposes of this study were to (1) examine the relationship between changes in muscle latency and changes in gait mechanics following a bout of activity, and (2) investigate factors that may explain variations in latency.

Methods

Twenty individuals (9F/11M; 63.8±3.4yrs; 11 Healthy/9 Knee OA) performed a 34-minute treadmill walk (34MTW). For the first (pre) and last (post) 4 minutes of data, we collected quadriceps and hamstrings EMG and motion capture. Variables of interest were muscle latency, peak knee flexion angle, rate of EMG rise, peak EMG activation, and quadriceps and hamstrings coactivation, all during early stance. We assessed correlations between changes (Δ=post-pre) in: (1) latency and knee flexion angle, and (2) muscle activation parameters and latency.

Results

Decreases in latency of the rectus femoris, vastus lateralis, and medialis were correlated with increases in peak knee flexion angle ($r=-0.67$, $p=0.0014$; $r=-0.63$, $p=0.0029$; $r=-0.75$, $p=0.0001$, Figure). This means that when the time between peak muscle activation and peak knee flexion angle shortened, the peak knee flexion angle increased. Increases in peak vastus medialis activation magnitude were correlated with decreases in vastus medialis latency ($r=-0.50$, $p=0.0244$).

Discussion

Our findings suggest that muscle latency may influence changes in gait mechanics following activity, and that fatigue-induced changes in latency may relate to changes in muscle activation magnitude. Latency reflects muscle activity specific to the gait mechanics of interest, whereas other commonly used measures of muscle activity lack this context. Future research may benefit from measures that combine multiple facets of movement control, such as latency, to help understand factors that influence changes in gait mechanics.

KAIST, Yuseong-gu, Daejeon, Korea, Republic of

Mr. Minho Chae

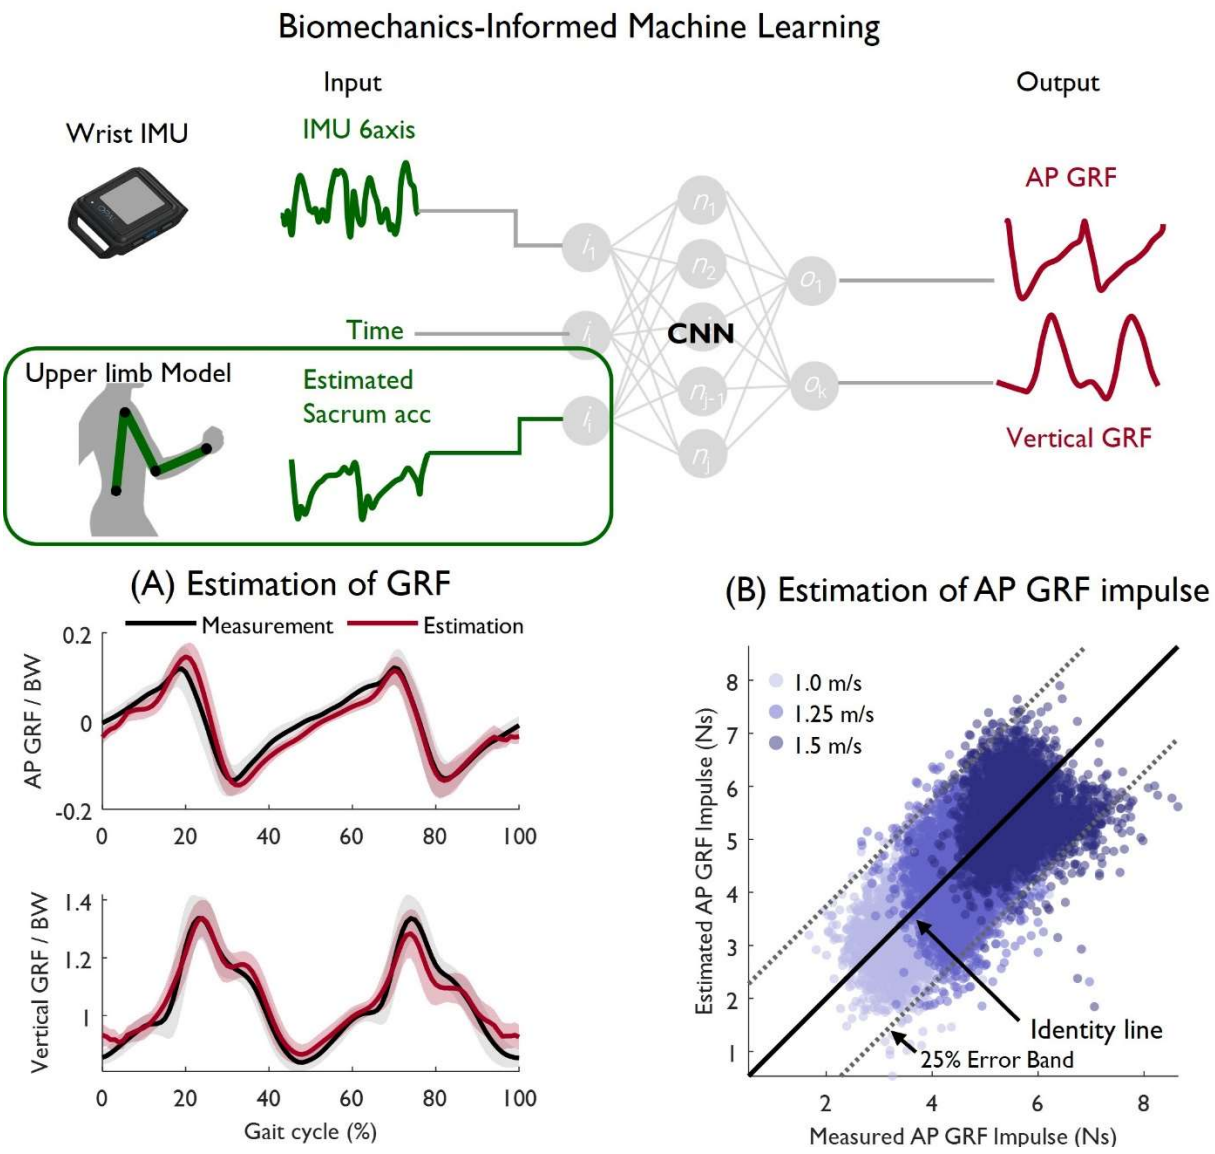
Ms. Guena Park

Introduction

Lower limb muscle weakness caused by sarcopenia reduces gait efficiency and mobility, thereby diminishing quality of life. Even after its official designation as a disease in 2021, the absence of therapeutic drugs has made early detection and prevention increasingly important. Since muscle strength decline tends to precede changes in gait speed, indicators capable of quantitatively monitoring lower limb muscle strength are needed. Ground reaction force (GRF) is a key biomarker reflecting lower limb muscle strength, but conventional measurements are impractical for daily life use. Although IMU-based GRF estimation techniques have recently been proposed, limitations in practicality remain, including multi-sensor attachment requirements, large training datasets, and black-box modeling. This study proposes a method to estimate GRF using a single wrist-worn IMU through a machine learning approach that incorporates biomechanical domain knowledge.

Methods

To estimate GRF using only a single wrist-worn IMU signal, we leveraged the COM-GRF relationship in gait. We quantified the kinematic coupling between the forearm, upper arm, trunk linkage and the center of mass (COM), and used the estimated COM acceleration as input features for a machine learning model for GRF estimation. The performance of the proposed method was validated using GRF data collected from 19 young adults under various walking speed conditions.



Results

The model integrating upper limb–COM kinematic coupling information as input features from a single wrist-worn IMU signal demonstrated high accuracy (nRMSE ≈ 9%) in personalized GRF estimation. Among the 6-axis IMU signals, the 2-axis acceleration and angular velocity of the forearm in the sagittal plane provided key information for GRF estimation. The movements of the upper arm and trunk exhibited speed-proportional scaling of forearm motion, indicating functionally dependent patterns. The proposed method consistently reproduced the trend of increasing forward impulse with increasing walking speed.

Discussion

This study demonstrated that GRF estimation is achievable across various walking speeds using only a single wrist-worn IMU by modeling upper limb-COM coupling and integrating it as machine learning input. The proposed method predicted GRF change trends with high linearity, suggesting the potential for long-term GRF monitoring using smartwatches and its application in early detection of lower limb muscle strength decline.

The Influence of Plantar Heel Pain on Foot and Lower Extremity Walking Gait Kinematics in Middle-Aged Adults

Dr. Mohammed Alamri[1,2], Ms. Zahra Mollaei[2], Ms. Breanna Lee[2], Dr. Stephen Cobb[2]

[1]King Saud University, Riyadh, Riyadh, Saudi Arabia. [2]University of Wisconsin–Milwaukee, Milwaukee, Wisconsin, United States

Introduction

A recent study reported that 1.1% of U.S. adults were diagnosed with plantar heel pain (PHP) in the past year, with the highest prevalence among those aged 45–64. Despite intervention, PHP often persists for 6–96 months. Clinically, PHP is thought to result from mechanical overload of the plantar aponeurosis. However, the pathomechanics during gait remain poorly understood. Previous gait research has primarily examined spatiotemporal and kinetic variables, whereas investigations of kinematics have been limited and inconsistent. This study aimed to identify foot and lower-extremity walking gait dysfunction in middle-aged adults with PHP. We hypothesized that patients with PHP would demonstrate gait kinematics consistent with increased pronation in early stance and insufficient supination in mid-to-late stance.

Methods

30 middle-aged adults with PHP (54.33±4.42 years, 85.82±15.84 kg) and 30 age-matched uninjured individuals (54.53±5.69 years, 76.18±18.22 kg) participated. 3D positions of markers located on the pelvis, thigh, shank, and foot were recorded using a 14-camera system. Three force plates were used to identify stance phase events during five barefoot walking trials (1.3 m/s±10%). A MATLAB program was used to calculate 3D hip, knee, and six functional foot articulation (rearfoot, medial and lateral midfoot, medial and lateral forefoot, first metatarsophalangeal) kinematics. Group differences within three stance subphases (loading response, mid/terminal stance, pre-swing) were examined using one-way ANCOVAs, adjusting for sex and BMI.

Results

During loading response, the PHP group demonstrated decreased rearfoot complex lateral rotation ($p=0.02$), decreased medial midfoot dorsiflexion ($p=0.05$), and increased medial forefoot dorsiflexion ($p=0.03$) ROM. During mid/terminal-stance the PHP group demonstrated decreased rearfoot complex dorsiflexion ROM ($p=0.01$).

Discussion

Although the PHP group demonstrated altered foot kinematics, only the increased medial forefoot dorsiflexion during loading response was consistent with the initial hypothesis. In contrast, the decreased rearfoot complex lateral rotation and decreased medial midfoot dorsiflexion observed early in loading response, along with the decreased rearfoot complex dorsiflexion during mid/terminal stance, may represent a pain-avoidant gait adaptation aimed at reducing pain from initial impact and limiting plantar aponeurosis strain during push-off.

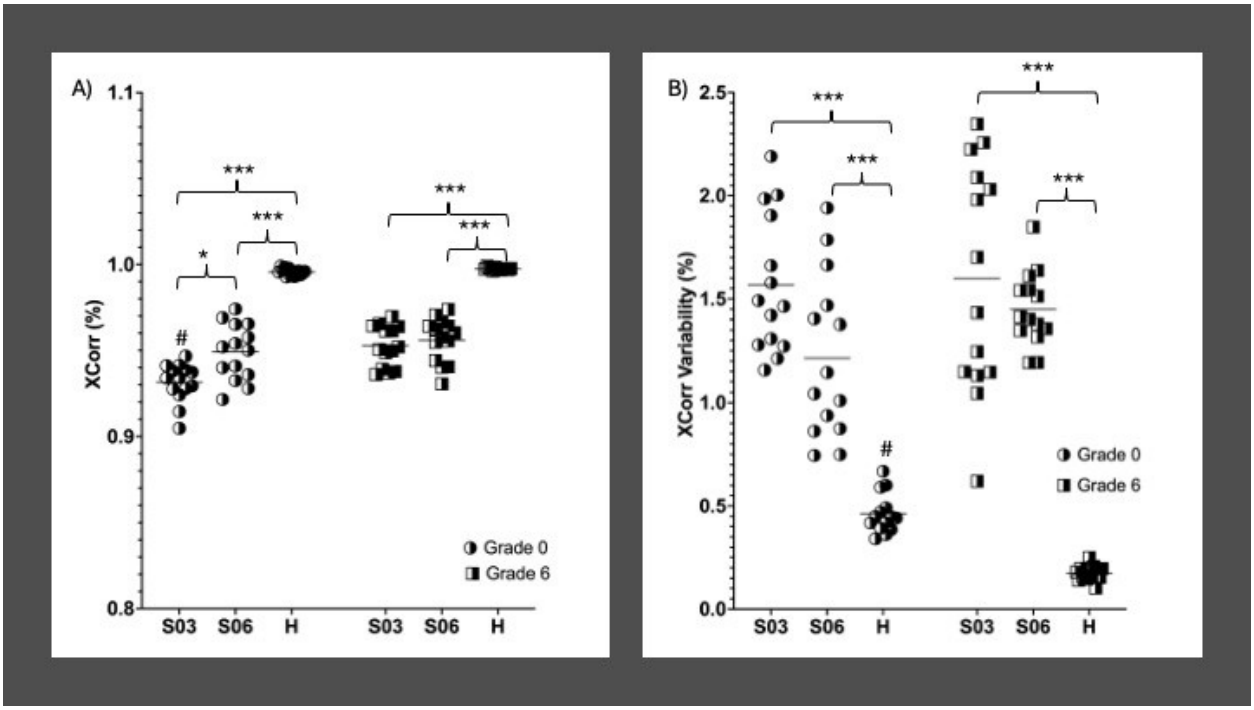
Doctor of Physical Therapy (DPT) Muchen Ren

Introduction

Gait asymmetry is a common and disabling post-stroke sequela, frequently assessed using ratios of discrete peak values. However, this method neglects the full time-series information available in biomechanical waveforms, such as the vertical ground reaction force (vGRF) profile. Furthermore, existing literature primarily focuses on gait asymmetry in chronic rather than subacute stroke survivors, largely because the highly variable vGRF profiles in the subacute phase are difficult to compare using traditional ratio metrics. This study investigated vGRF symmetry in subacute and chronic stroke survivors during level and inclined walking using a waveform-based approach (cross-correlation, XCorr).

Methods

Fourteen subacute stroke survivors, fourteen chronic stroke survivors, and fourteen healthy age-matched controls walked on a treadmill at 0% (level) and 6% inclines. vGRF symmetry was assessed using normalized cross-correlation (XCorr), and variability was measured using the coefficient of variation. A two-way mixed measures ANOVA was used to evaluate the effects of stroke chronicity and incline angle.



Results

Subacute stroke survivors demonstrated significantly lower XCorr values compared to chronic stroke survivors ($p<0.05$) and controls ($p<0.001$) during level walking. At the 6% incline, there was no significant difference in XCorr between subacute and chronic groups; however, both stroke groups exhibited significantly lower XCorr values than controls. Similar to XCorr, the XCorr variability was highest in subacute stroke survivors than other groups.

Discussion

XCorr effectively identifies vGRF asymmetry across different stages of stroke recovery, offering insights into whole-body mechanics that conventional peak measures often miss. Walking on a steeper grade (6%) significantly increased asymmetry and variability in stroke survivors, potentially indicating an increased risk of falls, indicating that stroke survivors need more in step-by-step adjustment during walking. Therefore, XCorr and XCorr variability are valuable clinical metrics for quantifying gait asymmetry, particularly in the subacute stage.

Using Instrumented Insoles During Six Minute Walk Test in Older Adults

Dr. Nicole Chimera PhD, Ms. Chyenne Neath BSc (Hons)

Brock University, St. Catharines, Ontario, Canada

Introduction

The Six Minute Walk Test (6MWT), a commonly used sub-maximal assessment of aerobic capacity, serves as a predictor of cardiovascular events; 6MWT performance decreases with age and reduced physical activity (PA). However, PA mitigates cardiac disease and may impact 6MWT performance. 6MWT is typically performed with participants walking along a 30-meter track marked at 3-meter increments to determine walking distance through manual calculation. The development of new instrumented insoles may provide a more streamlined measurement of 6MWT distance while also providing information on walking speed and gait asymmetries. Therefore, the purposes of this study were to 1) assess agreement between 6MWT distance measured manually and with instrumented insoles and 2) determine differences in walking speed, walking distance, and asymmetries during 6MWT in older adults of different PA.

Methods

A cross-sectional design assessed 6MWT in healthy individuals aged ≥55 years categorized into high, medium, and low PA via Godin-Shephard Leisure-Time Physical Activity Questionnaire. Participants were outfitted in insoles instrumented with inertial measurement units (IMU; Plantiga Technologies, Vancouver, British Columbia, Canada) to perform the 6MWT along a 30-meter indoor track. Walking distance (m) on the indoor track was recorded manually, and the IMU data included walking distance (m), walking speed (m/s), and asymmetries (%) in ground contact time and push off and impact accelerations. Agreement in 6MWT distance measured from the indoor track versus IMU was assessed with intraclass correlation coefficients (ICC); ANOVA determined differences in walking speed, distance, and gait asymmetries between older adults of different PA levels. Statistical analyses were performed in IBM SPSS (v.30; $p<.05$).

Results

Thirty older adults completed the 6MWT (Table 1); there was very strong agreement between manually measured walking distance and IMU walking distance (ICC: .998 [95%CI: .996;.999]). There was a main effect of PA for walking distance (p=.014) and speed (p=.011). Post hoc analysis indicated participants with high PA levels walked significantly

farther than moderate (p=.028) and low (p=.046) PA and significantly faster than moderate (p=.028) and low (p=.031) PA (Table 1).

Discussion

Instrumented insoles can be used to ascertain walking distance while also assessing meaningful gait parameters elucidating information otherwise unavailable with the standard 6MWT protocol.

Effects of DIVA Cognitive Load on Gait Parameters in Healthy Young Women under Single- and Dual-Task Conditions

MSc Nikola Chmura, PhD Wanda Forczek-Karkosz, PhD Agnieszka Wojtowicz

University of Physical Culture in Krakow, Krakow, małopolskie, Poland

Introduction

Dual-task (DT) situations compel the central nervous system to divide limited attentional resources between simultaneous motor and cognitive processes. While DT paradigms are frequently utilized in aging research to detect fall risk, healthy young adults serve as the critical "gold standard" reference due to their optimal gait stability. However, the extent to which complex visuo-spatial tasks compromise this stability remains an important area of study. This study aimed to investigate spatiotemporal gait modifications and attentional performance across three experimental conditions: natural walking, cognitive task only, and dual-tasking - to quantify specific "dual-task costs" in a homogeneous group of healthy young women using the DIVA-gait protocol.

Methods

Fifteen healthy women (20–30 years; BMI: 18.5–24.9 kg/m^2) participated. Exclusion criteria included neurological, musculoskeletal, or visual impairments affecting gait or task performance. Three conditions were assessed: Single-Task Walking (ST-Walk), Single-Task Cognitive (ST-DIVA: standing), and Dual-Task (DT: walking+task). Motion data were captured using a 32-camera Vicon system. Spatiotemporal parameters included Walking Speed, Step Length, Step Width, Cadence, and Single and Double Support Phases. The DIVA-gait task involved rapid visual discrimination; Reaction Times (RT) and Error Rates assessed cognitive cost.

Results

Comparison of the conditions revealed only subtle gait modifications, indicating a high level of motor control preservation. Relative to ST-Walk, the DT condition resulted in a slight but significant reduction in Walking Speed and Step Length. Notably, other spatiotemporal parameters-specifically Step Width, Cadence, and Single and Double Support Phases-remained comparable to the single-task baseline, showing no signs of destabilization. Conversely, cognitive performance declined; compared to ST-DIVA, the DT condition

resulted in increased Error Rates, suggesting the dual-task cost was primarily absorbed by the cognitive domain.

Discussion

The findings demonstrate that healthy young women have sufficient attentional capacity to handle the DIVA task with minimal impact on gait stability. In contrast to clinical populations, these participants maintained spatial consistency-specifically, their Step Width remained unchanged. They simply reduced their Speed and Step Length slightly as a safety buffer. This indicates a high level of gait automaticity and a successful "posture-first" strategy, where cognitive performance drops to protect the walking pattern.

Shifting Preferred Joint Kinetics Distally Reduces the Metabolic Cost of Walking in Young Adults

Dr. Ross Miller PhD[1], Ms. Ningzhen Zhao MS[2], Dr. Owen Beck PhD[2]

[1]University of Maryland, College Park, MD, United States. [2]University of Texas, Austin, TX, United States

Introduction

Deviations from preferred walking mechanics tend to increase metabolic cost, suggesting that these mechanics minimize metabolic cost. Because producing joint moments at the ankle requires less metabolic energy than at the hip [1], re-distributing joint moment production from the hip to the ankle may reduce the metabolic cost of walking. The purpose of this study was to increase the voluntary kinetic output of the ankle during walking, and determine the concomitant effects on hip kinetics and metabolic cost of walking.

Methods

Fourteen young healthy adults walked on a treadmill at 1.25 m/s. After familiarization, participants performed a 5-minute baseline walking trial, then walked for 10 minutes with bilateral functional electrical stimulation (FES) of the soleus during late stance. Following a 20-25 minute rest, participant performed another 5-minute walking trial without FES. Walking neuromechanics and metabolism were compared cost pre- versus post-FES.

Results

Compared to pre-FES baseline walking, post-FES peak ankle power increased +13.9% ($p = 0.003$), peak hip power decreased -9.8% ($p = 0.015$), peak soleus electromyogram linear envelope increased +4.8% ($p = 0.047$), and gross metabolic power decreased -2.3% ($p = 0.034$). We emphasize that “post-stimulation” data are from a preferred walking trial after the removal of FES, the soleus was not being stimulated.

Discussion

These are the first data demonstrating voluntary, level-ground walking with a lower metabolic cost than pre-intervention preferred walking, and suggest that young healthy adults do not minimize metabolic cost during walking. We hypothesize that this effect is due to shifting joint-level kinetics to a more economical distribution [1] that still meets the constraint of the ground reaction force equaling body weight on average. The mechanism for these changes may be related to longer muscles with less economical fiber

characteristics at the hip versus ankle. Given that carryover effects of FES reduced the metabolic cost of walking by changing participant joint kinetics opposite those typically associated with aging [2], this paradigm may have implications for explaining the mechanics and energetics of older adult walking.

Effects of Step Rate Manipulation on Lower-Extremity Kinematics During High-Speed Running in Highly Trained Distance Runners

Undergraduate Researcher Noah Clemens, Assistant Professor Lauren Miutz PhD, Associate Professor Matthew Beerse PhD

University of Dayton, Dayton, Ohio, United States

Introduction

Running step rate (SR) is commonly manipulated to alter running biomechanics for injury prevention and performance optimization. Prior work studying elite runners at moderate running speeds has demonstrated that increasing SR leads to consistent changes in joint kinematics; however, it is unknown if a similar pattern emerges during high-speed running. Gait mechanics may differ at faster speeds; therefore, SR manipulation may not exert the same effects observed during slower running. The purpose of this study was to quantify the biomechanical changes associated with SR manipulation during high-speed running in elite male distance runners.

Methods

Twelve elite male distance runners (age: 22.5 ± 3.7 years) completed 4-minute trials under seven SR conditions ranging from 170 to 200 steps/minute. All trials were performed at 4.96 $m \times s^{-1}$ (5:24 $min \times mile^{-1}$), the average speed at anaerobic threshold identified via pilot testing. Thirty consecutive steps from the third minute of each trial were analyzed. Sagittal-plane hip range of motion (ROM), knee flexion at initial contact (IC), and peak knee flexion and hip adduction during stance phase were identified, as these variables have been linked to running-related injury and SR manipulation. Associations between SR and each variable were examined using linear mixed-effects models with participant-specific random intercepts.

Results

SR was significantly associated with peak knee flexion during stance ($p < 0.001$) and hip flexion-extension ROM ($p < 0.001$). SR was significantly but not meaningfully associated with knee flexion at IC ($p < 0.001$, $R^2_{part} = 0.009$). Partial R^2 values suggest that SR has a small to moderate association with peak knee flexion during stance ($R^2_{part} = 0.063$), and a moderate association with hip flexion-extension ROM ($R^2_{part} = 0.149$). Across participants, peak knee flexion during stance ranged from 32.7° to 62.4°, and hip flexion-extension ROM ranged from 64.9° to 91.4°.

Discussion

These findings align with results at slower running speeds, suggesting that SR manipulation influences sagittal-plane hip and knee mechanics during high-speed running in a similar manner. Thus, SR-based gait retraining strategies commonly applied at slow speeds may be similarly effective for injury mitigation and performance enhancement at faster, race-relevant velocities.

Balancing Energy and Stability: Older Adult Fallers Modulate Step-to-Step Transitions Under Visual Cueing

Ms. Olivia Greene MS, ATC, Dr. Jacob Thomas PhD, Mr. Paul McDonnell MS, Mr. Adam Grimmitt MS, Mr. Jonaz Moreno Jaramillo MS, Dr. Douglas Martini PhD, Dr. Wouter Hoogkamer PhD

University of Massachusetts Amherst, Amherst, MA, United States

Introduction

Humans typically self-select walking patterns that minimize metabolic energy consumption, requiring coordinated redirection of the center of mass during step-to-step transitions. Minimizing overlap between push-off and collision power reduces metabolic energy cost [1], whereas greater overlap enhances stability. Age-related changes in step-to-step transitions coordination have been described, but little is known about older adults with fall history. We evaluated step-to-step transitions coordination in young adults (YA), older adults (OA), and older adults with fall history (OAF) during regular and visually cued treadmill walking to assess effects of age and fall history on step-to-step transitions coordination in typical and novel tasks.

Methods

Fourteen young adults and 22 older adults (10 OA, 12 OAF) walked on an instrumented split-belt treadmill at self-selected walking speed under two conditions: regular gait (RG) and visually cued gait (VCG). In VCG, steppingstones were projected onto the treadmill at preferred step lengths and widths. Participants targeted foot placements accordingly. Push-off and collision power overlap (Sequence Index) was calculated for ten step-to-step transitions [1], identified via center of mass velocity hodographs [2]. Sequence Index of 0 indicates push-off preceding collision, while 1 indicates push-off after collision. Group effects were tested using one-way ANOVA with Tukey's post hoc comparisons, and Bonferroni-corrected paired t-tests assessed within-group differences between conditions.

Results

In RG, YA walked with lower Sequence Index values than OA (p=0.018). During VCG, Sequence Index was lower in YA than OAF (p=0.002). Only OAF showed a significant increase in Sequence Index from RG to VCG (p=0.01).

Discussion

Older adults with fall history showed distinct adaptation of step-to-step transitions coordination when confronting a novel, visually guided stepping task. Their increased Sequence Index indicates greater push-off-collision overlap, suggesting a stability-oriented strategy when foot placement is modulated [3]. Since OA and YA maintained consistent coordination across tasks, fall history may shape how older adults modify step-to-step transitions mechanics in novel gait contexts. Modified step-to-step transition mechanics may signal fall risk in older adults, thus underscoring the need for prospective evaluation.

Images (Optional)

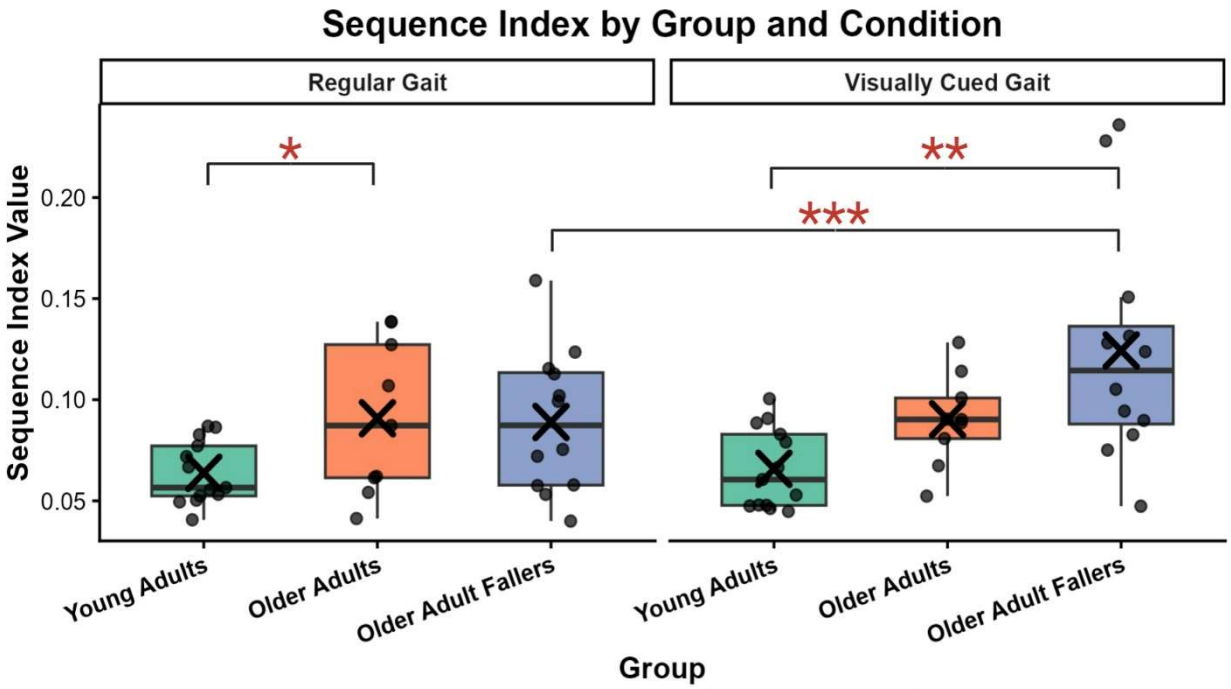

Figure 1. Box plots of push-off-collision power overlap (Sequence Index) across age groups during regular and visually cued gait. **"X"** indicates mean value. * indicates significance between groups during regular gait (p = 0.018). ** indicates significance between groups during visually cued gait (p = 0.002). *** indicates significant increase of 0.035 (p = 0.01).

Factors Associated with Gait Biofeedback Accuracy in Individuals with Knee Osteoarthritis: A Feasibility Study Including Wearable Sensor Translation

Ms. Olivia Stepp[1,2], Ms. Elizabeth Bjornsen PhD[3], Ms. Anna McDermott[1], Dr. Brian Pietrosimone PhD[1], Dr. Jason Franz PhD[1,2]

[1]University of North Carolina at Chapel Hill, Chapel Hill, NC, United States. [2]North Carolina State University, Raleigh, NC, United States. [3]East Carolina University, Greensboro, NC, United States

Introduction

Knee osteoarthritis (KOA) is associated with maladaptive changes in lower-extremity loading during walking. Notably, less dynamic and more sustained vertical ground reaction force (vGRF) profiles associate with greater compressive cartilage strain[1]. Our research team has successfully used gait biofeedback to alter vGRF in individuals at risk for KOA[2]; however, the feasibility of deploying biofeedback in individuals with KOA is unknown. Our purpose was to determine whether KOA-associated factors affect the ability of individuals with KOA to augment compressive limb loading through gait biofeedback. We hypothesized that greater self-reported pain, lower self-reported function, and slower habitual walking speed would result in larger errors in achieving biofeedback targets. As a secondary objective to support translation, we assessed the accuracy of wearable sensors to estimate changes in peak vGRF with biofeedback.

Methods

13 individuals (aged 51-74) with mild-to-moderate KOA have thus far participated. Participants completed a habitual walking trial on a dual-belt, force-sensing treadmill at their habitual speed while wearing custom inertial-measurement units (IMUs) on their waist and ankles. Participants then completed four 2-minute blinded, randomized biofeedback conditions that visually-cued peak vGRF targets (-3, +3, +6, +9%body weight [BW]). Participants self-reported pain (Visual Analog Scale [VAS]) and overall joint function (Western Ontario and McMaster Universities Arthritis Index [WOMAC]). We calculated absolute error as the difference between target and measured peak vGRF, analyzed for the affected (unilateral KOA) or more symptomatic (bilateral KOA) limb. Linear regressions assessed the effect of (i) baseline pain, (ii) WOMAC score, and (iii) habitual walking speed, on absolute error. vGRF-estimate machine learning models trained on IMU signals were compared with ground-truth values.

Results

When targeting +6%BW vGRF, higher (i.e., worse) WOMAC scores and slower walking speeds associated with larger absolute errors ($p \leq 0.048$). When targeting +9%BW vGRF, higher baseline pain associated with larger absolute errors ($p=0.043$). Wearable sensor comparisons are ongoing.

Discussion

Individuals with KOA achieved significant differences in vGRF with biofeedback (*data not shown*). However, translation and prescription must consider self-reported pain, function, and walking speed, which we show here can all affect biofeedback accuracy.

Effects of Prosthesis Stiffness on Running Limb Symmetry in Persons with Unilateral Limb Amputation

Miss Paige Agnew MS, Dr. Hunter Bennett PhD

Old Dominion University, Norfolk, Virginia, United States

Introduction

The goal for individuals with lower limb loss is to achieve bilateral symmetry during locomotion. Limb and neuromuscular asymmetry can result in abnormal gait strategies and commonly lead to back pain, inefficient gait patterns, and increased loading to the unaffected limb. For runners, additional aspects must be addressed to optimize performance, such as prosthetic stiffness. As prosthetic limb stiffness increases with running speed, it is possible variations in prosthetic stiffness itself could improve running mechanics. Therefore, the purpose of this study was to assess bilateral symmetry in individuals with unilateral transtibial amputations running on two different stiffness prosthesis.

Methods

Two amputee running athletes volunteered for this study: Participant A (PA) is an endurance-trained 55-year-old female with K-4 level and Participant B (PB) is an Olympic-level sprinter 55-year-old male with K-4 level. Full body motion capture (including prosthesis), ground reaction forces (GRF), and electromyography of the glutes, rectus femoris, and biceps femoris were collected while running at a self-selected speed. Inter-limb symmetry indices for GRF loading rate, stance time, and iEMG were calculated and compared for running on prescribed and non-prescribed (i.e., stiffer/more compliant) prostheses.

Results

Due to constraints, PA used a stiffer than prescribed (mass at lowest prescription level) and PB used more compliant than prescribed (mass at highest prescription level) prosthetic. Symmetric indices are in Table. For both subjects, stance time was <10% different between prosthetics. PA had doubly greater GRF loading rate asymmetry running on prescribed prosthetic. PA demonstrated greater glute asymmetry but reduced semimembranosus asymmetry running on a stiffer prosthetic. PB demonstrated no asymmetries for rectus femoris, but doubly increased asymmetry in the glutes and vastus lateralis and reduced semimembranosus asymmetry when running on the less stiff prosthetic.

Discussion

This study found >10% asymmetry between the prosthetic limb and non-prosthetic limb for almost all lower extremity muscles. Increased GRF loading rate and muscle asymmetry within the glute maximus and the vastus lateralis could cause instability in the knee during loading. To reduce limb asymmetry, it is recommended users utilize the prescribed prosthetic based on manufacturer recommendations or opting for a stiffer prosthesis rather than a less stiff.

Plantarflexor Muscle Activity as a Surrogate for Propulsion Measurement During Treadmill Walking

Ms. Paromita Kundu[1], Dr. Sagar Doshi Research Assistant Professor[2], Dr. Jill Higginson Professor[1]

[1]University of Delaware, Newark, DE, United States. [2]Center for Composite Materials, University of Delaware, Newark, DE, United States

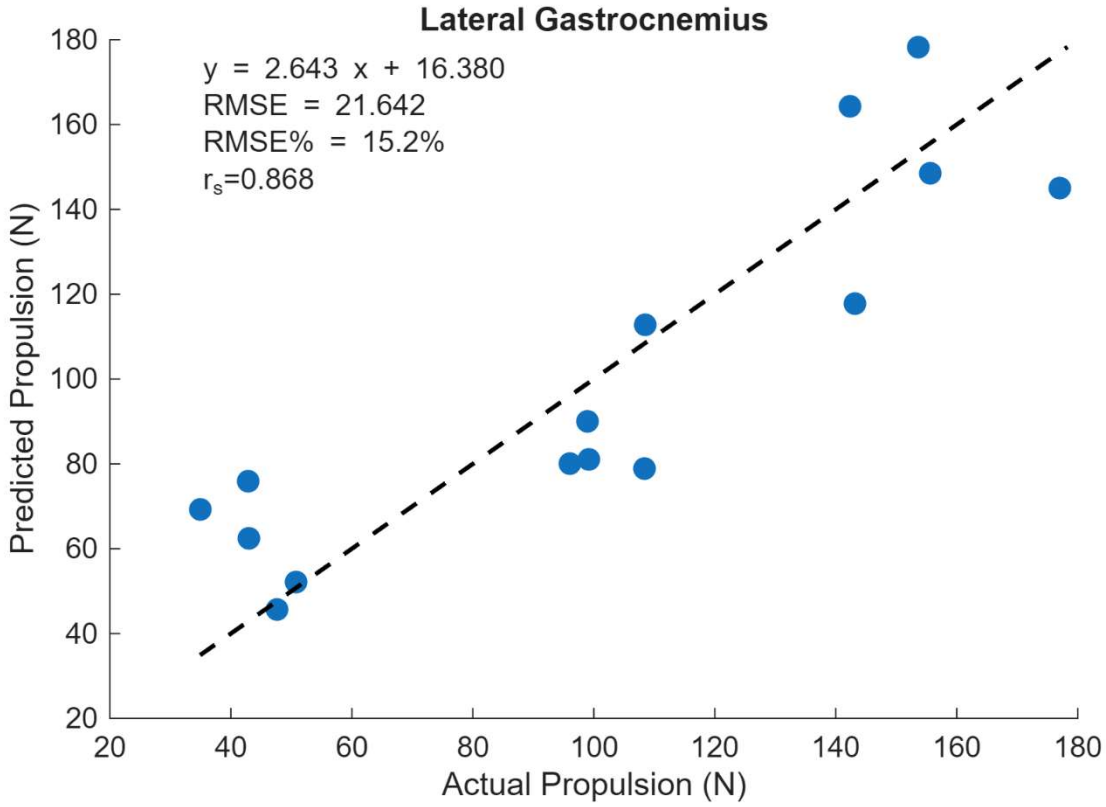
Introduction

Propulsion, a key biomechanical variable used to characterize walking, is widely targeted in rehabilitation strategies. It is primarily generated by the ankle plantarflexor muscles in late stance. Prior work has shown that increased plantarflexor activation is strongly associated with paretic propulsion [1]. Since plantarflexor activity is a primary contributor to propulsion during gait, it is possible that plantarflexor EMG could serve as a practical surrogate for propulsion measurement. Therefore, the purpose of this study was to quantify how accurately plantarflexor muscle activity reflects propulsion across different walking speeds.

Methods

Five healthy adults walked on a force-plate instrumented treadmill for two minutes each at three fixed speeds: slow(0.5 ms^{-1}), medium(1.0 ms^{-1}), and fast (1.5 ms^{-1}). For each trial, synchronized ground reaction force (GRF) and surface EMG were recorded from the medial gastrocnemius (MG), lateral gastrocnemius (LG), and soleus (SOL) muscles at f_s = 2000 Hz. Raw EMG and GRF signals were processed, stance phase was identified, and each stride was segmented. Mean peak propulsion and mean peak EMG activity during late stance were extracted at each speed for all subjects. Spearman correlations were computed to examine the relationship between peak EMG activity and peak propulsion.

Results



All three plantarflexor muscles showed strong correlations between peak EMG and peak propulsion. The correlation coefficients were MG: r_s = 0.73, LG: r_s = 0.87, and SOL: r_s = 0.79. Prediction accuracy based on EMG–propulsion linear models was moderate, with RMSE values of 18.8% (MG), 15.2% (LG), and 17.3% (SOL).

Discussion

Plantarflexor activity is a reliable indicator of changes in propulsion across walking speeds. Both gastrocnemius and the soleus contribute to increased propulsion, with LG showing

the highest correlation and lowest RMSE. This may indicate more consistent activation patterns and cleaner surface EMG signals for LG compared to MG, which is more variable, and SOL, which is a deeper muscle with lower signal-to-noise ratio. RMSE values in the 15–19% range are acceptable for EMG-based modeling due to inherent EMG variability [2]. Future work will focus on developing real-time EMG biofeedback based on plantarflexor activity.

Does Bilateral Symmetry Maximize Bipedal Running Speeds?

Dr. Peter Weyand Professor, Dr. Sunil Prajapati PhD

Texas Christian University, Fort Worth, TX, United States

Introduction

Bilateral symmetry is generally considered functionally beneficial for bipedal running gaits. However, runners could theoretically meet the running gait requirement of supporting the body's weight with unequal contributions from the right and left limbs. Here, we compared the bilateral symmetry of competitive sprinters and athlete non-sprinters to test the importance of bilateral symmetry for achieving faster speeds. We hypothesized that between-limb differences in the stance-average ground forces applied during high-speed running would not differ between the two groups.

Methods

Sixteen participants, eight competitive sprinters (n=5 males, 3 females) and eight athlete non-sprinters (n=5 males, 3 females) performed a series of progressive, constant-speed runs on a force-instrumented treadmill. Stance-averaged forces for each limb were determined from the vertical ground reaction forces at 60-100% of each athlete's measured maximum speed. Bilateral symmetry was quantified on a per trial basis as the percent difference between the forces applied by right vs. left limb [{(L-R)/mean}•100)]. A total of 143 trials and 1966 steps were analyzed.

Results

The mean maximum speeds of the competitive sprinters exceeded those of the athlete non-sprinters (10.7±0.8 vs. 9.2±0.9 m/s). Between-limb asymmetries in stance-average ground forces were significantly greater for the competitive sprinters vs. athlete non-sprinters (7.90±3.5% vs. 5.30±2.8%, $p<0.01$).

Discussion

Contrary to expectation, competitive sprinters had greater differences in the stance-averaged ground forces applied by their right and left limbs than did athlete non-sprinters across the nearly 2000 high-speed running steps we analyzed. We attribute this result to: 1) some competitive sprint athletes applying greater ground forces with their left vs. right limb in nearly every trial they completed, and 2) other competitive sprint athletes running with relatively asymmetrical patterns at faster trials speeds, but without consistent

directionality from trial to trial. We conclude that faster human runners achieve their greater speeds with relatively asymmetrical patterns of ground force application.

Changes in mediolateral CoP dynamics, not excursion, are linked to reduced gait stability in a virtual walking environment

Miss Prachi Pisay PT, MSc, Dr. Ashwini Kulkarni PT, ACSM-EP, PhD

Old Dominion University, Norfolk, Virginia, United States

Introduction

Virtual reality (VR) provides a controlled, task-specific walking environment with real-time multisensory feedback. Because VR relies heavily on visually perceived space, and this perception can shift with different spatial dimensions, the influence of visual information may be amplified, potentially altering gait control. This secondary analysis [Simonlehner et al. (2024). Scientific Data, 11(1)] evaluates whether the environment (real vs VR), the perceived size of the environment (small vs large), alters mediolateral (ML) center of pressure (CoP) dynamics (velocity and acceleration), and ML local dynamic stability.

Methods

Participants (37.2 ± 8.7 years, 73.9 ± 15.7 kg, 170.3 ± 6.6 cm) wore HMD and walked overground across four environments: a real lab (A), virtual (VRLab (B)), small (VRLab- (C)), and a large (VRLab+(D)) virtual room. Outcome variables included step length, step width, ML CoP excursion, velocity, acceleration, and ML short-term Lyapunov exponent (λ_{ml}). Repeated-measures ANOVA compared outcome variables across conditions, and VR-induced changes were calculated using difference scores (Δ) to the real condition and correlated with λ_{ml}.

Results

VR did not change step length/width or ML CoP excursion, but increased CoP velocity ($p = 0.02$) and acceleration ($p = 0.03$). Participants who showed larger VR induced increases in CoP velocity ($r = 0.6$, $p = 0.007$, Fig.1) and acceleration ($r = 0.48$, $p = 0.04$, Fig.1) were significantly associated with higher λ_{ml} (reduced stability), and these relationships were consistent across all VR conditions (velocity: $r = 0.33$, $p = 0.01$; acceleration: $r = 0.29$, $p = 0.03$).

Discussion

VR alters the dynamics of ML control rather than the magnitude of ML control. Increased COP velocity and acceleration indicate faster and more reactive lateral weight shifting.

These were associated with higher Lyapunov exponents, indicating reduced local dynamic stability. No significant differences were observed between small and large VR environments, suggesting that the magnitude of spatial scaling was not the primary factor driving these changes. This means that even simple VR environments can meaningfully challenge balance control, offering useful opportunities for task-specific rehabilitation, particularly for individuals at risk of falls.

Images (Optional)

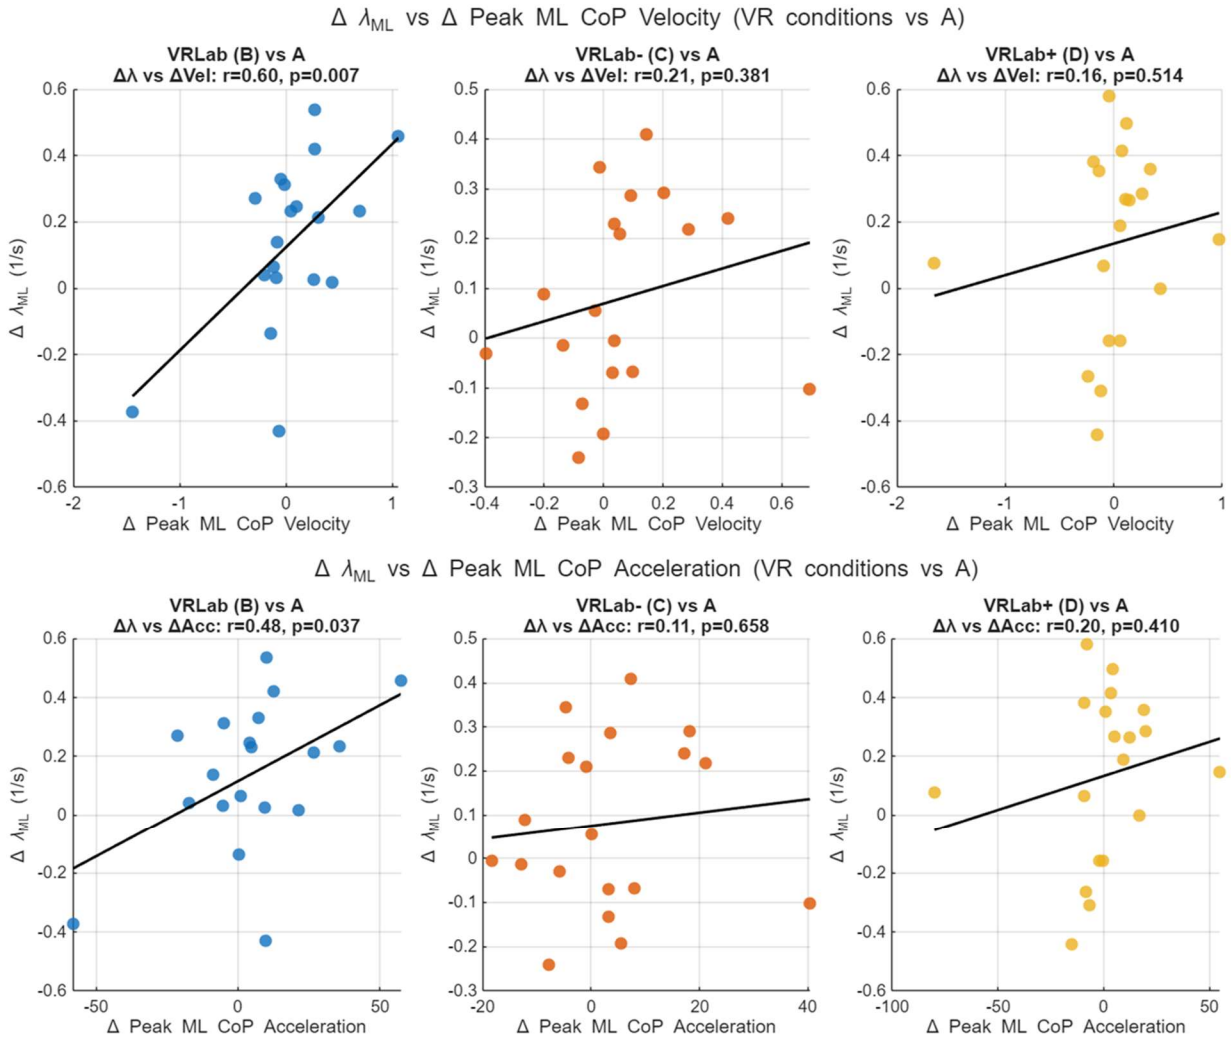

Figure 1. Scatter plots illustrating the relationship between within-subject changes in mediolateral Lyapunov exponent ($\Delta\lambda_{ml}$) and changes in peak mediolateral center of pressure (CoP) velocity (top) and acceleration (bottom) for virtual reality walking conditions (B (VR environment), C (small VR environment), D (large VR environment)) relative to real-world walking (A). Lines represent linear regression fits. Significant positive associations were observed only in the standard VR condition (B), suggesting that increases in CoP dynamics were linked to reduced local dynamic stability in VR.

Prosthetic-Limb Mediolateral Instability Drives Functional Differences Between K2 and K3 Transfemoral Amputees

Miss Jade Carter MS student[1], Miss Prachi Pisay MSc[2], Dr Ashwini Kulkarni PT, PhD[2]

[1]Teachers College, Columbia University,, NY, NY, United States. [2]Old Dominion University, Norfolk, VA, United States

Introduction

The Medicare Functional Classification Level (K-level) guides prosthetic prescription but relies heavily on walking speed and subjective judgement, leaving its relationship to dynamic stability and its control unclear [1]. The Margin of stability in antero-posterior (MoSAP) and medio-lateral (MoSML) direction quantifies dynamic stability [2], and has been studied in amputees [3], yet how these differ by K-level, and ipsilateral/contralateral limb in transfemoral amputees remains unknown. The purpose of this study is to quantify MoSAP, MoSML, and synergies stabilizing these across prosthetic and intact limbs in K2 and K3 walkers.

Methods

This is a secondary analysis [4] where 18 unilateral transfemoral amputees (9 K2, 9 K3) walked on an instrumented treadmill at five group-specific speeds (K2: 0.4–0.8 m/s; K3: 0.6–1.4 m/s). We computed MoSAP, MoSML, and synergies stabilizing MoSAP and MoSML at heel strikes from the middle 10 steps per trial.

Results

No differences in MoSAP by K-level, limb, or speed. Δvz_{AP} was greater than 0. There were main effects of the limb. ΔVz_{AP} was weaker on the prosthetic limb ($p<0.01$). V_{UCM} and VORT were higher for prosthetic limbs ($p<0.01$) and increased with speed ($p<0.01$). In contrast, MoSML showed an interaction between K-level × Side × Speed for MoSML. The prosthetic limb had smaller MoSML ($p<0.01$) at higher speeds for K3. ΔVz_{ML} was greater than zero but no differences across factors were observed.

Discussion

The absence of differences in MoSAP suggests similar overall AP stability across K-levels and limbs, however $\Delta Vz_{AP} > 0$ indicates that MoS was actively controlled through error compensation between step length (SL) and extrapolated center of mass (XCoM). The

higher V_{UCM} and V_{ORT} for prosthetic limb indicate increased corrective effort and higher variability in SL and XCoM. In contrast, the presence of differences in MoSML suggests reduced ML stability on prosthetic limb at faster speeds, suggesting they operate closer to their ML stability limits. Although ΔVzML was > 0, indicating active stabilization of MoSML, the lack of group differences suggests similar step-to-step control strategies despite differences in average ML stability.

Stepping Into Motherhood - Teasing Out Foot Mechanical Adaptations in Pregnancy Gait

Ms. Rachel Todd[1], Dr. Lauren Williams[2], Dr. Dustin Bruening[1], Dr. Adrienne Henderson[1]

[1]Brigham Young University, Provo, Utah, United States. [2]University of Utah, Salt Lake City, Utah, United States

Introduction

During pregnancy, musculoskeletal adaptations occur including increased anterior weight and increased joint laxity from altered hormones.[1] These changes increase the load on the foot's arch which may cause pain during daily activities including walking.[2] Prior research focusing on static measures of arch height are mixed. The purpose of this study was to determine how pregnancy alters static and dynamic arch function compared to non-pregnant individuals with simulated weight gain. We hypothesize static arch height will not change, and dynamic arch height during walking will significantly decrease with added weight (pregnancy or simulated).

Methods

Thirteen pregnant participants had static arch height (AHI) and dynamic navicular height measured during walking in their 1st (TR1) and 3rd (TR3) trimesters (TR1:1.65±0.07m, 65.9±14.8kg; TR3:77.3±15.9kg). Participants walked at1.0-1.2m/s, and navicular height was defined as the lowest vertical position of a marker on the navicular tuberosity during stance. Thirteen non-pregnant controls (1.65±0.08 m, 66.2±15.7 kg) were age-, height-, and TR1 weight-matched to pregnant participants. Controls completed identical AHI and walking assessments under 2 randomized conditions: unweighted and weighted (equal to matched TR3 mass). T- tests determined significance between weight conditions and groups.

Results

There were no significant differences in any static measures but significant decreases in all dynamic measures (Table 1).

Discussion

Added weight didn't result in decreased static AHI regardless of pregnancy status, possibly because plantar loads during quiet standing may be insufficiently high or too posterior to elicit measurable arch deformation. Intrinsic and extrinsic foot muscles may also increase activation to compensate for the added load. In contrast, added weight resulted in

decreased dynamic arch height for both groups. This is likely due not only to the increased load on the foot from added weight, but increased forces needed for gait in conjunction with the anterior center of pressure in mid- and terminal stance. These results emphasize that foot mechanics should be evaluated dynamically when treating the foot.
