A Cognitive Dual Task Alters Spatiotemporal Control of Gait

Dr. Reed Gurchiek[1], Dr. William Bridges[1], Ms. Olivia Cunningham[1], Ms. Sophia Somerville[2], Mr. Harrison Nodes[1]

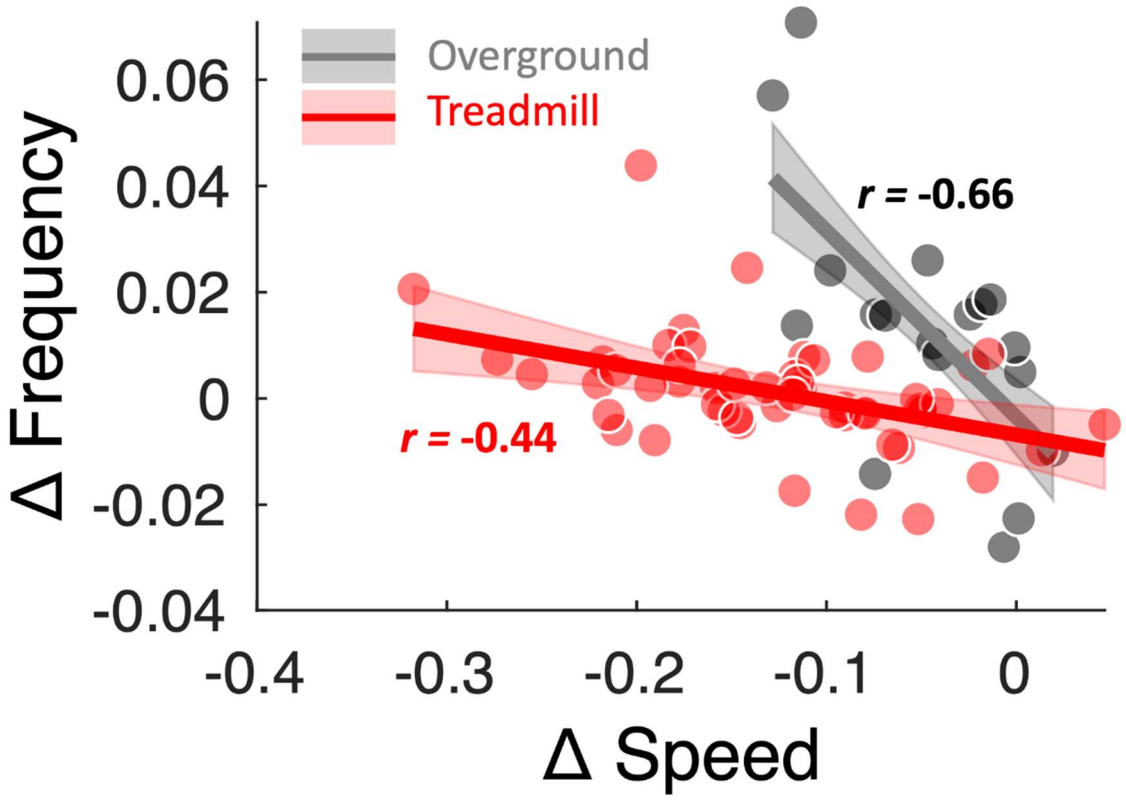
[1]Clemson University, Clemson, SC, United States. [2]Boston University, Boston, MA, United States

Introduction

Reduced gait speed is a well-known effect of cognitive dual-task gait, but the extent to which cognitive processes interfere with gait control beyond reduced gait speed remains unclear. A better understanding of this relationship could improve development of digital biomarkers of cognitive impairment for early detection of Alzheimer's disease.

Methods

Eighteen healthy subjects walked overground (self-selected speed) and on a treadmill (0.8, 1.0, and 1.2 m/s) with and without a cognitive dual task. We calculated stride frequency from gait events identified using shank-worn gyroscope data and overground gait speed using pelvis kinematics (via OpenCap). We fit a two-parameter power function to each subject's speed-frequency data collected in an additional 8 overground walking trials at prescribed frequencies (45-150 steps/minute) to model subject-specific spatiotemporal control strategies. Differences in the measured and model-predicted (based on speed) frequency during the overground dual-task gait were taken to indicate altered control. Frequency differences between single- and dual-task treadmill gait were interpreted similarly. We used regression analysis of these frequency differences to determine the effect of the cognitive dual-task on spatiotemporal control and cluster analysis to identify unique groups of subjects with a similar response.



Results

Frequency deviations in the dual-task condition negatively correlated with gait speed (relative to self-selected speed) independent of goal-directedness (overground vs. treadmill) with a more pronounced effect for overground gait. The effect of the cognitive dual task on spatiotemporal control varied across people according to four unique clusters. The general negative correlation observed overall was preserved for three of the four clusters where the slope magnitude was the distinguishing factor among the three.

Discussion

Our results suggest a cognitive dual task alters spatiotemporal control of gait independent of reduced gait speed. The preferred speed-frequency relationship is thought to optimize some motor control objective. It remains unclear if the observed shift from the preferred relationship indicates an altered objective or an impediment to optimizing the original. In either case the effect varies across people, and future research should explore this phenomenon in older adults with variable cognitive abilities.

Leveraging Ankle Foot Orthoses Kinematic Constraints to Assess Markerless Motion Capture

Mr. Riley Horn BS[1], Mr. John Collins MA, ATC[1], Dr. Heather Waters PT, DPT[1], Dr. Christine Amacker PT, DPT[1], Mr. Martins Amaechi MS[1], Dr. Rachel Thompson MD[1,2], Dr. Patrick Curran MD[1,2]

[1]Rady Children's Hospital, San Diego, CA, United States. [2]University of California San Diego, San Diego, CA, United States

Introduction

Marker-based motion capture is the clinical standard for gait analysis but is time-consuming and requires expertise for accurate marker placement. Theia3D offers a markerless alternative, though comparisons to marker-based kinematics are constrained by the inherent limitations of marker-based approximations [1]. Patients wearing ankle-foot orthoses (AFOs) present a unique opportunity to assess markerless systems, due to their predictable kinematic constraints. Hinged and posterior leaf spring AFOs restrict ankle range of motion (ROM) predominantly to the sagittal plane only [2]. We compared kinematic outputs between Theia3D and marker-based motion capture in children wearing these orthoses to determine the validity of the markerless system in capturing accurate kinematics.

Methods

Ambulatory children (Gross Motor Function Classification System (GMFCS) I-II) with cerebral palsy wearing AFOs were included for analysis (29 patients; 26 GMFCS II; age = 10.8±2.5y; 16 female). Data were collected with synchronized Qualisys systems (10 Arqus cameras, 120 Hz; 10 Miqus cameras, 85Hz; CAST 6DoF marker set) then processed in Theia3D (Theia 2025.1.2) and Visual3D (HAS-Motion). Three gait trials were averaged for each AFO-limb (n=36: 17 hinged, 19 posterior leaf spring). Ankle kinematics were compared between systems using statistical parametric mapping (SPM, spm1D.org). ROM was calculated as the difference between maximum and minimum joint angles during gait for each participant and assessed using paired t-tests.

Results

In the sagittal plane, significant between-system differences were identified during toe-off ($p=0.023$). Sagittal plane ROM differed between systems (Marker-based=14.5°; Markerless=19.3°; $p<0.001$). In the frontal plane, differences were found throughout the gait cycle ($p<0.001$), but ROM was comparable between systems. In the transverse plane,

differences were identified from initial contact to midstance (p=0.023), at pre-swing (p=0.046), and during mid-to-terminal swing (p=0.010). Transverse plane ROM differed significantly between systems (Marker-based=6.1°; Markerless=18.3°; p<0.001).

Discussion

Markerless-derived ankle kinematics showed substantial disagreement with marker-based kinematics for AFO-constrained limbs. Most notably, the markerless system reported greater transverse plane ROM relative to the marker-based system, contrary to expectations given the physical constraints of the AFOs. This disagreement between systems suggests limitations in Theia3D's foot segment definition when applied to atypical populations.

Are Toe Strength and Foot Compliance Predictive of Gait Speed in Older Adults With and Without Carbon Fiber Insoles?

Mr. Rohit Kundu[1], Dr. Daniel Davis[1], Dr. Jason Franz[2], Dr. Kota Takahashi[1]

[1]University of Utah, Salt Lake City, Utah, United States. [2]The University of North Carolina, Chapel Hill, North Carolina, United States

Introduction

Aging-induced structural and functional changes in the foot can alter foot mechanics and impair gait propulsion [1]. Increasing footwear stiffness with carbon fiber insoles can augment gait propulsion in young adults [2]. However, a feasibility study in older adults reported no group-level improvement in 6-minute walk distance with increased footwear stiffness [3]. Older adults with weaker toe flexors walked farther with carbon fiber insoles, suggesting that increased footwear stiffness effectiveness may depend on individual foot properties. Therefore, the purpose of this study was to examine how foot properties (toe flexor strength and passive foot compliance) modulate the effects of carbon fiber insoles on comfortable and maximum walking speeds in older adults.

Methods

Twenty-six healthy older adults (60-79 yrs) completed three overground comfortable and maximum walking speed trials over 20-m and 10-m distances, respectively, each under three randomized footwear conditions: 1) Control Shoe (S00), 2) Control Shoe+1.6 mm insole (S16), and 3) Control Shoe+3.2 mm insole (S32). Isometric toe flexor strength (N/kg) and passive foot compliance (inverse of foot stiffness; mm/kN) were assessed to characterize individual foot properties. A Linear Mixed Model (α=0.05) investigated how toe flexor strength and passive foot compliance affect comfortable and maximum walking speed across footwear conditions.

Results

There was no significant footwear × toe flexor strength or footwear × passive foot compliance interactions for comfortable (p=0.198-0.350) or maximum walking speeds (p=0.741-0.745), indicating that neither foot property modulates footwear stiffness effects on walking speed in older adults. Unlike passive foot compliance (p=0.340-0.745), toe flexor strength was positively associated with maximum (p<0.001) but not comfortable walking speed (p=0.097), independent of footwear conditions.

Discussion

Our results support previous findings that toe flexor strength contributes to overall walking performance[4, 5]. By reporting that the contribution holds independent of footwear condition, our findings further underscore the importance of strengthening toe flexor muscles to enhance walking performance in older adults.

Images (Optional)

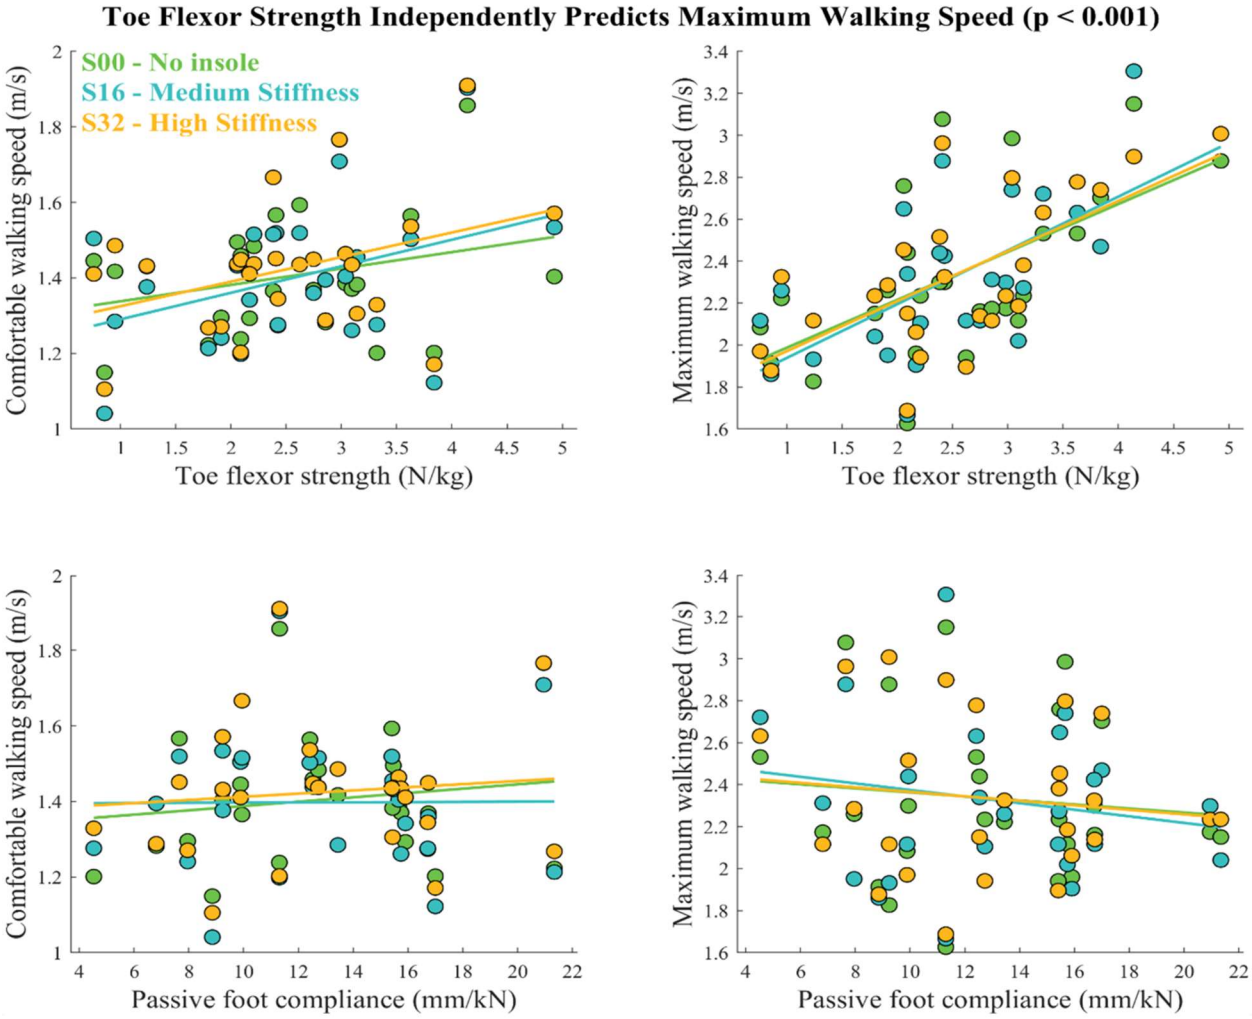

Figure 1. A Scatterplot illustrates the modulating effect of toe flexor strength and passive foot compliance on comfortable and maximum walking speed across three footwear conditions (S00 (green), S16 (blue), S32 (yellow)). Solid lines indicate condition-specific linear fits.

The Effects of Age on Multi-Segment Foot Joint Moments During Walking

Dr. Ross Smith PhD[1], Dr. Christopher Long MS[2], Dr. Jason Franz PhD[3], Dr. Kota Takahashi PhD[2]

[1]University of Memphis Lambuth, Jackson, TN, United States. [2]University of Utah, Salt Lake City, Utah, United States. [3]University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, United States

Introduction

Walking speed and metabolic economy decline with age, largely due to reduced push-off from ankle muscle–tendon units [1]. Recent work indicates walking push-off is further subverted by increased net energy dissipation at the foot in older adults, especially at faster or uphill speeds [2], potentially reflecting altered foot joint kinetics. We therefore investigated peak midtarsal (MT) and metatarsophalangeal (MTP) moments and early (0–50%) and late (51–100%) stance impulse during decline, level, and incline walking in younger and older adults (YA, OA). Prior work indicates MT moments align temporally with positive foot work and MTP moments with negative foot work; thus, we hypothesized that OA would exhibit smaller sagittal MT peaks and late-stance impulse and larger sagittal MTP peaks and early-stance impulse across slopes.

Methods

26 YA (24 y) and 19 OA (70 y) walked barefoot at 1.2 m/s on an instrumented treadmill at 5° decline, 5° incline, and level conditions. We calculated net internal joint moments for the MT and MTP joints using inverse dynamics and joint impulse as each moment's metric integral. For each participant, twenty steps from both feet were averaged and analyzed. Two-way ANOVAs assessed age and condition effects. Significant interactions were further assessed with estimated marginal means.

Results

Peak moments and impulse increased with steeper slopes ($p<.001$). Peak MT moments showed a significant interaction ($p < .001$), driven by a nonsignificant trend for YA to increase MT moment more than OA when walking uphill (trend: $p = .071$, $d = 0.57$). Late MT impulse also showed an interaction ($p<.001$) but without age differences at any slope. Older adults produced greater early MT impulse overall ($p=.049$), driven by level walking ($p=.048$). No age effects or trends were observed for the MTP joint.

Discussion

Age-related differences in MT kinetics were present during level walking, but most apparent during incline walking, which may explain previously reported gait propulsion deficits in older adults. The strength of effects shown here indicate structures not captured by inverse dynamics likely contribute to age-related changes in foot energetics.

Images (Optional)

A Study on Human Gait Adaptation on Vertically Vibrating Surfaces

Miss Ruijie Fan

Newcastle University, Newcastle, Tyne and wear, United Kingdom

Introduction

While human bipedal locomotion evolved on stable terrain, modern environments often require walking on oscillating or deformable support surfaces. Continuous external perturbations from such surfaces increase the difficulty of balance control, necessitating constant adaptive adjustments throughout the gait cycle. Existing studies are often limited to single scenarios with scattered evidence, and a systematic understanding of human gait adaptation mechanisms in varying dynamic environments remains lacking. This study investigates gait adjustment strategies during walking under different vertical vibration conditions to systematically explore human response patterns to external vertical perturbations.

Methods

Fourteen healthy adults performed walking tasks on a treadmill mounted on a vertical vibration platform while wearing a 39-marker motion capture system. The experimental design included two acceleration levels (0.5 and 2.0 m/s^2) and three vibration frequencies relative to the individual's preferred step frequency (PSF) (0.9×, 1.1×, and 2.0× PSF). Whole-body kinematic data were recorded using a 3D motion capture system to calculate joint angles and spatiotemporal gait parameters. Statistical Parametric Mapping (SPM) and multiple comparison corrections were employed to compare each experimental condition against the baseline static walking condition.

Results

Results indicated that the displacement amplitude of the support surface was the dominant factor affecting gait behaviour. Under the low acceleration condition $0.5m/s^2$, participants adapted to vibrations primarily through rhythmic adjustments at the lower limb joint level, particularly at 0.9× and 2.0× PSF. These adjustments mainly manifested as subtle temporal changes in the hip and knee joints to maintain the intrinsic gait rhythm. Notably, the 1.1× PSF vibration condition did not induce significant gait changes under

either acceleration level, suggesting that gait remains relatively stable when the external vibration frequency approaches the human preferred step frequency.

Discussion

This study demonstrates highly selective gait synchronization to vertical vibration. Weaker vibration conditions allow individuals to maintain their natural step frequency, relying more on inertial motor control strategies to preserve stability. Furthermore, gait exhibited stronger adaptability to driving frequencies higher than the natural step frequency. These findings provide a basis for understanding whole-body coordination mechanisms and offer potential value for establishing structural vibration limits and assessing fall risks in dynamic environments

Evaluation of Center of Pressure Trajectories in XSensor Insoles

Ms. Sakura Herron, Ms. Chelsea Maynard, Dr. Cherice Hill

University of Rochester, Rochester, NY, United States

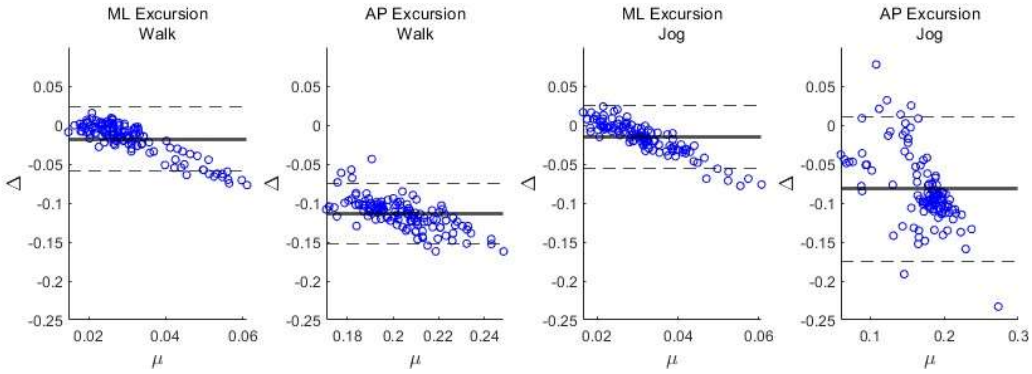
Introduction

The study of biomechanics is used to inform injury and disease prevention, clinical care, and athletic performance. As the use of this data continues to grow, ensuring its broad accessibility becomes increasingly important. Movement kinetics are commonly captured using force plates within gait lab settings, but in-shoe pressure insoles such as the XSENSOR X4 system have shown potential to enhance practical application and accessibility. Building on previous work validating the XSENSOR X4's force estimations during dynamic tasks, the aim of this study was to compare the center of pressure (COP) trajectories between the insoles and force plates.

Methods

30 participants completed walking and jogging tasks across an embedded force plate walkway while wearing shoes containing the XSENSOR X4 high resolution insoles. 128 walking and 116 jogging stance phases were extracted for pairwise comparison. COP excursions in the medial-lateral (ML) and anterior-posterior (AP) direction were compared between the force plates and insoles using paired t-tests in SPSS and Bland-Altman analyses in MATLAB (α=0.05).

Results



The XSENSOR insoles consistently produced shorter COP trajectories in the ML and AP directions in both tasks compared to the force plates ($p<0.001$, d: 0.74-5.83). The methodological biases were consistent across tasks. Excursion biases were smaller in the ML direction, although biases were proportionally similar considering greater AP excursion; most but not all data fell within 95% confidence intervals.

Discussion

COP trajectories measured by the insoles are shorter in both directions than those measured by force plates. While force plates capture contact between the shoe and ground, in-shoe insoles capture contact between the foot and shoe. This difference likely accounts for some of the observed biases, although additional systematic error may be present. Differences in COP trajectories should be considered when interpreting insole data compared to force plate data and when determining appropriate use cases. : The

significance of this study lies in its potential to enhance the practical application and accessibility of biomechanics research. Findings of this study demonstrate that XSENSOR Intelligent Insoles have the potential to provide a force plate alternative, given that systematic biases do not impact the question of interest.

Use of the Roll-Step Marching Style Gait Reduces Ground Reaction Forces at Impact

Miss Sarah Hofecker BS, Dr. Jean McCrory PhD

West Virginia University, Morgantown, WV, United States

Miss Sarah Hofecker

Introduction

The roll-step is used by members of marching bands theoretically to reduce impact load and prevent it from disputing the instrumental tone. The roll-step technique is completed by taking shorter strides and striking the ground with the heel, then rolling forward while distributing weight onto the lateral aspect of the foot until the toe hits the ground. The purpose of our study was to compare ground reaction forces (GRFs) in band members performing normal-walking and the roll-step technique.

Methods

Twenty-eight healthy experienced band members participated. After consent, subjects practiced walking at a comfortable pace through timing gates to determine average speed. GRFs were collected (1000Hz) while the band member walked at their average±5% speed in each technique. The order of conditions was randomized with three trials collected per condition. Outcome variables in the vertical forces were stance time, impact and active peaks, time to impact peak, vertical average loading rate (VALR), vertical instantaneous max loading rate (VILR), and impulse. In the shear forces, braking and propulsive peaks and impulses were calculated, as well as medial and lateral force peaks. An ANOVA was used to compare between normal and roll-step conditions (α=0.05).

Results

Data and statistical results are provided in Table 1. Speed was not different between conditions. Stance time was less in the roll-step condition. Impact peak force was lower when using the roll-step, although VIRL was greater, when compared to normal-gait. No differences were noted in VALR, active peak, and vertical impulse between conditions. In the shear forces, braking and propulsive AP peaks and medial peak were larger in normal-gait, but the lateral peak force was larger in the roll-step technique.

Discussion

As hypothesized, vertical impact force was reduced in the roll-step condition. Anteroposterior forces were also lower when using the roll-step, likely due to the shorter step length. The lateral forces were greater in the roll-step condition; however, they were only 5% BW. On-going research includes an inverse dynamics assessment of both conditions to determine if the roll-step also reduces lower extremity compressive forces at impact. If so, this may have clinical relevance for patients with lower extremity joint pain.

ANKLE JOINT INDEX AND HIP POWER CHANGES WITH INCREASING FOOTPLATE STIFFNESS

Ms. Sarah Overby[1], Dr. Adrienne Henderson[2], Dr. Dustin Bruening[2], Dr. Elisa Arch[1]

[1]University of Delaware, Newark, DE, United States. [2]Brigham Young University, Provo, UT, United States

Introduction

Joints perform distinct functions during gait, which can be described using Functional Joint Indices (FJI) that determine percentages of each joint's spring, motor, damper, and strut-like behavior[1]. FJI may aid in examining how assistive devices impact each joint's functional roles. Post-stroke, individuals commonly have reduced propulsion during walking due to plantar flexor weakness, demonstrated by a decrease in the ankle's motor role[2]. We are investigating if deformable foot orthoses (DFOs) can improve post-stroke gait by storing energy during late stance toe dorsiflexion and returning energy to improve ankle-foot energetics, including the ankle's motor role. This may reduce compensatory mechanisms at other lower limb joints, improving overall gait. This study aims to determine whether varying DFO stiffness impacted the ankle's FJI and, if so, whether other joints are affected.

Methods

Four stroke survivors walked on an instrumented treadmill under four conditions: No DFO, and three DFOs with different stiffnesses (5-ply, 7-ply, 9-ply). All trials were conducted at participant's self-selected speed, determined via a 10-meter walk test. Six degree-of-freedom kinematics and kinetic data were collected. Ankle FJI[1] and lower extremity kinematics and kinetics were calculated.

Results

Three participants showed little changes across conditions. However, for Participant 1, the ankle's motor-like behavior doubled while walking with the 7-ply and 9-ply DFOs compared to No DFO and 5-ply DFO. Late stance hip power showed a small, concomitant decrease in the 7-ply and 9-ply conditions.

Discussion

While data are preliminary, DFO use showed potential in impacting the ankle's functional role and, potentially, higher-level joint compensations in one participant. For slow gait

(0.995m/s), normalized hip powers are around 0.4w/kg in late stance[3]. For this participant (1.02m/s) while using the two stiffest DFOs, normalized late stance hip powers decrease from near 0.5w/kg to 0.35w/kg while doubling ankle motor-like behavior. This may signify improved propulsion at the ankle and reduced hip "pull-off" commonly observed post-stroke. Future work should investigate if positive impacts are seen in additional participants post-stroke, potentially with a wider range of DFO stiffnesses. Impacting FJI and joint kinetics for 25% of post-stroke participants is promising and warrants further investigation.

Virtual Neuromuscular Ankle Exoskeleton Control Provides Speed-Adaptive Gait Assistance Without High-Level Modulation

Mr. Rish Rastogi M.Eng[1], Dr. Max Shepherd PhD[1,2], Dr. Seungmoon Song PhD[3]

[1]Department of Mechanical & Industrial Engineering, College of Engineering, Northeastern University, Boston, MA, United States. [2]Department of Physical Therapy, Movement, & Rehabilitation Sciences, Bouvé College of Health Sciences, Northeastern University University Department of, Boston, MA, United States. [3]Department of Mechanical & Industrial Engineering, College of Engineering, Northeastern UniversityUniversity Department of Mechanical and Industrial Engineering, College of Engineering, Boston, MA, United States

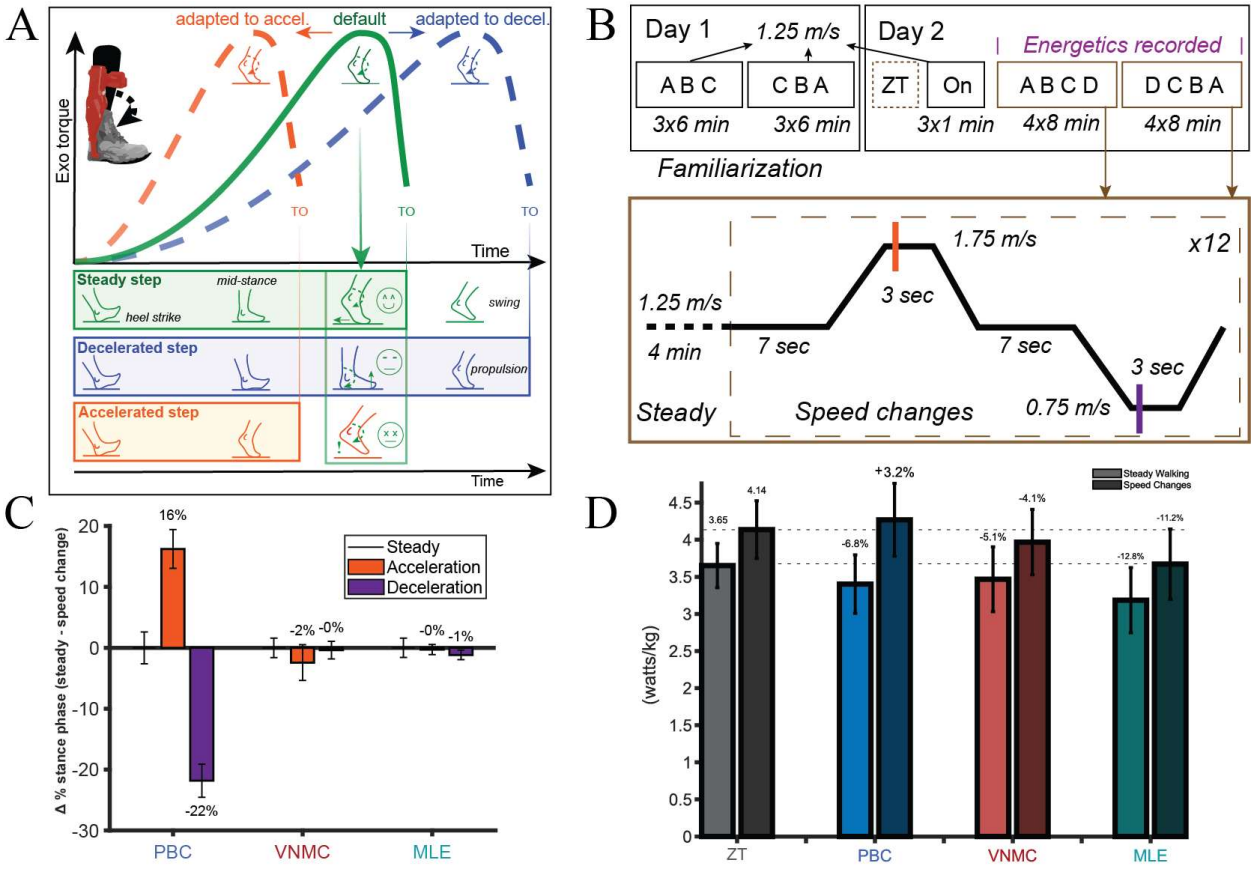
Introduction

Lower-limb exoskeletons promise to augment user mobility. However, their controllers often struggle in non-steady-state conditions. **Phase-based control (PBC)** applies torque based on predicted gait phase and can reduce the metabolic cost of transport [1], but may be ineffective or even unsafe when phase estimation is inaccurate, for instance during abrupt speed changes. A higher-level data-driven model can improve phase prediction [2], however it is unclear whether such a **machine learning estimator (MLE)** generalizes to conditions it was not trained on.

Methods

We propose **virtual neuromuscular control (VNMC)** as an alternate approach. VNMC emulates a reflex-based human locomotion model [3] by driving a virtual muscle with encoder-derived ankle kinematics to generate a virtual torque. This torque is then scaled and applied to the exoskeleton, with no need for gait phase estimation. Healthy young adults (n=10) walked through abrupt speed changes on a treadmill (B) while wearing powered ankle exoskeletons controlled in zero torque mode, PBC, VNMC, and MLE. To evaluate controller adaptability, we introduced a metric that quantifies how much the relative timing of delivered assistance during speed changes deviates from steady-state assistance.

Results



Both VNMC and MLE adapted to users during abrupt speed changes while PBC did not (C). On average, PBC deviated by **16%** ($p<0.01$) during accelerations and **22%** ($p<0.01$) during decelerations, whereas both VNMC and MLE adapted well (≤2%). While PBC, VNMC, and MLE reduced metabolic cost of transport by **6.8%**, **5.1%**, **13.8%** ($p<0.05$) in steady

walking compared to zero torque, **only PBC did not save energy during speed changes** (p<0.01) (D).

Discussion

These results highlight the importance of controller adaptability in augmenting user mobility, demonstrate VNMC's speed-adaptive nature, and support data-driven high-level control. Pairing the last with VNMC could enable the combined system to generalize beyond the machine learning model's out-of-distribution conditions because the low-level controller itself is robust. By evaluating lower-limb exoskeletons in non-steady-state conditions in the lab, we take one step closer to making exoskeletons viable in the real world.

Does PD-AFO deformation affect the mechanical cost of walking for individuals post-stroke?

Mrs. Shay Pinhey, Dr. Darcy Reisman, Dr. Elisa Arch

University of Delaware, Newark, DE, United States

Introduction

Passive-dynamic ankle-foot orthoses (PD-AFOs) can help improve cost of walking for some individuals post-stroke, but results are inconsistent [1]. This inconsistency may be because some do not appropriately engage the PD-AFO to reap its expected energetic benefits. This study's purpose was to examine if a relationship exists between degree of PD-AFO engagement and mechanical cost of transport (COT) for individuals post-stroke using a PD-AFO. If such relationship exists, future interventions could target PD-AFO engagement to increase the number of individuals post-stroke who experience the PD-AFO's energetic benefits.

Methods

17 chronic stroke participants (9F, Mass: 83.6±20.2kg, Height: 1.7±0.1m, Age: 65.9±6.4yrs, Time Since Stroke: 10.4±5.6yrs) completed the protocol so far. Participants were fit to a PD-AFO, acclimated to the PD-AFO, then completed 10-meter walk tests to determine self-selected walking speed (SSWS). Participants walked on an instrumented treadmill while 6 degree-of-freedom kinematics and kinetics were recorded. Markers were placed on the PD-AFO cuff to track deformation.

PD-AFO deformation was calculated as the peak dorsiflexion angle between the foot and PD-AFO segments during stance. COT was calculated as the sum of positive and absolute value of negative work at all lower limb joints normalized by mass and stride length. A linear regression model was run to analyze the association between COT and PD-AFO deformation when controlling for SSWS.

Results

Table 1 shows COT, PD-AFO deformation, and SSWS for each participant. Linear regression showed that PD-AFO deformation did not significantly predict COT when accounting for SSWS (R^2=0.169, F(17,14)=1.42, p=0.274). However, notably, one participant never dorsiflexed the PD-AFO (negative deformation) and had the highest COT. Additionally, data followed a visual trend that COT decreases as PD-AFO deformation increases.

Discussion

Results indicate that PD-AFO deformation is not significantly related to COT for individuals post-stroke when accounting for SSWS. We will determine if a relationship emerges with additional participants (being recruited). Understanding the effect of PD-AFO deformation on COT is an important step in determining which factors of PD-AFO use are important for improving walking energetics and ultimately improving community ambulation and quality of life for individuals post-stroke.

Images (Optional)

Ms Eleonora Lubisco

Introduction

Knee osteoarthritis is a degenerative condition affecting over 7% of the global population [1], resulting in the progressive deterioration of knee cartilage, leading to pain and reduced mobility. Despite the condition's prevalence, the choice between surgery and conservative treatments still relies on clinical and radiological evaluation and the surgeon's experience. Since osteoarthritis affects gait kinematics [2], this study aims to examine whether variability in parameters could distinguish patients and support clinicians in their decision-making.

Methods

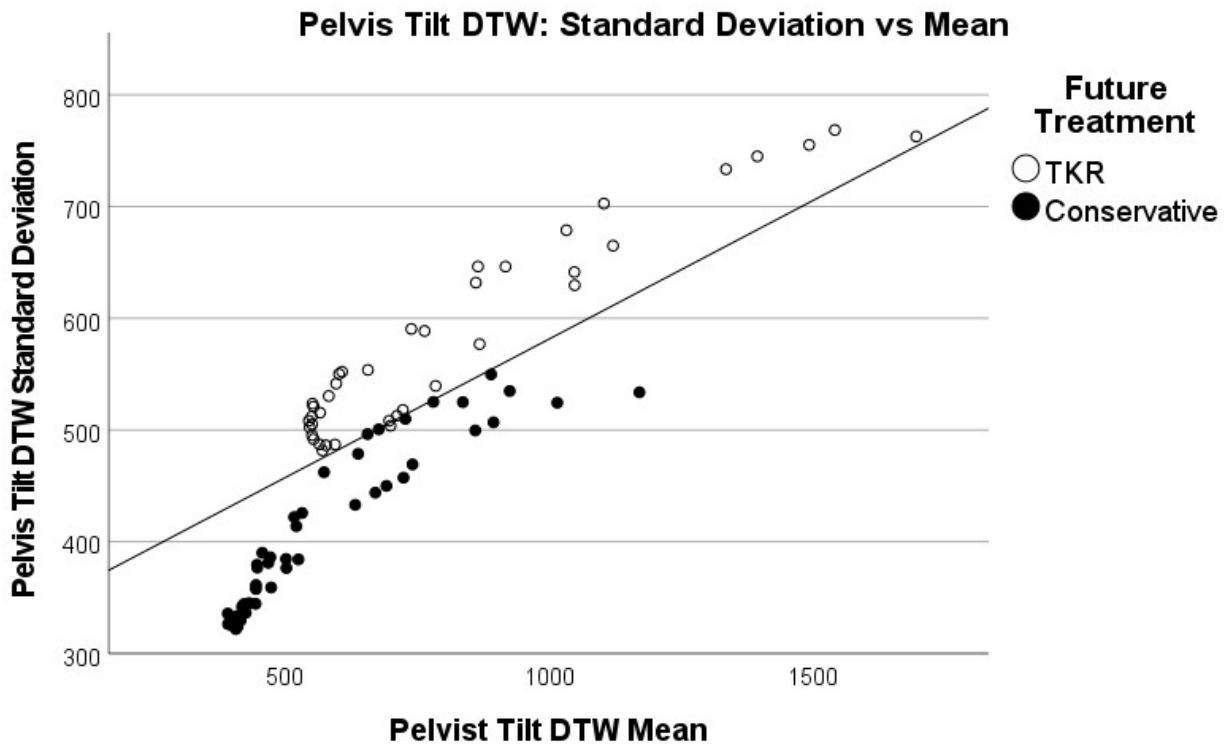
Eighty-six patients with osteoarthritis (KL grade 2–3) were divided into two groups according to the suggested future treatment: conservative or total knee replacement (TKR). Gait kinematics were recorded through a motion-capture system, focusing on key parameters such as pelvis tilt, knee and hip flexion/extension [3]. The analysis employed Dynamic Time Warping (DTW), which enables robust comparison of time-series gait signals [4].

For the inter-patient analysis, a DTW Barycenter Averaging (DBA) signal was computed for each patient as their representative gait pattern, then compared across all subjects to build a distance matrix from which the mean and standard deviation of distances were extracted.

The intra-patient analysis measured individual gait variability using DTW on repeated cycles. Group differences were evaluated with a student's t-test, and binary logistic regression assessed classification performance.

Results

The conservative group showed low variability across subjects, whereas the TKR group exhibited markedly higher dissimilarity in all gait signals, except one, both in inter- and intra-patient analysis.



Intra-patient analysis results were significant for all parameters, especially pelvic tilt, with a p-value of 10^{-5}.

The average DTW distance and its standard deviation for pelvis tilt were sufficient to correctly classify 97.7% of the subjects (2 errors out of 86 subjects—see figure).

Discussion

The study identified clear and statistically significant gait differences between conservative and TKR patients. Pelvic tilt emerged as the most informative parameter, demonstrating strong discriminative power. The DTW-based transformation suggests the potential to build an objective decision-support model, although further validation is required for clinical application

AMP: An Automated Pipeline for Marker Label Correction and Gap Filling in Motion Capture Data

Mr. Sixu Zhou, Mr. Ryan Casey, Mr. Joseph Walter, Dr. Aaron Young

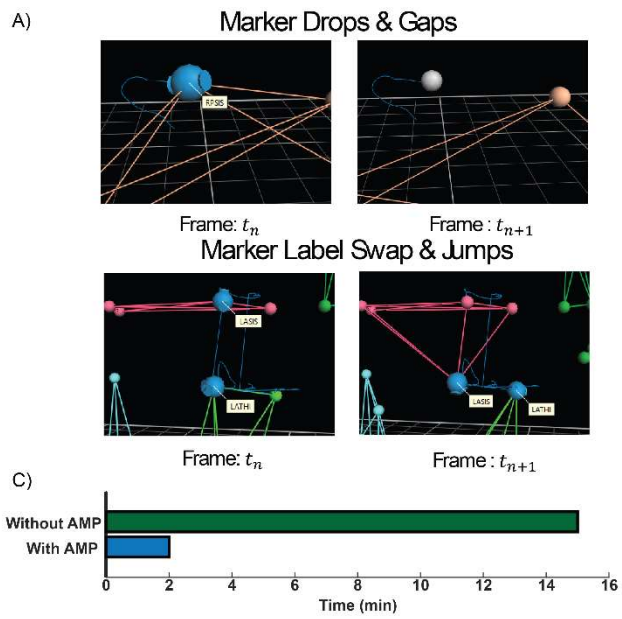
Georgia Institute of Technology, Atlanta, Georgia, United States

Introduction

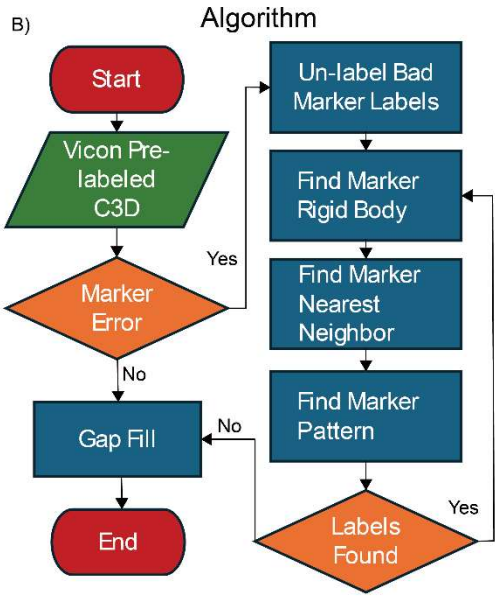
Marker-based optical motion capture (MoCap) is a fundamental tool in biomechanics and widely used for investigating animal or human locomotion such as biomechanical modeling and gait analysis [1]. The recorded trajectories of the markers are then used to compute joint inverse kinematics and inverse dynamics. Processing marker-based MoCap data is commonly challenging from marker tracking errors such as mislabeling, occlusion, or trajectory discontinuities shown in Fig 1A [2]. These distortions require a substantial amount of manual post-processing time and efforts from human experts. Previous studies have developed automated approaches to reduce manual interventions using deep learning techniques to gap fill the missing markers. However, there is no solution to provide a fully automated mocap processing workflow. Thus, we present an automated mocap processing pipeline (AMP) that determines the correctness of the marker labels, fixes the incorrect labels, and fills the missing marker trajectories using analytical methods. We tested the hypothesis that the AMP pipeline would reduce the processing time without human interventions compared to manual processing.

Methods

The AMP pipeline used three different approaches to infer the marker labels including using rigid body geometry, the Kalman Filter, or the patterns of the adjacent markers shown in Fig 1B. One trained human expert processed a sample trial that contains marker mislabels, swaps, jumps, drops, and missing marker trajectories using both the AMP pipeline and standard manual procedures. The processing time was evaluated in these two conditions.



Results



As shown in Fig 1C, the typical manual processing of a 1000-frame trial took around 15mins of manual time from an expert to fix the labels and fills the gaps while the AMP took only 2mins while maintaining the same accuracy, therefore allowing us to accept the hypothesis.

Discussion

The AMP enables a fully automated and transparent processing workflow for marker-based MoCap by simultaneously addressing mislabeling, trajectory jumps, and gap filling. The pipeline also used analytical methods without requiring any pre-trained models for applications. It substantially reduced manual processing time and showed the potential to be utilized across large biomechanics datasets.

Advancing a Shank-Worn Single-Sensor Approach for Measuring Stride Length in the Real World

Mr Spencer Miller[1], Mr Julien Mihy[2], Ms. Mayumi Wagatsuma[2], Dr. Jocelyn Hafer[2], Dr. Stephen Cain[1]

[1]West Virginia University, Morgantown, WV, United States. [2]Univeristy of Delaware, Newark, DE, United States

Introduction

Real-world gait analysis has become a popular approach as sensor technology and algorithms improve. Foot-mounted inertial sensors (IMU) can enable highly accurate calculations of spatiotemporal metrics using the zero-velocity-update (ZUPT) approach, which utilizes the fact that the velocity of the foot is approximately zero when the foot is on the ground. However, a foot sensor is often removed throughout the day resulting in incomplete data capture. To combat this issue, we developed a single-sensor-based approach using a shank-mounted sensor with a novel correction factor to limit the consistent underestimation of stride length when calculated from a shank sensor inertial data.

Methods

Using data from our IRB-approved study, we analyzed data from five participants, two with symptoms matching ACR clinical criteria for medial compartment knee osteoarthritis and three healthy controls. Participants wore a total of five IMUs for three consecutive days. The minimum shank angular velocity during stance defined midstance points, which were used as the start and end points of each stride. In our advanced approach, we integrate linear acceleration in a stride reference frame to calculate shank velocity and position, where we assume zero displacement in the medial-lateral direction, apply a ZUPT in the vertical direction, and apply a non-zero-velocity-update in the anterior-posterior direction using velocity estimates calculated from the angular velocity of the shank about a medial-lateral axis. In the standard shank approach, only a ZUPT is applied. Stride lengths were calculated using the change in position between midstance points using both our advanced and the standard approach and were compared to stride lengths calculated using ZUPT with foot IMU data (real-world gold-standard).

Results

Our advanced approach improves upon the standard approach by decreasing differences in stride length from -0.239±0.37m (mean±stdev) to -0.112±0.236m (Fig1). Our approach works differently depending on the participant and the terrain they walked during data collection, but in all cases improves stride length estimates compared to the standard method.

Discussion

Our approach enables accurate stride length estimates from a shank-mounted IMU, which can improve participant compliance in long-duration data collections. Future work will implement additional corrections for gait when walking up slopes or stairs.

Prolonged Standing-Induced Low Back Pain Developers Do Not Develop Low Back Pain after 45 Minutes of Walking

Ms. Stephanie Cotariu[1], Dr. Abigail Schmitt[1], Dr. Erika Nelson-Wong[2], Dr. Kaitlin Gallagher[1]

[1]University of Arkansas, Fayetteville, AR, United States. [2]Regis University, Denver, CO, United States

Introduction

Laboratory studies associate prolonged standing with low back pain (LBP), and walking breaks are beneficial for reducing standing-induced LBP. To date, it is unknown whether continuous walking, another upright task, would also elicit LBP in these individuals. Thus, this study sought to determine whether standing-induced LBP developers would also develop LBP after 45 minutes of continuous walking, and after a subsequent 30-minute standing bout.

Methods

Twenty-three adults (18-40 years) without LBP history completed two randomized testing days. On the Stand-Only day, participants stood for 75 minutes to determine their prolonged standing pain group. On the Walk-Stand Day, participants walked for 45 minutes, followed by 30 minutes of standing. Participants walked through a markerless motion capture system at 0 minutes, after 45 minutes of walking, and after 30 minutes of standing. Outcome measures were three-dimensional trunk-pelvis range of motion (ROM), trunk-pelvis vector coupling angle, and continuous relative phase deviation angles. Participants were considered pain developers (PD) if they had > 9mm increase in Visual Analog Scale (VAS) on the Stand-Only day. A McNemar's test was used to assess PD frequency on the Stand-Only and Walk-Stand days. Linear mixed-effects models were used with a between-factor of prolonged standing pain group, a repeated measure of time, and a covariate of speed.

Results

On the Stand-Only day, nine participants were classified as PDs after 75 minutes; eight reached the threshold after 45 minutes. On the Walk-Stand day, 22 of 23 participants were non-PDs after 45 minutes of walking (McNemar's test: p=.039 for 45 minutes of standing versus walking). There was a main effect of time on trunk-pelvis flexion-extension ROM (p<.001), which increased after prolonged walking and then returned to baseline following prolonged standing (see figure). There were no differences in the other outcome measures.

Discussion

LBP was not reported after 45 minutes of walking in all participants who reported standing-induced LBP. Cyclic movements in the lumbar region and observed changes in the flexion/extension angle with walking may be protective and shed light on mechanisms underlying standing-induced LBP. Future research will investigate the relationship between muscular activity and gait kinematics.

Development of a Gait Pattern–Based Person Identification Algorithm under Various Footwear Conditions

Ms. Subin Kim[1], Ms. Yookyeong Sa[1], Prof. Gwanseob Shin[1], Prof. Seobin Choi[2]

[1]Ulsan National Institute of Science and Technology (UNIST), Ulsan, Ulsan, Korea, Republic of. [2]Incheon National University, Incheon, Incheon, Korea, Republic of

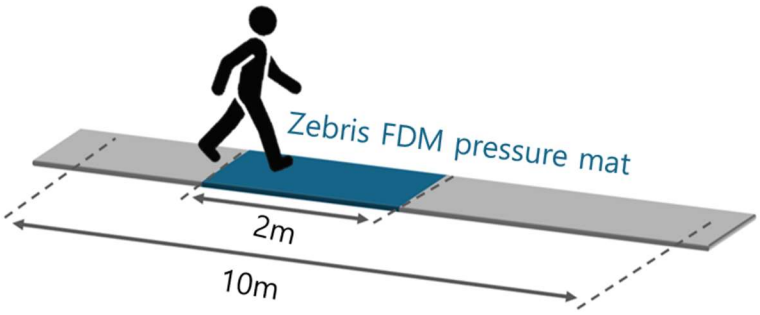
Introduction

Gait recognition technology has gained popularity in recent years due to its contactless nature. However, existing literature suffers from small samples and an over-reliance on either barefoot or single shoe types. As a result, current methods have failed to replicate the variability encountered in a real-world environment. Therefore, stable operation in varying environments is required. To address this, we sought to develop and test a Machine Learning-based algorithm for robust gait-based identification under varied footwear conditions, using large scale plantar pressure data of 50 subjects.

Methods

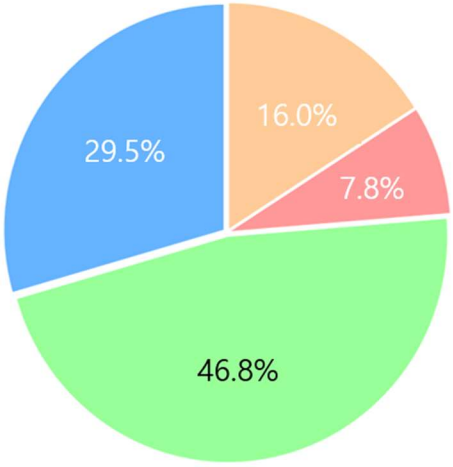
We recruited 50 healthy adults (25 males, 25 females) for the experiment. Gait data were collected using a Zebris FDM pressure mat on a 10-meter walkway. Subjects walked at their normal pace under four conditions: barefoot, running shoes (Asics Jog 100), sneakers (Vans Old Skool Low), and their own personal shoes. Five minutes of data was captured per condition. All data collected were subjected to noise removal, normalization, and sliding window preprocessing (window = 40 frames, overlap = 20 frames). Each window yielded 27 spatial and dynamic gait features to train a Random Forest classification model with optimized parameters.

Results



Integrated evaluation indicated that the proposed algorithm had a test accuracy of about 88.4%. The model optimization reduced the discrepancy between training and test accuracy to effectively prevent overfitting and ensure generalization. Feature importance analysis indicated that mean maximum pressure and Center of Pressure (CoP) are both key indicators. Furthermore, variables that are most strongly correlated with body weight also ranked high in importance, thus indicating that physical characteristics like weight significantly impact gait patterns.

Discussion



This study demonstrates the validity of plantar pressure-based gait characteristics for identification across different types of footwear in a population of 50 subjects. This is significant as prior studies were limited in their generalizability due to small sample sizes. Additionally, the results indicate that gait patterns are influenced by inherent physical traits; the application of the sliding window technique combined with an optimized model also effectively mitigated data variability. Overall, these results indicate that this methodology supports the development of effective biometric identification techniques, customized footwear design, and healthcare monitoring.

Knee Extensor Strength Correlates with Temporal Gait Parameters Derived from In-shoe Sensors in Older Women

Dr. Takuma Inai, Dr. Shoma Kudo, Dr. Wakako Tsuchida, Dr. Masahiro Fujimoto

Integrated Research Center for Self-Care Technology, National Institute of Advanced Industrial Science and Technology (AIST), Takamatsu City, Kagawa, Japan

Introduction

A decline in knee extensor strength in older women is linked to a higher risk of musculoskeletal disorders, such as knee osteoarthritis [1]. Regular assessment and maintenance of this strength are essential for disease prevention. Conventional methods (e.g., handheld dynamometers) require voluntary, sustained effort, which can be difficult for individuals with low health motivation. This study examined the relationships between knee extensor strength and force and temporal parameters measured using insole force sensors during walking. Clarifying these relationships may enable simple strength assessment by wearing sensor-equipped shoes in daily life.

Methods

Thirty-seven older women participated in the study (mean age: 78.1 ± 4.1 years). Each participant wore shoes equipped with insole force sensors (loadsol Pro, novel GmbH Inc.) and completed five round trips along a 15-m walkway at a comfortable speed. Vertical ground reaction force data were collected to calculate two force and 12 temporal parameters from 60 gait cycles per participant. Maximal isometric knee extensor strength was assessed using a Biodex System dynamometer. Each leg was tested three times, and the highest value for each leg was recorded. The mean of the right and left maximal values was then calculated for analysis. Correlation analyses were performed to examine the relationships between knee extensor strength and both force-related and temporal parameters.

Results

As shown in Table 1, knee extensor strength was significantly associated with the timing of the first peak of the vertical ground reaction force ($r = -0.58$, large), the percentage of the stance time ($r = -0.58$, large), and the percentage of the double stance time ($r = -0.59$, large).

Discussion

The findings of this study revealed that maximal knee extension strength is associated with the timing of the first peak of the vertical ground reaction force and with the percentages of stance time and double-stance time. These insights may contribute to the development of methods for evaluating and estimating maximal knee extension strength using data collected by insole force sensors during natural daily walking.

Dynamic Time Warping Reveals Unique Insight into Gait Symmetry Recovery Compared to Traditional Metrics in ACL-Injured Population

Scientist I Taliah Carlson MS, Assistant Professor Meredith Owen PhD, Associate Dean for Research Brian Noehren PT, PhD, FACSM

University of Kentucky, Lexington, Kentucky, United States

Introduction

Limb symmetry index (LSI) is utilized to help gauge recovery after an anterior cruciate ligament (ACL) injury; however, it only assesses a discrete time point of interlimb asymmetry during walking. LSI lacks temporal context, providing an incomplete and sometimes inaccurate measure of gait symmetry. In contrast, dynamic time warping (DTW) compares the full waveform, capturing differences in both shape and timing throughout stance. DTW may therefore provide more insight into interlimb coordination and recovery following ACL injury. To date, DTW has not yet been applied to assess knee moment symmetry in this population.

Methods

Sagittal-plane knee moments were analyzed from twenty unilateral ACL-injured participants across five standardized walking-speed steps. Data was time-normalized to 100% stance and average waveforms were compared between injured and contralateral limbs using DTW with a Sakoe-Chiba window (±12% stance, $\lambda = 0.05$). The local cost matrix, based on the absolute Euclidean difference between signals, quantified differences in waveform shape and timing. DTW normalized distance was measured as the average misfit per alignment step (raw distance/path length) to quantify waveform dissimilarity between limbs. Paired t-tests were used to compare differences between limbs at pre-surgery (PRE) and 6 months post-surgery (6MO). Pearson correlations were used to look at associations between variables.

Results

Statistical findings are summarized in Table 1.

Discussion

DTW and LSI captured different aspects of interlimb asymmetry early on following the ACL injury. Temporal symmetry (DTW) improved significantly by 6 months, indicating earlier

recovery of interlimb coordination, whereas magnitude symmetry (LSI) lagged, reflecting persistent underloading of the injured limb despite improved movement patterns shown by DTW. The strong association between DTW and late-stance peak timing at pre-surgery suggests early asymmetry was largely driven by temporal mismatches between limbs. By six months, DTW and LSI converged indicating that once coordination was recovering, both metrics reflected the same underlying asymmetry through different approaches. These findings demonstrate that coordination and magnitude recover on different timelines and that continuous waveform metrics, such as DTW, provide unique insight during early stages following injury when timing and waveform differences remain prominent.

Spatiotemporal Parameters of Gait Reveal Very Slow Walking Is Not Walking Slowly

Ms. Theresa E. McGuirk MS[1,2], Dr. Anita Bagley PhD, MPH[3], Dr. Carolynn Patten PhD, PT, FAPTA[1,2]

[1]University of Washington, Seattle, WA, United States. [2]VA Puget Sound Health Care, Seattle, WA, United States. [3]Shriners Hospital for Children, Northern California, Sacramento, CA, United States

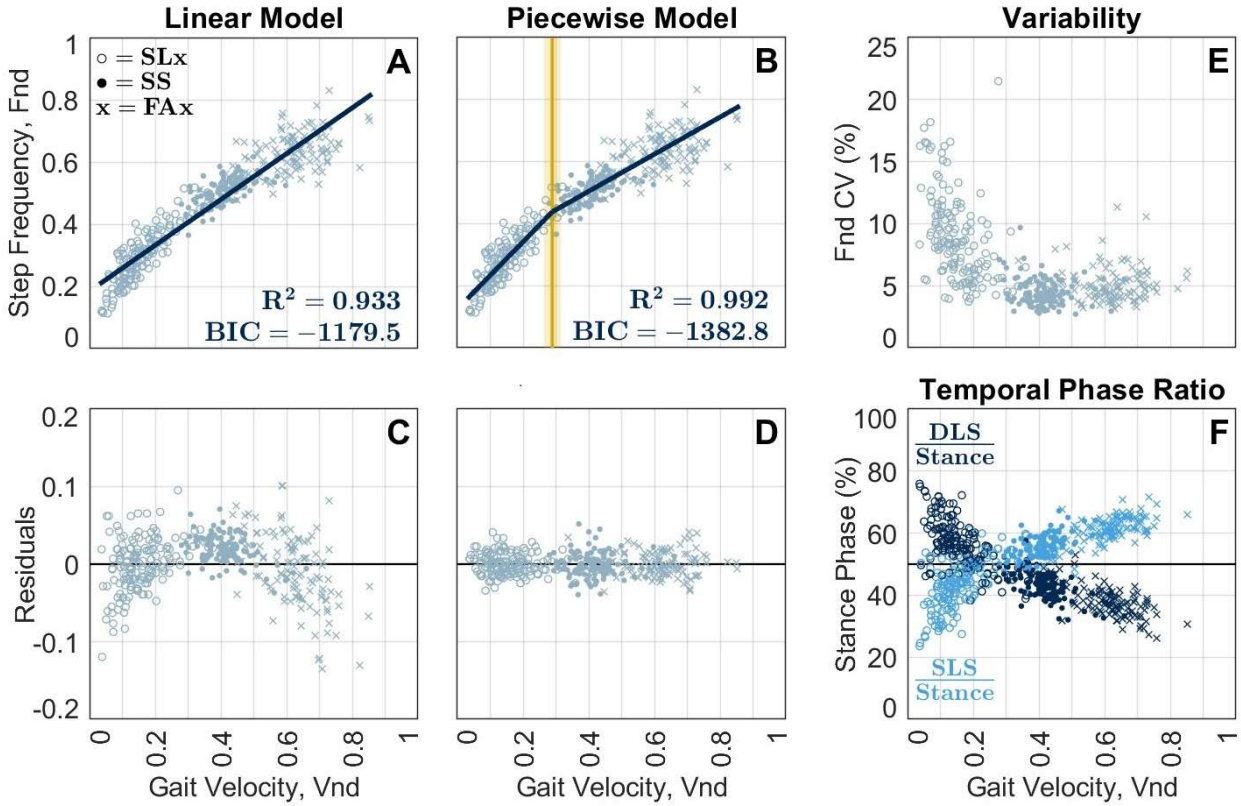
Introduction

Human bipedal gaits (walking, running), are defined as distinct forward progression solutions along the speed continuum. Very slow walking (VSW) has been considered an extension of typical walking behavior, with heuristic speed thresholds used to predict functional decline [1]. Paradoxically, habitual walking in some clinical populations (stroke, Parkinson's) is often limited to VSW, while others (older, sedentary females) [2] appear unable to access it voluntarily. We examined spatiotemporal gait parameters (STP) across a broad walking speed range to interrogate whether VSW is distinct from habitual walking.

Methods

Participants walked across a pressure-sensing floor at slowest (SLx), self-selected (SS), fastest (FAx) speeds. STP were calculated by stride, normalized [3], with mean and coefficient of variation (CV) calculated by task. Nondimensional velocity (Vnd) was used [3]. Linear and piecewise mixed-effects regression models with significant biological variables (Age, Sex) were applied to each STP/Vnd relationship.

Results



113 healthy adults (18-85yrs, 66F) participated with Vnd mean(stdv): SLx=0.141(0.067), SS=0.412(0.066), FAx=0.622(0.091). Piecewise models were preferred for all STP/Vnd relationships except Stride Width based on decreased BIC (Fig1A-D), and no 95%CI overlap between segment slopes. Piecewise models identified three similarly positioned breakpoints for temporal (Vnd=0.270), spatial (Vnd=0.235), and StepRatio (Vnd=0.185) parameters. In SLx, CV increased ($p<.001$) (Fig1E) for all STP except Stride Width, and gait cycle temporal phasing reversed to dominant double limb support (DLS) (Fig1F).

Discussion

The position of walking gait on the speed continuum, between standing posture and running gait, presupposes the presence of a walk-stand transition like the well-defined walk-run transition. Three STP characteristics differentiating VSW from walking were

identified: 1) breakpoint presence in STP/Vnd relationship, 2) increased variability, 3) DLS dominance. These characteristics (connected but not discontinuous breakpoint, increased variability, same temporal phases as walking with reversed ratios) paired with proximity to standing on the speed continuum, point to VSW as a walk-stand transition. This distinction, that VSW is not a linear extension of walking at slower speeds, redefines our interpretation of gait performance in this speed range.

Fourier Analysis of Vertical GRF Shape Reveals Very Slow Walking is a Distinct Behavior

Ms. Theresa E. McGuirk MS[1,2], Dr. Anita Bagley PhD, MPH[3], Dr. Carolynn Patten PhD, PT, FAPTA[1,2]

[1]University of Washington, Seattle, WA, United States. [2]VA Puget Sound Health Care, Seattle, WA, United States. [3]Shriners Hospital for Children, Northern California, Sacramento, CA, United States

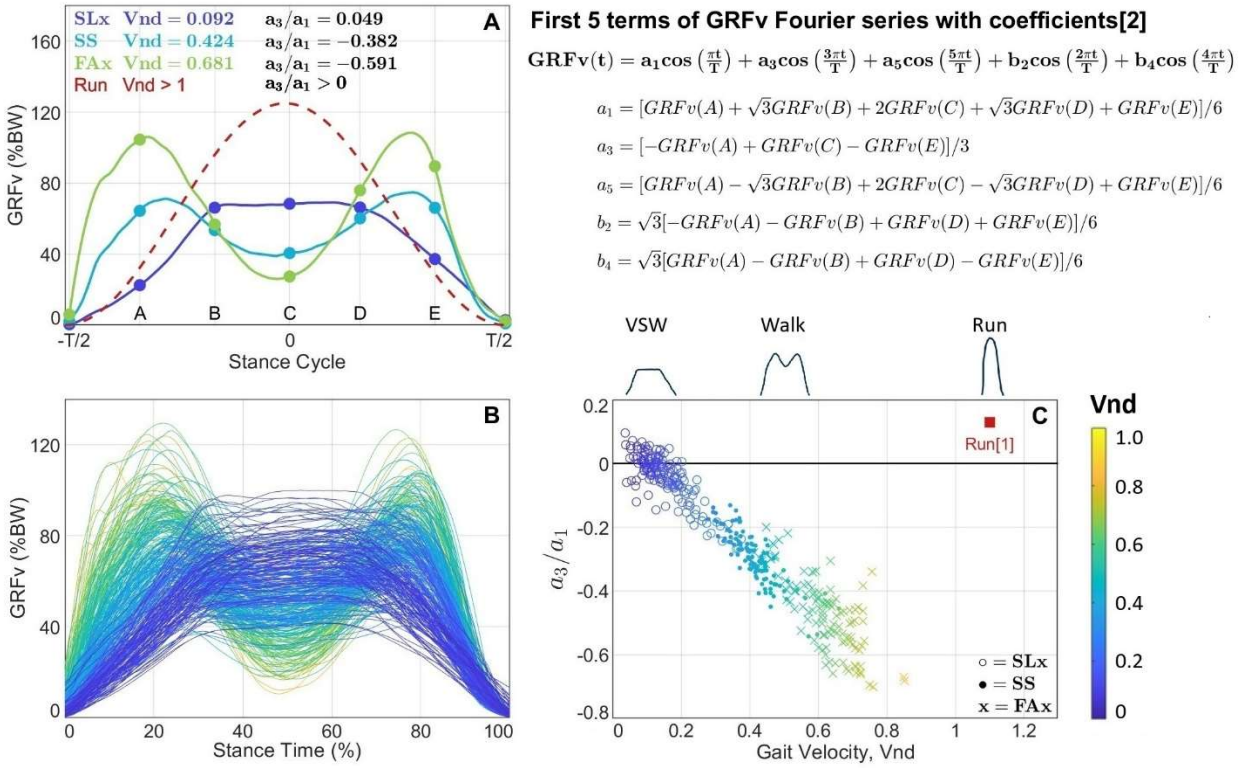
Introduction

Human bipedal gaits (walking, running), are defined by distinct forward progression solutions along the speed continuum. Very slow walking (VSW) has been considered an extension of typical walking. However, when modeled simply as an inverted pendulum, kinetic energy during walking becomes insufficient to vault body mass over the stance leg at speeds <0.56m/s [1], suggesting VSW solves forward progression differently. We applied Fourier analysis to vertical ground reaction force (GRFv) curves over a broad range of walking speeds to investigate mechanistic differences between walking and VSW.

Methods

Participants walked across a pressure-sensing floor (spatial resolution=5mm; SF=100Hz) at slowest (SLx), self-selected (SS), fastest (FAx) speeds. Estimated GRFv (GRFv = Pressure x Sensor Area), was normalized to stance time (101-points) and body weight (BW) and averaged by task (Fig1B). GRFv curves were expressed as first five terms of Fourier series [2] with term coefficients (Fig1A) examined relative to nondimensional velocity (Vnd) [3].

Results



113 healthy adults (18-85yrs, 66F) participated with Vnd mean(stdv): SLx=0.141(0.067), SS=0.412(0.066), FAx=0.622(0.091). a3/a1 shifted predominantly positive at Vnd<0.2 (Fig1C). b2/a1 shifted positive near Vnd<0.5 with smaller +b2/a1 at Vnd<0.2.

Discussion

Fourier analysis has been used to distinguish signature walking and running GRFv shapes [2]. The a3/a1 sign indicates maxima quantity, where +a3/a1 captures the bell-shaped GRFv of running, and –a3/a1 the M-shaped GRFv of walking. The b2/a1 sign characterizes shape symmetry, with –b2/a1 skewed left (loading/absorption) and +b2/a1 skewed right (unloading/propulsion). Our analysis revealed +a3/a1 and +b2/a1 at Vnd<0.2. This right-skewed, bell-shaped GRFv reveals deliberate, controlled locomotion with long, shallow

loading/unloading slopes and steady plateau in single limb phase. Such behavior requires intentional, deliberate control. This finding aligns with theoretical threshold Vnd=0.18 (V=0.56m/s) [1] of the inverted pendulum model and points to the forward progression solution during VSW emerging without the automated motor control employed during habitual walking. This distinction that VSW operates by intrinsically different mechanism informs how gait performance in this speed range should be interpreted, particularly in clinical populations (stroke, Parkinson's) often limited to VSW speeds.

[5]Institute of Health Sciences at the University of Applied Sciences St. Pölten, St. Pölten, Niederösterreich, Austria

Introduction

Manually detecting gait events of walking trials is time-consuming. IntellEvent, a deep learning-based algorithm, has been validated for detecting initial contact (IC) and toe-off events during overground (OVG) straight-line walking [1]. Walking and turning on a complex setup such as an omnidirectional treadmill with virtual reality (ODTVR) involves gait adaptations [2] that may challenge automated event-detection methods. This preliminary study investigates whether IntellEvent can accurately detect IC events when executing 90° turns during OVG and ODTVR walking, compared with manual detection.

Methods

Data of five participants from a previous study [2] involving 90° turns towards the right during OVG and ODTVR walking were analyzed. A trained evaluator manually identified six IC events per trial (one gait cycle before, during, and after the turn for each leg). This process was repeated three times, with at least one week between five-hour sessions of manual IC detection. IntellEvent was then used to automatically estimate IC events within the same time window as the manual detections. Mean absolute errors were estimated to inform the consistency of manual detections and the accuracy of IntellEvent relative to the averaged manual results.

Results

Between-day differences in the manual detection of IC ranged from 0.3 ± 0.8 to 0.9 ± 1.8 frames, with lower variability in OVG versus ODTVR trials. IntellEvent closely matched averaged manual detection values, with errors of 0.3 ± 0.8 frames (OVG), 0.7 ± 1.6 frames (ODTVR), and 0.48 ± 1.3 frames overall. IntellEvent identified IC events within 3 frames in 97.8% of OVG trials and 92.2% of ODTVR trials.

Discussion

The preliminary results indicate that IntellEvent yields good accuracy of gait detection events when executing turns during OVG and ODTVR walking, with errors that fall below the threshold (20 ms or 2.4 frames) that was shown to meaningfully impact kinematic measures [3]. Importantly, IntellEvent has not yet been trained on ODTVR data, indicating a promising generalizability of the current algorithm to different walking conditions. IntellEvent processed each trial within seconds, greatly improving efficiency compared with manual detection.

A Framework for Robust Spatiotemporal Analysis of Dynamic Plantar Pressures Measured in Healthy and Deformed Feet

Mr. Tyce Marquez MS, Mr. Owen Kautman, Dr. Bopha Chrea MD, Dr. Jason Wilken PT, PhD, Dr. Donald Anderson PhD

University of Iowa, Iowa City, Iowa, United States

Introduction

Barefoot dynamic plantar pressure systems provide discrete pressure values over defined region of interests. This approach lacks standardization and misses important spatiotemporal features [1, 2]. Previous spatiotemporal plantar pressure analysis approaches are limited in generalizability to deformed feet. Here we present a newly developed framework for robust spatiotemporal analysis of plantar pressures in healthy and deformed feet.

Methods

Dynamic plantar pressures (3 trials per foot) were collected using the Novel-EMED platform from 10 healthy feet and 10 feet with Charcot-Marie-Tooth (CMT) peripheral neuropathy exhibiting varying deformities. Maximum pressure distributions and time series pressures sampled at 10 ms intervals were exported for analysis. The foot progression angle (FPA) was calculated on maximum pressure distributions as the average between lines tangent to the medial/lateral boundaries of the foot relative to the posterior-to-anterior platform axis [3]. Pressure distributions were rotated by the FPA, and bounding box indices collected. Time series pressures were linearly interpolated at 5% intervals across stance, rotated by the FPA, and bounding box values extracted and scaled to a standard 50x18 sensor grid. This yielded 20 aligned pressure distributions per foot for sensor-level comparisons (Figure 1). Framework reliability was assessed using intraclass correlation coefficients (ICCs) of FPA selection from two observers and the minimum detectable change (MDC) at a sensor-level from aligned maximum pressure distributions.

Results

Intra-observer ICCs from both observers were ≥ 0.94 with an inter-observer value of 0.98. The MDC across all sensors was 34.88±50.72 kPa. The maximum MDC was 355.09 kPa in the lateral forefoot, with larger MDC values generally in regions that experience increased plantar loading.

Discussion

The spatiotemporal analysis framework presented provides a straightforward and generalizable approach to analyzing healthy and deformed feet superior to prior approaches. Studies have shown altered loading in deformed feet by reporting discrete peak pressures, pressure-time integrals, and centers of pressure. However, these fail to adequately define spatiotemporal gait patterns. The new framework enables sensor-level comparisons between healthy and deformed feet, providing critical insights into load progression.

Uneven Treadmill Terrain Weakens Gait Complexity in Low- but Not High-Functioning Older Adults

Dr. Tyler Wiles, Dr. Daniel Ferris

University of Florida, Gainesville, FL, United States

Introduction

Gait patterns are often dictated by the world around us and our level of cognitive function. The ground that we walk on is rarely perfectly flat. To dynamically respond to irregular and uneven walking surfaces in our environment, gait patterns must also contain a certain degree of irregularity and complexity. These two gait characteristics can be measured using sample entropy (SampEn) and the Hurst exponent, respectively. We hypothesized that walking over increasingly uneven treadmill terrain would increase SampEn and decrease the Hurst exponent, indicating the onset of less regular and less complex gait patterns.

Methods

A total of 26 high-functioning older adults (HFOA) and 43 low-functioning older adults (LFOA) were included in our analysis [1]. Three-minute walking trials were completed, twice, over a flat (control), low (1.3 cm pucks), medium (1.3 & 2.5 cm pucks), and high (1.3, 2.5, 3.8 cm pucks) series of treadmill terrains [1]. SampEn and the Hurst exponent were calculated from the final fifty right stride intervals. From these time series, Bayesian repeated measures ANOVAs produced Bayes Factors (BF_{10}) indicating the strength of evidence supporting a difference in the Hurst exponent or SampEn.

Results

SampEn had no evidence of a terrain or cognitive function effect at any level ($BF_{10} < 1$). Extreme evidence of an interaction and terrain main effect ($BF_{10} > 100$) suggested LFOA and HFOA should be tested independently. LFOA pairwise comparisons revealed that the Hurst exponent decreased with the onset of uneven terrain ($BF_{10} > 12$) but not increasing terrain height ($BF_{10} < 1$). HFOA Hurst exponents remained stable for all terrain ($BF_{10} < 1$).

Discussion

Reductions in the Hurst exponent, but not SampEn, suggest that LFOA adjusted their gait to become less complex, while maintaining irregularity, to overcome uneven terrain. Alternatively, HFOA appear to deploy gait patterns robust to uneven treadmill terrain. Lack of a difference in terrain height suggests that the motor strategy used to respond to

irregular and uneven surfaces is independent of terrain height, up to 3.8 cm. These results also suggest that weakening gait complexity is a feature of low-functioning older adults.

Can Surface Topography of the Back Detect Surgically Fused Segments? - A Videorasterstereographic Study With Spondylodesis Patients

Dr. Ulrich Betz[1], Dr. Johanna Kniepert[2], Dr. Jürgen Konradi[1], Dr. Janine Huthwelker[1], Ms. Henriette Rönsch[1], Mr. Roman Paul[3], Prof. Philipp Drees[2]

[1]Institute of Physical Therapy, Prevention and Rehabilitation of the University Medical Center of the Johannes Gutenberg University, Mainz, Rhineland-Palatinate, Germany. [2]Department of Orthopaedics and Trauma Surgery of the University Medical Center of the Johannes Gutenberg University, Mainz, Rhineland-Palatinate, Germany. [3]Institute of Medical Biostatistics, Epidemiology and Informatics of the University Medical Center of the Johannes Gutenberg University, Mainz, Rhineland-Palatinate, Germany

Introduction

Videorasterstereography (VRS) can analyze the surface of the back and its changes during walking very accurately. However, it is not yet known whether the results reflect the movement of the spinal segment beneath the surface. To address this question, subjects were examined using VRS after surgical fusion of one or more segments.

Methods

A total of 34 subjects were analyzed who had undergone successful fusion of at least one spinal segment between C7 and L5 at least one year prior (X-ray control) and were able to walk hands-free on a treadmill at a speed of at least 2 km/h (two-minute walk test). We used a DIERS Formetric III 4D (60 Hz) VRS-system to measure the back surface at 2, 3, 4, and 5 km/h where possible. With this we obtained results for spinal rotation sum of motion per gait cycle for a total of 113 fused segments. With the target variable: observed movement a model was fitted for multiple observations per subject adjusted for sex and age.

Results

The participants had varying numbers of segments fused (1-12) and different numbers of subjects could be measured for the spinal segments (1-13). The estimated rotation for the various segments at the various speeds was between 1.39° and 5.18° with large upper 97.5%-confidence intervals up to 8.40° (L4/pelvis at 5kph). The cranial and caudal segments show more movement than the middle. Up to a margin of error of 70%, the results were significantly different from 0 (Binominal Test, adjusted lower 99.375%-confidence limit). There is a trend indicating movements above 1.5°, but this is not

significant across all speeds and segments. The speed is significantly associated with the estimated rotation ($p<0.0001$), region of the spine, number of fixed segments, age, sex, segment are not (F-Test).

Discussion

In a heterogeneous group of patients with one or more surgically stiffened segments, VRS indicates movement of stiffened spinal segments when walking. This probably reflects not a measurement error but the influence of the spine overlying soft tissue on the measurement result. The extent of the measured movement varies in the different spinal segments.

Humans Modulate Feedback Control to Improve Long Term Performance Through Locomotor Adaptation

Mr. Vinayak Bansal, Dr. Nidhi Seethapathi

Massachusetts Institute of Technology, Cambridge, Massachusetts, United States

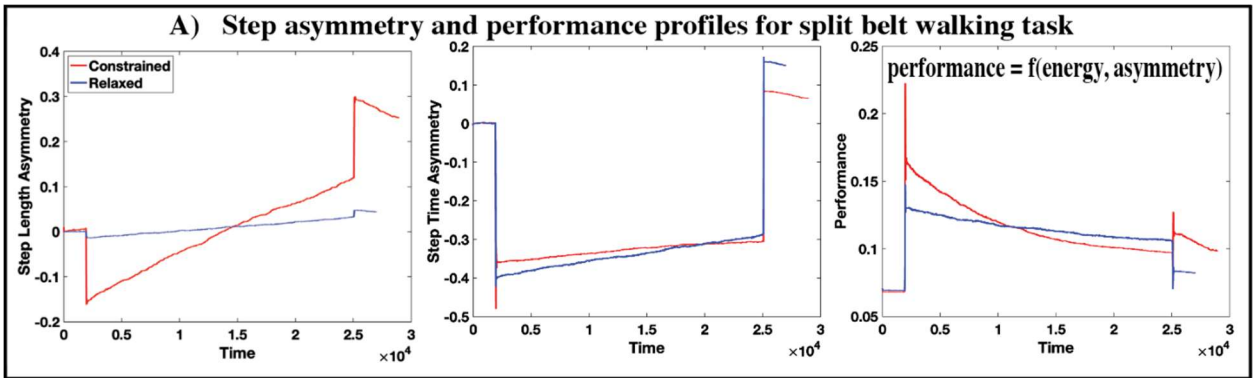
Introduction

Understanding how humans adapt locomotion is central to motor control, biomechanics, and rehabilitation. Locomotor adaptation is thought to arise from interactions between fast feedback control and slow changes in biomechanical performance. However, the role of feedback control in this process is poorly understood. Existing models assume a specific feedback controller structure, such as one with equal limb angles at pushoff and heelstrike. While such choices may result in good performance in one condition, it is unclear how they affect performance across conditions. Here, we modified the controller choice across two adaptation tasks, split belt (one condition) and dynamic treadmill with sudden speed changes (four conditions) [1], examining how controller choice interacts with biomechanical performance.

Methods

Using a locomotor adaptation model [2], we studied the dynamics of asymmetry and energetics for two controllers: one that assumes equal limb angles (constrained) and one that does not (relaxed). For each condition and controller, we independently fit the model's parameters to avoid bias. We formalized the biomechanical performance metric as a weighted sum of energy, symmetry, and timing accuracy to compare the controllers.

Results



The relaxed controller better explained observed asymmetry in two conditions, the constrained controller in one, and both controllers performed similarly in the remaining two. Also, the two controllers had different energy consumptions and resulted in different timescales for asymmetry adaptation. Using the performance metric, we found that humans tend to choose a controller that maximizes long term performance. For the conditions best explained by a single controller, choosing this controller over the other

alternative resulted in long term performance benefits of 41.4 ± 24.3 %. For the conditions where both controllers explained behavior equally well, this difference was only 4.6 ± 4.7 %.

Discussion

Overall, these findings suggest that the choice of feedback controller plays an active role in how biomechanical performance changes through adaptation. We find that humans choose the feedback controller that maximizes long term performance. Rehabilitation interventions should therefore account not only for biomechanical performance, but also for which controller they engage during adaptation and learning.

Images (Optional)

A) The constrained controller has an asymmetric step length profile, which matches observed behaviour. The constrained controller is also performance optimal in the long run (t > 1.5e4). The relaxed controller does not explain behaviour and has suboptimal performance in the long run.
B) Predictions that match observed are in green. Long term performance consistently explains controller choice.

B) Asymmetry and performance results for all 5 conditions

Comparative Analysis of Locomotion Control Models in Neuromechanical Simulations

Mr. Vincent Ton, Dr. Seungmoon Song Ph.D.

Northeastern University, Boston, MA, United States

Mr. Vincent Ton

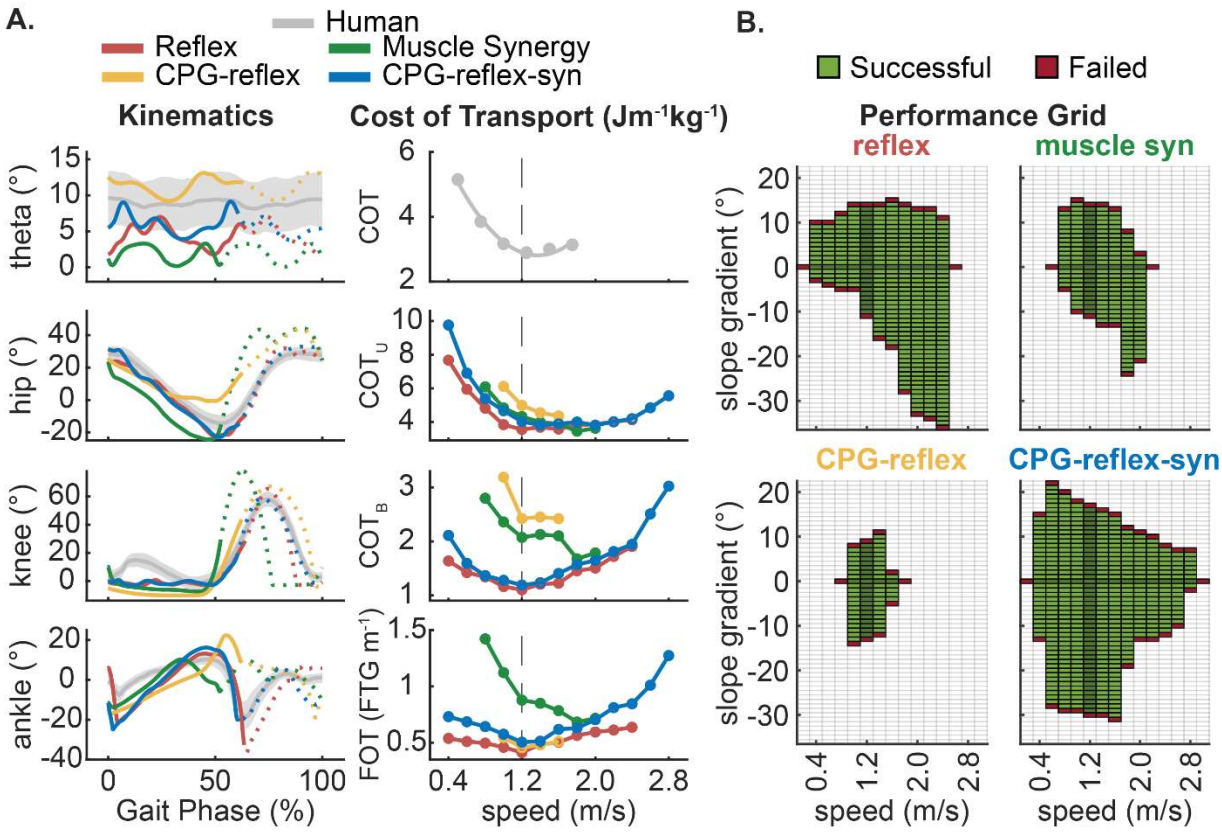
Introduction

Understanding how the nervous system generates locomotion is fundamental to movement science. Although central pattern generators (CPGs), spinal reflexes, and muscle synergies are widely discussed as key neural mechanisms, their respective roles and contributions to locomotion remain unresolved. Neuromechanical simulations with explicit control models offer a practical way to evaluate how different control hypotheses influence gait behavior. However, these proposed models have been implemented across different environments with varying musculoskeletal properties and optimization criteria, preventing direct comparison. Here, we compare four neurophysiologically-inspired control models within a unified framework to assess their diverse gait behaviors.

Methods

We investigated four representative locomotion control models: reflex-based [1], muscle-synergy-based [2], CPG-reflex-based [3], and CPG-reflex-synergy-based [4]. Using a unified neuromechanical simulation framework (MATLAB/Simulink; two-dimensional musculoskeletal model with 18 leg muscles; CMA-ES optimization), we evaluated each model's ability to: 1) produce human-like gait and 2) generate walking across speeds and slopes.

Results



While comprehensive biomechanical analyses will be presented at the conference, the main findings are summarized here. When optimized for minimum muscle effort at normal walking speed, the reflex-based and CPG-reflex-synergy-based models generated the most human-like and efficient gait, while the muscle-synergy model showed the largest deviations (Fig. A). Across the speed–slope space, the CPG-reflex-synergy model achieved the widest range of stable walking, followed by the reflex model, with the CPG-reflex model

performing worst (Fig. B). Representative animations: https://neumove.org/project/NM4models.html.

Discussion

Although the models show clear performance differences, interpretation requires caution. These results reflect specific implementations rather than definitive judgments about underlying control hypotheses, as each strategy can be formulated in multiple ways. These models emphasize spinal mechanisms, while human walking outside nominal conditions involves supraspinal control, so performance at extreme speeds or slopes should not be over-interpreted. Additionally, other evaluations such as perturbation responses were not included. Nevertheless, this work provides the first systematic comparison within a unified framework. The codebase will be shared to facilitate further model development and hypothesis testing.

Dynamic Obstacle Avoidance Alters Gait Spatiotemporal Parameters and Variability During Walking

Dr. Wendi Weimar PhD, Mr Bahman Adlou MS, Mr John Grace MS

Auburn University, Auburn, AL, United States

Introduction

Obstacle avoidance is a tool required for everyday locomotion; however, too often our research is focused on navigation around stationary barriers. Yet dynamic obstacles pose a significant real-world challenge and offer valuable insight into assessing individuals with mobility impairments. Therefore, this project investigated the influence of stationary and dynamic obstacles on spatiotemporal gait parameters and variability.

Methods

Twenty-nine healthy young adults (14F/15M, age 22.7±3.1 years) completed 20 trials along a 16-foot instrumented walkway under four conditions: baseline (C1), stationary obstacle (C2), perpendicular-moving obstacle (C3), and head-on-moving obstacle (C4). Spatiotemporal gait variables including stride length, step length, and stride width were recorded, with both mean values and coefficient of variation (%CV) calculated to quantify gait variability. Linear mixed models (LMMs) with participant as a random effect were employed to compare gait parameters across conditions, using C1 as reference. Pairwise comparisons between all conditions were conducted with effect sizes quantified using Cohen's d.

Results

Linear mixed models with participant random intercepts revealed significant increases in stride length (C2: +9.4 cm, C3: +8.6 cm, C4: +4.0 cm; all $p<0.001$) and step length (C2: +5.0 cm, C3: +5.2 cm, C4: +2.9 cm; all $p<0.001$) across all obstacle conditions. Step length variability increased most dramatically with perpendicular-moving obstacles (C3: +12.3% coefficient of variation, $p<0.001$), significantly more than stationary (+6.1%) or head-on-moving (+10.0%) obstacles. Sex differences emerged, with males demonstrating greater stride lengthening in stationary and perpendicular conditions.

Discussion

This project indicates that moving obstacles, particularly those moving toward the participant regardless of direction, challenge gait stability more than stationary obstacles. The increased neuromuscular demands created by dynamic obstacles may

allow for deeper analysis of real world challenges. Dynamic obstacle performance may provide earlier detection of balance deficits and offer a more ecologically valid assessment tool. Additionally, rehabilitation programs incorporating unpredictable moving obstacles may better prepare patients for community mobility than static balance training. Future research should validate this paradigm in older adults and clinical populations to determine its predictive validity for fall risk.

Explainable Machine Learning Identifies Mechanisms of Gait Improvement After a Multicomponent Exercise Program in Long-Term Care

Dr. Xiaoping Zheng[1], Ms. Ziwei Zeng[1], Mr. Cheuk Yin Ho[1], Prof.dr. Junhong Zhou[2], Prof. dr. Yijian Yang[1]

[1]The Chinese University of Hong Kong, Hong Kong, Hong Kong, Hong Kong. [2]Harvard Medical School, Boston, Massachusetts, United States

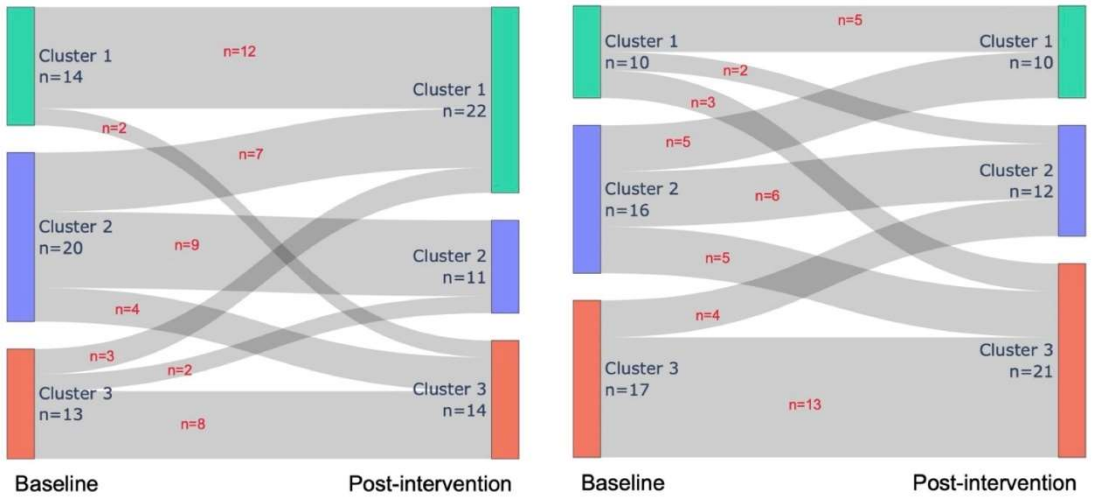
Introduction

Falls are highly prevalent in long-term care (LTC) settings and nearly half (49%) of them occur during walking. Improving gait is therefore critical for fall prevention. Mobility-Fit, a 12-week multicomponent exercise program, was developed to enhance mobility in this population [1]. Given the heterogeneity in physical and cognitive function and the varied responsiveness to intervention among LTC residents, conventional analysis approaches that rely on group-level mean comparisons may be insufficient to capture meaningful changes. Facing this challenge, this study aimed to use machine learning to evaluate individual- and group-level intervention responses so as to uncover the underlying mechanisms contributing to gait improvements.

Methods

This study was a 2-arm cluster randomized controlled trial including 90 older adults from 20 LTC facilities in Hong Kong (mean age 82.2 ± 9.1 years; 64.4% female) who completed gait assessments. Participants were randomized into the intervention (Mobility-Fit; n=47) or control (standard care; n=43) groups. Gait was assessed using a 3D-accelerometer during two 5-m walking trials at baseline and post-intervention. Thirty-two gait outcomes were extracted. Unsupervised machine learning (K-means clustering) was applied to baseline gait data to identify latent gait patterns. The trained K-means clustering was then used to assign post-intervention gait patterns. Individual responsiveness was evaluated through gait pattern transitions, and group-level intervention effects were examined using chi-squared tests. Explainable AI (XAI) was employed to determine gait outcomes contributing to intervention responsiveness.

Results



Three distinct gait patterns were identified: better-performing, moderate-performing, and poorer-performing. Gait pattern improvement was defined as: (1) transitioning improved-performing patterns (e.g., moderate to better), or (2) maintaining moderate- or better-performing patterns over time. As shown in Figure 1, the intervention group demonstrated a

higher rate of gait pattern improvement compared with the control group (70% vs. 47%, p = 0.038). XAI analyses indicated that improvements were primarily driven by enhanced gait regularity (reduced stride frequency variability; increased stride regularity) and gait smoothness (higher harmonic ratios).

Discussion

Mobility-Fit significantly improved gait quality among LTC residents, particularly in gait regularity and smoothness. Our analytic framework provides a novel approach for evaluating and optimizing exercise interventions for older adults in LTC.

P1-245

Gait Variability, but Not Gait Speed, Differ Among Older Adults With Multimorbidity

Mr. Yale Hughes M.S., Dr. Ashlyn Jendro PhD, Dr. Abigail Schmitt PhD

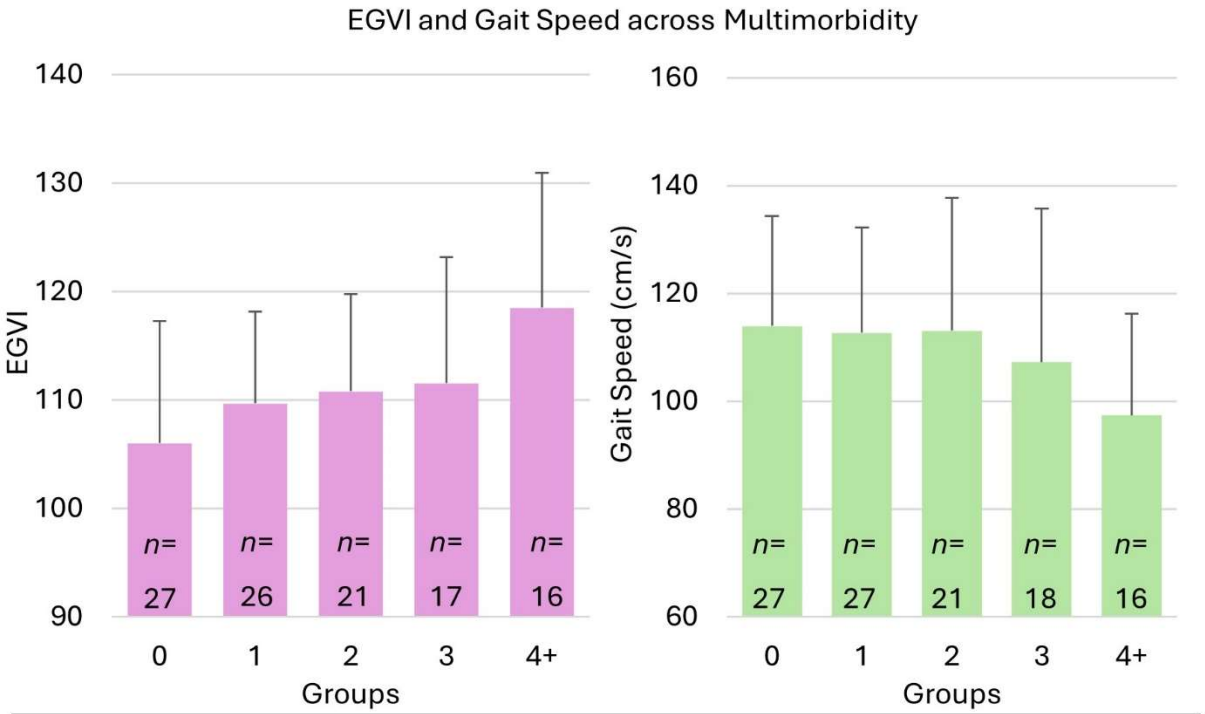
University of Arkansas, Fayetteville, Arkansas, United States

Introduction

Slower gait speeds are associated with reduced quality of life and often used as a clinical indicator of overall health, functional status, fall risk, and mortality risk in older adults. Likewise, multimorbidity, having one or more chronic conditions, is greatly related to decreased gait speed and quality of life, as well as increased fall risk. While gait speed and multimorbidity are independently associated with fall risk in older adults, gait variability may be a more sensitive measure in predicting falls. The Enhanced Gait Variability Index (EGVI) characterizes an individual's gait variability relative to healthy levels of gait variability. The EGVI more accurately predicts fall risk than gait speed alone, with increased EGVI indicating higher fall risk. This study sought to compare differences in EGVI and gait speed among community-dwelling older adults with multimorbidity. We hypothesized that participants with greater multimorbidity burden will exhibit slower gait speed and increased gait variability.

Methods

Data was collected from independently living older adults (n= 109, 73±6 years, 80 female) in community locations. Participants completed health history questionnaires and gait evaluations on a 6-meter instrumented pressure mat (Zeno Walkway). Gait assessments included four passes of comfortable pace walking, then EGVI and gait speed were calculated using ProtoKinetics Movement Analysis Software. Participants were grouped by number of self-reported chronic conditions (0, 1, 2, 3, and 4+), then separate analysis of variance (ANOVA) were performed to determine differences between groups for both gait parameters.



Results

EGVI differed significantly among groups (p= .008, η^2= 0.125, see figure); individuals with 4+ conditions exhibited significantly higher EGVI (M= 118.5, SD= 12.5) than those without chronic health conditions (M= 106.0, SD= 11.3), p= .002. Gait speed did not differ among groups (p= .145, η^2= 0.063, see figure).

Discussion

Higher EGVI scores reflect greater stride-to-stride variability, and our findings suggest having more chronic health conditions negatively impacts gait stability in older adults. Further, the lack of significant differences in gait speed indicates gait speed alone may not be a sensitive enough measure to evaluate multimorbidity burden on gait in older adults.

Images (Optional)

Note: Enhanced Gait Variability Index (EGVI) could not be calculated for 2 participants; thus, EGVI has 2 less participants (*n*= 107) than gait speed (*n*= 109).

Frontal Plane Dynamics in Sprinting: Step Width is Determined by Center of Mass Displacement and Hip Control, Not Static Morphology

Ms Hazuki Tsubata Physical Therapis, Dr Yasuko Hirono PhD, Dr Norihisa Fujii PhD

University of TSUKUBA, Tsukuba, Ibaraki, Japan

Dr Yasuko Hirono

Introduction

Step Width, the lateral distance between consecutive foot placements in locomotion, is a critical metric resulting from complex motor control strategies that balance functional demands for stability and propulsion against inherent biomechanical constraints. Step Width variability is hypothesized to be governed by the dynamic interaction of two main factors: static morphological characteristics (e.g., pelvic width) and dynamic kinematics (e.g., hip joint angles, pelvic motion, and Center of Mass control). Understanding Step Width determinants is crucial for minimizing injury risk. The purpose of this study was to identify the morphological and/or kinematical determinants of Step Width during maximal sprinting, a key step for developing personalized intervention strategies for safer and more efficient locomotion.

Methods

Twenty-six college students performed 10 maximal running trials. Data were collected approximately 35 m from the standing start, representing the maximum velocity phase of the sprint, using a motion capture system and force platforms. Kinematic and kinetic variables were calculated using three-dimensional marker trajectories and ground reaction force measurements. The mean value of 10 trials was used as the representative value for each participant. The relationships among Step Width and the morphological, kinematic, and kinetic variables were evaluated using Pearson's product–moment correlation coefficient (significance level set at $p < 0.01$).

Results

Step Width showed significant positive correlations with lateral movement of Center of Mass displacement during flight phase (r=0.60) and lateral impulse (r=0.58). It also exhibited a significant positive correlation with the hip abduction angle at toe-off (r=0.55),

but not at touchdown. The pattern of hip adduction/abduction varied greatly between subjects. Importantly, no significant correlations were found between Step Width and static morphological variables, including pelvic width, leg length, and Q-angle.

Discussion

These findings suggest that Step Width is determined lateral displacement of the Center of Mass and the lateral impulse. However, since the generation of lateral ground reaction force cannot be solely explained by hip adduction/abduction, the results indicate that diverse, individualized motor control strategies are employed during sprinting. This finding underscores the need for coaching interventions to focus on dynamic hip and pelvic stability rather than generalized running form adjustments based on static body measurements.

Side-Dependent Foot Joint Power during Turning Gait

Mr. Yufan He[1], Dr. Lauren Williams[2], Mr. Jose Anguiano-Hernandez[2], Dr. Jenna Burnett[2], Dr. Kota Takahashi[2,3,4]

[1]Department of Mechanical Engineering, University of Utah, Salt Lake City, UT, United States. [2]Department of Health & Kinesiology, University of Utah, Salt Lake City, UT, United States. [3]Department of Biomedical Engineering, University of Utah, Salt Lake City, UT, United States. [4]Department of Physical Medicine & Rehabilitation, University of Utah, Salt Lake City, UT, United States

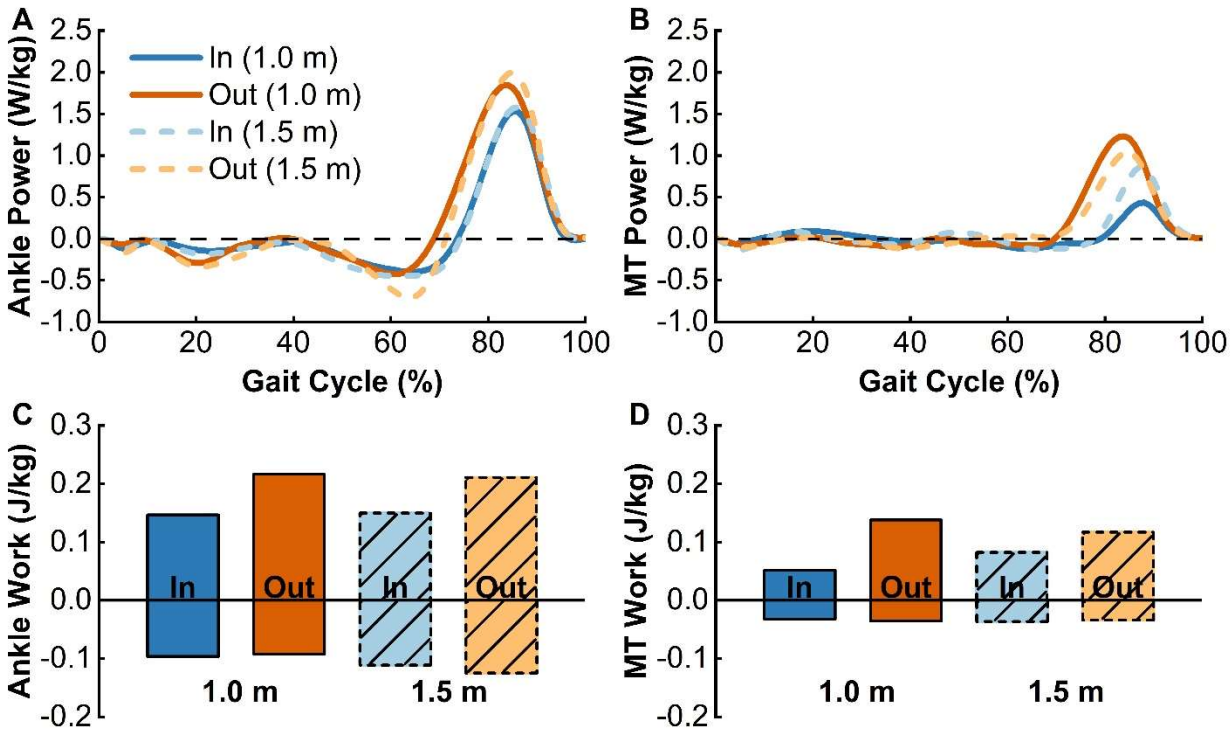
Introduction

Turning gait is a common walking pattern, requiring different power demands from the outside and inside limbs' ankle joints [1]. While ankle asymmetries are observed in turning gait, it remains unknown whether this side-dependent power pattern also holds for more distal joints of the foot (e.g., midtarsal). Because the midtarsal joint is a major source of foot energy generation, examining its behavior may reveal how energy is redistributed during turning gait and inform prosthetic design. Therefore, this study aims to compare energetics at the ankle and midtarsal joints between outside and inside limbs across different turning radii.

Methods

One healthy adult (data collection is ongoing) walked counterclockwise at 1.0 m/s along circular paths with two radii (1.0 m, 1.5 m). Motion capture and ground reaction force data were collected, and a multi-segment foot model [2] was used to compute ankle and midtarsal joint power. Power curves were integrated to obtain positive and negative work.

Results



Across both radii, the outside limb generated more positive work than the inside limb at the ankle (1.0 m: 0.217 vs. 0.147 J/kg; 1.5 m: 0.211 vs. 0.150 J/kg) and midtarsal joints (1.0 m: 0.138 vs. 0.051 J/kg; 1.5 m: 0.117 vs. 0.083 J/kg). Negative work was similar between limbs. As turning radius increased, the difference in the positive work between the limbs decreased (**Figure 1**).

Discussion

Turning gait seems to rely on an asymmetric strategy of energy generation across the ankle and foot. The outside limb generated more positive work at the ankle, a pattern that also appeared at the midtarsal joint, suggesting that the midfoot may also contribute to

propulsion during turning. Negative work was similar between limbs at both joints, suggesting that energy absorption demands may not differ between the outside and inside limbs. As turning difficulty changes, energetic demands at the midtarsal joint redistribute, suggesting that the midfoot may act as a dynamic regulator of power distribution. These findings highlight the foot's contribution to turning mechanics and may guide prosthetic designs.

Introduction

Custom insoles (CIs) are commonly used to redistribute pressure, reduce abnormal loading and cumulative stress, and improve walking comfort [1]. Statistical Parametric Mapping (SPM) is used to comprehensively evaluate the effect of CIs on plantar force (PF) by comparing its temporal changes over the stance phase [2]. However, human movement is inherently noisy, and extracting dominant features is necessary to comprehensively evaluate the effect of CIs. To this end, we present a Functional Principal Component Analysis (FPCA)-Guided SPM analysis method that first extracts dominant waveform features and then compares the temporal changes. We then use the method to evaluate the differences in temporal changes in PF using CIs.

Methods

Walking trials were collected from 16 older women (age > 55) working in prolonged weight-bearing occupations to compare the effects of CIs with control insoles (CONs). CIs were fabricated with TPU using a 25% gyroid infill printed using the foot scan of the participants captured using the MediACE3D foot scanner. PF data were recorded at 100 Hz using the Pedar system. FPCA was first applied to PF waveforms to extract dominant features from the first 2 PCs. The waveform differences between CIs and CONs were then computed, and SPM regression was used to identify statistically significant time points. These results were compared with traditional SPM applied directly to PF waveforms ($p < 0.05$).

Results

Traditional SPM detected only one brief significant interval, revealing significantly lower PF with CIs during the 0–2% stance phase. FPCA-guided SPM revealed significant differences over a larger area of the stance phase: the first two functional principal components (FPCs) showed significant differences across 2–80% of stance (Fig.1).

Discussion

Our study demonstrates that applying FPCA before SPM enabled a more comprehensive evaluation of the effect of CIs on PF. While traditional SPM detected only a brief early-stance difference, FPCA revealed significant changes across much of the stance phase, indicating broader alterations in foot–ground interaction with CIs. These findings highlight FPCA-guided SPM as a more sensitive method for capturing meaningful temporal differences in PF with CIs.

Age-Related Increase in the Energy Cost of Walking: Metabolic Factors and Impact on Fatigability

Ms. Zoe Smith M.S., Mr. Luke Arieta M.A., Dr. Michael Busa PhD, Dr. Jane Kent PhD

University of Massachusetts Amherst, Amherst, MA, United States

Introduction

The typically greater metabolic cost of walking (CoW) in older age is generally attributed to neuromuscular and biomechanical factors [1]. However, the potential role of metabolic factors such as substrate (carbohydrate, fat) oxidation for energy production has not been evaluated. Because fat oxidation for a given task consumes more oxygen (VO_2) than carbohydrate oxidation, we hypothesized that more use of fat by older adults could contribute to their greater CoW. Further, a consequence of the greater CoW in older adults, coupled with their expected lower aerobic capacity (VO2 peak), would be a smaller "energy reserve" during walking; we examined whether a lower energy reserve might contribute to a greater perception of fatigue [2] in response to the walking task.

Methods

Seventeen young (29 ±5yr; 6F) and 15 older (72 ±5; 7F) adults completed an aerobic capacity test, followed by a 30-min treadmill walk ($1.3 m \cdot s^{-1}$) in a room calorimeter during which VO_2 and carbon dioxide production were measured. CoW (VO_2, $ml \cdot kg^{-1} \cdot min^{-1}$), carbohydrate and fat oxidation ($kJ \cdot kg^{-1}$), and energy reserve (peak minus steady state walking VO_2) were calculated. Final minus baseline Borg rating of perceived exertion (ΔRPE) was used as the measure of fatigability. Statistics: ANOVA, linear regression.

Results

CoW was ~10% greater in older than young (Figure 1A). Fat oxidation was also greater in older (44 ±9% total energy) than young (34 ±9%; $p=0.007$) and associated with CoW overall ($n=32$; $r^2=0.25$, $p=0.002$). The greater CoW and ~35% lower aerobic capacity (VO_{2peak}: older = 27.7 ±0.7 ($n=13$), young = 42.3 ±0.8; $p<0.001$), in older resulted in a lower energy reserve compared with young ($p<0.001$), which was associated with greater fatigability only in the older (Figure 1B).

Discussion

As hypothesized, these results provide intriguing new evidence that, in addition to neuromuscular and biomechanical factors, metabolic factors related to greater fat oxidation can increase CoW in older age. Additionally, the relationship between energy

reserve and fatigability in the older group only suggests that a consequence of this greater CoW is greater perceived fatigue during a standardized task in older adults.

Force and Kinematic Analysis of Fatigue in Collegiate Baseball Players in a Simulated Game Environment

Mr. Aaron Austin Undergraduate Researcher, BESc/BA Concurrent Program, Departments of Integrated Engineering and Kinesiology[1], Dr. Thomas Jenkyn Associate Professor, Department of Mechanical and Materials Engineering[1], Dr. Ryan Crotin Executive Vice President, ArmCare.com; Baseball Performance Research Associate, Department of Kinesiology[2,3], Dr. Emily Lalone Associate Professor, Department of Mechanical and Materials Engineering[1]

[1]Western University, London, Ontario, Canada. [2]ArmCare.com, Indialantic, Florida, United States. [3]Louisiana Tech University, Ruston, Louisiana, United States

Introduction

Major improvements in injury prevention for baseball players have occurred over the past decade via pitch-count and workload tracking. Despite this, shoulder and elbow injuries persist at all levels, highlighting the need for deeper work on fatigue management. Injury risk stems from multiple interconnected factors, but fatigue is a critical factor which contributes to injury risk. A major limitation of previous research has focused on isolated fatigue-related risk factors rather than examining how these variables interact as an integrated system. This study aims to investigate the interactions and changes between strength, coordination, and performance with the onset of fatigue.

Methods

Six collegiate pitchers (mean age: TBD) completed a simulated four-inning game consisting of 80 pitches. Full-body pitching kinematics were captured using a 12-camera 3D motion capture system, and ball velocity was recorded. Shoulder strength, range of motion, and pinch grip strength were assessed using a handheld dynamometer with shoulder strength also measured after each inning. Participants then self-reported perceived fatigue of the arms, legs, and overall exertion using a visual analog scale.

Results

Participants generally reported increasing fatigue in their arms, legs, and overall exertion as the simulated game progressed, yet individual fatigue profiles differed widely. Several pitchers reported minimal fatigue levels (<6/10 visual analogue fatigue scale score) despite measurable declines in shoulder strength, suggesting that perceived exertion may not

accurately reflect physiological fatigue. Preliminary results collected on velocity suggest that pitch velocity remains constant over the course of the simulated game.

Discussion

Our findings suggest that relying on an athlete's self-reported fatigue or coaching observations may not be a reliable way to assess fatigue as perceived exertion does not always reflect measurable declines in strength. Incorporating simple, objective strength testing during games could help identify when a pitcher is truly fatigued and therefore assist coaches in making safer substitution decisions.

Do Upper Extremity Mechanics Predict Pitch Outcome in Softball Pitchers?

Dr. Abbie E. Ferris PhD[1], Mr. Zac Bridger[2], Mr. Monte McDonald[2]

[1]University of Northern Colorado, Greeley, CO, United States. [2]Triple Crown Sports, Fort Collins, CO, United States

Introduction

Softball windmill pitching is a unique motion among competitive sports. In particular, it has received little attention in injury prevention or performance enhancement [1,2]. The windmill pitch can be used to deliver a variety of pitches designed to deceive the batter. Arguably, the two most common types of pitches are fastball (FB) and change up (CH). Yet, it is unknown how either pitch is able to produce effective changes in pitch type. Thus, we hypothesize, these two pitch types will result in significantly different upper extremity kinematics effecting ball flight trajectory.

Methods

Ten top club female softball pitchers were recruited for this study (16-18y/o, 68.18 ± 11.39kg, 1.64 ± 0.07m). Each participant threw 4 FB and CH pitches while recorded with a markerless motion capture system (Qualisys, Göteborg, Sweden). Ball flight trajectory data were simultaneously recorded for each pitch (Rapsodo, St Louis, MO). RMANOVA were preformed on joint angles and ball flight data and correlation analysis between ball flight and kinematic variables (R-Studio, Boston, MA).

Results

All participants demonstrated slower pitch speeds with a CH than FB (45.29 ± 3.88 vs 60.51 ± 2.60mph) with reduced total spin (1385.75 ± 343.68 vs 877.43 ± 206.06 deg/s). Elbow flexion velocity ($p = 0.0059$, $r = 0.796$) contributed to ball velocity during CH pitches. CH significantly reduced angular velocities at the shoulder, elbow, and wrist (Table 1). CH vertical approach angle was significantly steeper (-3.81 ± 2.37 vs -10.37 ± 3.81 deg) driven by increased shoulder flexion ($r = -0.454$). CH ball spin increased due to shoulder flexion and internal rotation. CH showed higher variability in measures than FB particularly in elbow flexion velocity (28.8% vs 42.7%CV).

Discussion

Pitchers are able to manipulate ball trajectory through the shoulder and elbow kinematics. These data support that while ball velocity can be modulated via the elbow, it is likely driven by the lower extremities and torso rotation during the launch phase of the pitch.

Given the higher variability in kinematics in CH pitches, coaches and athletes should focus on increasing consistency within each pitch type to increase ball flight trajectory accuracy.

The Coefficient of Propulsion: A Novel Metric for Characterizing Trail Leg Ground Reaction Forces During Baseball Pitching

Mr. Adam Barrack PhD(c), CSCS, TSAC-F

University of Southern California, Los Angeles, CA, United States

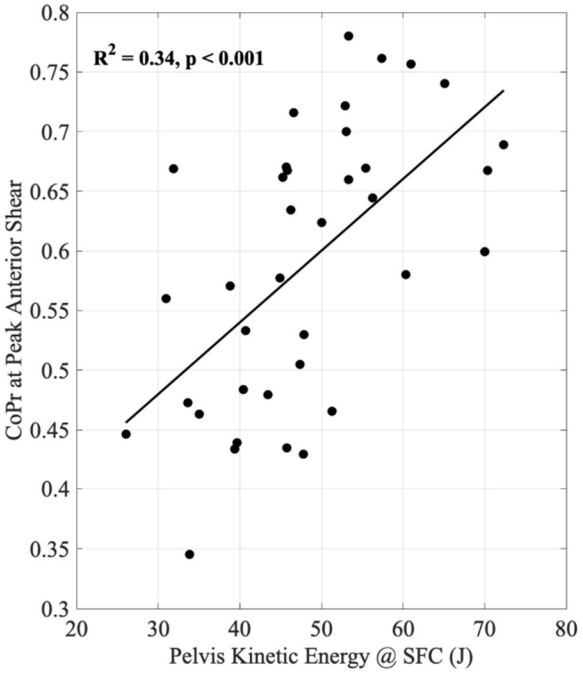
Introduction

Introduction: The baseball pitch relies on coordinated ground reaction forces (GRFs) from the trail leg to initiate and transfer energy through the kinetic chain. Prior studies have described vertical and anterior shear forces independently, but forward propulsion depends on their coupled action. To capture this relationship, we introduce the coefficient of propulsion (CoPr), defined as the ratio of anterior shear to vertical force during the stride phase. CoPr provides a dimensionless index reflecting both the magnitude and timing of its GRF components, potentially offering a more meaningful representation of trail-leg propulsion than single-force measures. This study examined whether CoPr at peak anterior shear force better predicted pelvis kinetic energy (PKE) at stride foot contact compared to anterior shear magnitude alone. PKE was selected because it captures the mechanical linkage through which the trail-leg generates and transfers energy to the rest of the kinetic chain, making it a useful indicator of trail-leg propulsion efficiency.

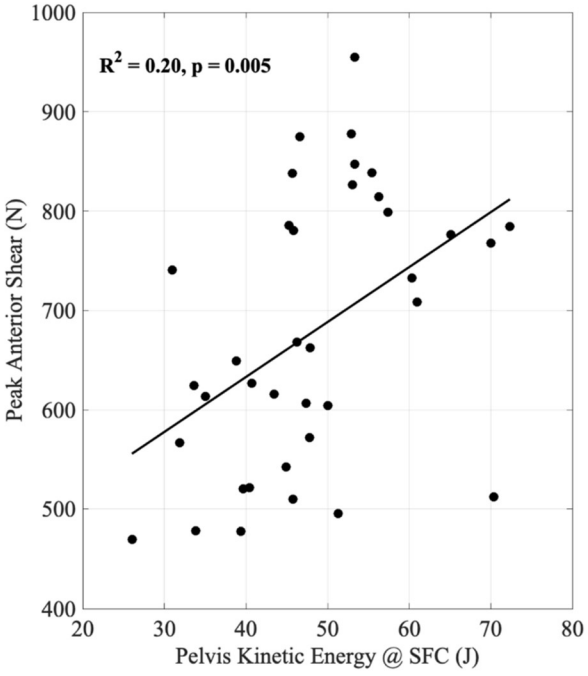
Methods

Methods: Thirty-seven healthy collegiate pitchers threw full-effort fastballs from an instrumented mound while kinematic data (300Hz) and GRFs (1200Hz) were collected. CoPr was calculated for each trial as the ratio of anterior shear to vertical force, and its value was extracted at peak anterior shear force. PKE was computed at stride foot contact from segmental translational and rotational kinetic energy. For all variables, the average of 10 trials per pitcher were analyzed. Simple linear regression determined the proportion of variance in PKE explained by CoPr and peak anterior shear force.

Results



Results: CoPr exhibited substantial variability across pitchers ($\bar{x}$=0.6[0.4–0.8]). Both CoPr and peak anterior shear force significantly predicted PKE. However, CoPr explained a



greater proportion of variance in PKE (R^2=0.34,p<0.001) than peak anterior shear force alone (R^2=0.20,p=0.005).

Discussion

Discussion: CoPr provides an integrated measure of trail-leg force production that captures the functional coupling of vertical and anterior shear forces during the stride phase. CoPr was a stronger predictor of pelvis kinetic energy than anterior shear magnitude alone, suggesting enhanced utility for characterizing propulsion strategies and energy transfer in baseball pitching. Further research should examine its implications for performance and injury risk.

Asymmetric Loading Responses to Practice and Game Demands in Male and Female Ice Hockey Players

Miss Ainsley Svetek, Dr Neal Glaviano, Dr Julie Burland

University of Connecticut, Storrs, CT, United States

Introduction

Wearable technology has emerged to quantify longitudinal athlete load during practice and competitive settings. While these metrics are becoming more common, data specific to ice hockey is limited. The purpose of this study was to examine whether asymmetric loading increases in ice hockey games compared to practice between collegiate male and female ice hockey players to provide insight needed to refine training loads and address potential injury risk.

Methods

Data were collected utilizing a tri-axial, insole embedded inertial measurement unit (Plantiga) which was placed bilaterally into the ice skates. Twenty-one female and 24 male collegiate ice hockey players wore the sensors during practices and games over the course of a 9-week period. Load asymmetry data was collected and averaged by session-type. Negative values indicated greater left limb loading, whereas positive values indicated increased right limb loading; asymmetry is expressed as percent difference between limbs. A two-way mixed ANOVA was used to quantify changes in asymmetric loading from practices and game sessions and between males and females, with significance set at $p>.05$. Post-hoc testing was performed in presence of significant effects.

Results

Across nine weeks, females had 34 practices and 14 games, while men had 31 practices and 15 games.The two-way mixed ANOVA revealed a significant sex by session interaction ($F=8.741$, $p=.005$). There was no difference in asymmetric loading between males and females for practices, however there was a significant difference in games (mean difference=4.7±1.88, $p=.016$). There was no significant effect of session type on asymmetric loading for males or females ($F=1.144$, $p=.291$). Interestingly, females had an increase in asymmetric loading from left-loaded (-1.1%) in practices to right-loaded (2.0%) in games, while males showed an increase in left-loaded in practices (-1.1%) to games (-2.5%).

Discussion

Although there was no within-group effect of session type alone, the significant interaction between session type and sex indicates the different responses from males and females to the demands of games compared to practices. Varying shifts in loading asymmetry between males and females may reflect sex-specific skating mechanics or distinct adaptations in movement strategies as game intensity increases, highlighting the importance of sex-specific responses in athlete load monitoring.

Three-Dimensional Motion Analysis With Minimal Calibration Process Using Omnidirectional Cameras

Dr. Akinori Nagano[1], Dr. Akitoshi Makino[1], Dr. Shoma Kudo[2], Dr. Masahiro Fujimoto[2]

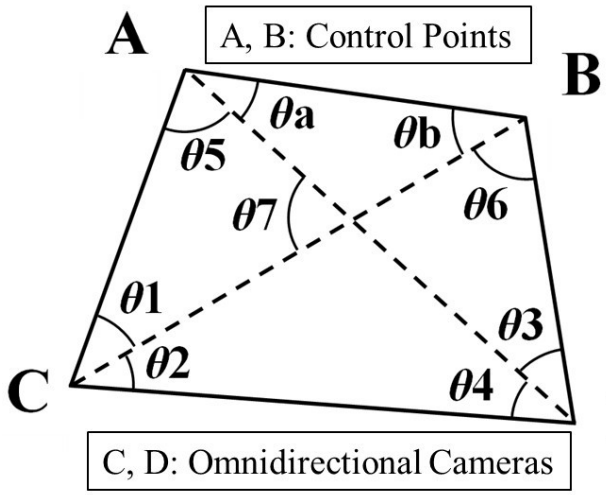
[1]Ritsumeikan University, Kusatsu, Shiga, Japan. [2]National Institute of Advanced Industrial Science and Technology, Takamatsu, Kagawa, Japan

Introduction

Motion analysis is a crucial method in the field of biomechanics. The Direct Linear Transformation method (1971) and the Non-Linear Transformation method (1982) are well-established gold standards. However, a major drawback of these established methods is the requirement for a time-consuming and technically demanding calibration process. We invented a novel method utilizing omnidirectional cameras. By exploiting the unique feature that omnidirectional cameras can observe not only the points of interest (POI) but also the cameras each other, we significantly reduced the calibration time and technical demands.

Methods

The new method firstly employs a geometric approach to determine the horizontal 2D (XY) position of target objects using two omnidirectional cameras, with only two control points of known coordinates [1]. We assume that the image from the omnidirectional cameras is represented in the equirectangular projection, in which the horizontal and vertical position corresponds to the longitude and latitude within the celestial sphere, respectively. The new method is based on the geometric formation of a quadrilateral ABDC (AB: control points, CD: cameras). By applying the law of sines to the constituent triangles, proportional relationships are derived (Figure 1). This system of equations allows for determination of the XY positions of the cameras. Position of POI is determined as the intersection of camera rays. Thereafter, for 3D positions, the vertical (latitude) location of POI in the equirectangular projection image is used, applying the tangent value of the latitude. With the XY positions of cameras and POI already determined, Z position of POI is determined.



Results

The accuracy of the new 2D method was verified within a flat indoor area measuring 5mX5m. The relative error with respect to the calibrated area was <0.6%. The accuracy of the new 3D method was verified in another experiment. The relative error was <3.6%.

Discussion

This method drastically reduces the calibration time and technical demands associated with motion analysis. The achieved high precision makes this method an attractive alternative to the conventional methods.

Dr. Felipe F. Gonzalez

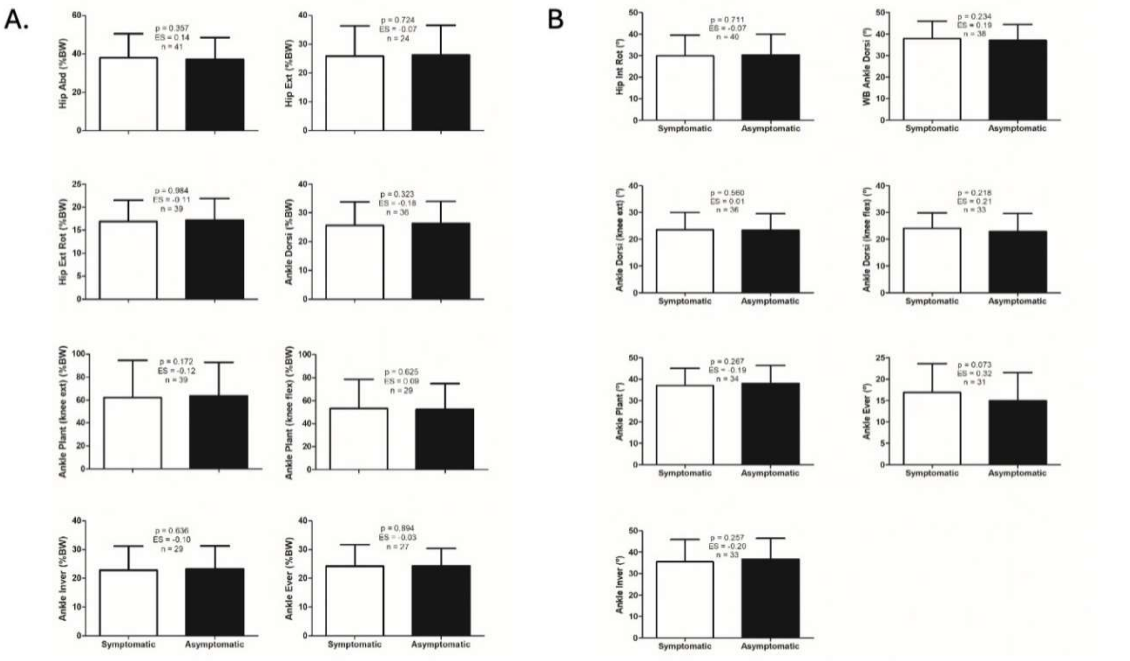
Introduction

Achilles tendinopathy (AT) is a common overuse injury, especially among runners, and is associated with various biomechanical factors. Interlimb differences in strength and range of motion (ROM) between the symptomatic and the asymptomatic limbs may propagate symptoms, and compensations at proximal segments, such as the hip, may be important to address. This study aimed to compare ankle and hip strength and ROM between symptomatic and asymptomatic limbs in individuals with unilateral AT.

Methods

This cross-sectional study included forty-four patients with unilateral AT (36 males, eight females; mean age 47.7 ± 10.2 years). Bilateral maximal isometric strength was assessed using a handheld dynamometer for the hip abductors, extensors, external rotators, as well as ankle dorsiflexors, plantar flexors (with the knee extended and flexed), ankle inverters, and ankle evertors. ROM was measured bilaterally with a digital inclinometer for hip internal rotation and ankle movements, including weight-bearing and open-kinetic-chain dorsiflexion (with the knee extended and flexed), plantarflexion, ankle eversion, and ankle inversion. Group comparisons were conducted using paired t-tests or Wilcoxon tests

depending on data normality, and effect sizes were calculated with Cohen's d. Statistical significance was set at $P < 0.05$ for all analyses.



Results

No significant differences were observed between symptomatic and asymptomatic limbs for any strength or ROM measures (all $P > 0.05$) (Figure 1). Effect sizes between limbs were minimal, ranging from –0.03 to 0.32. The average differences in strength (0.5–3.0%, mean 1.8%) and ROM (0.3–11.3%, mean 3.8%) were small, indicating symmetrical static performance across joints and muscle groups.

Discussion

Individuals with unilateral AT exhibited symmetrical isometric strength and ROM at both the ankle and hip. These findings indicate that static assessments alone might not capture the complex biokinetic factors involved in AT.

Using Wearable Data to Predict Speed and Injury Risk in Runners

Dr Sarah Johnson PhD[1,2], Dr Alex Gonzalez[2], Dr Johanna O'Day[2], Prof Scott Delp[1,2], Prof Ellen Kuhl[3], Dr Jennifer Hicks[2,1]

[1]Department of Bioengineering, Stanford University, Stanford, California, United States. [2]Wu Tsai Human Performance Alliance, Stanford University, Stanford, California, United States. [3]Department of Mechanical Engineering, Stanford University, Stanford, California, United States

Dr Sarah Johnson

Dr Alex Gonzalez

Introduction

Understanding how to manage training loads to maximize performance while minimizing injury risk is key for runners and coaches. We used longitudinal training and injury data to quantify the relationship between weekly running distance, performance, and injury risk in 203 athletes.

Methods

Athletes (age 30±6; 150 females; 43% semi-elite; 8% elite) shared 2.5 years of retrospective daily training data from their Garmin smartwatch and labelled injury and illness periods. Participants reported 58 bone stress injuries (BSIs) and 278 soft tissue injuries. We extracted athletes' average weekly running distance from time periods with no reported injury or illness. We determined best performance in the 5000m and marathon by extracting the fastest average speed during runs of sufficient length. We analyzed relationships between weekly running distance, top speed in the 5000m and marathon, and rates of BSI and soft tissue injury using statistical models that controlled for age, body mass index, and total days of training, where relevant.

Results

Speed increased with weekly running distance, with diminishing returns that occurred earlier for females than males in both the 5000m and marathon (Fig. 1A,B). The rate of BSIs

increased with weekly distance for both sexes, with nearly double the rate in females versus males (0.13 vs 0.07 yearly injuries; p=0.01; Fig. 1C) inline with previous studies[1]. Soft tissue injury rate did not correlate with weekly distance for either sex. Combining model results enabled us to compare how performance and injury risk varied with increasing weekly distance. For example, the models predict that females going from 80km to 100km per week increase their speed by 0.15 m/s (5%) in the 5000m and by 0.15m/s (7%) in the marathon, but increase their expected yearly BSI rate by 0.05 (29%) (Fig. 1D).

Discussion

Our analysis reveals relationships between weekly running distance and both speed and BSI injury risk, which differ between males and females. The rate of soft tissue injuries was not associated with weekly distance, suggesting alternative contributing factors to risk for these injuries.The observed trade-offs between performance and injury risk could help inform training plans.

Images (Optional)

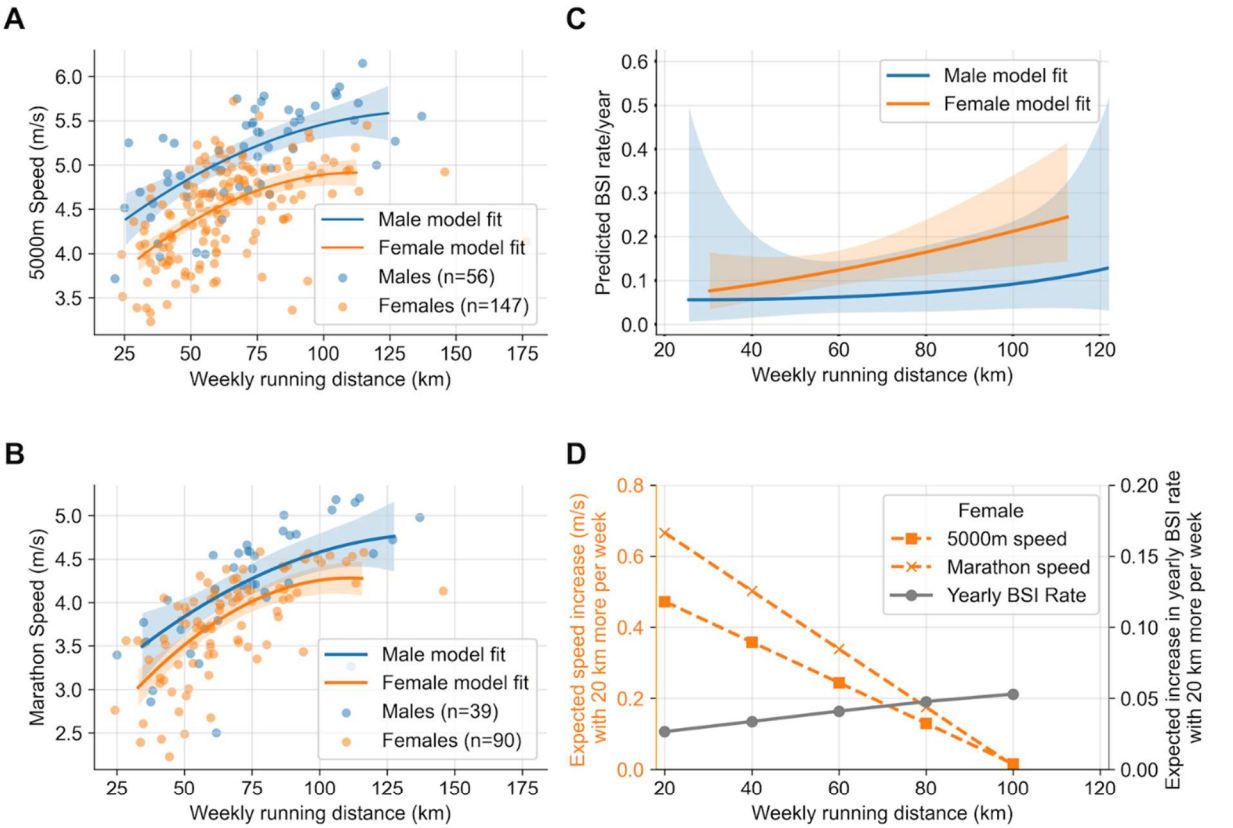

Figure 1. Speed versus weekly running distance for A) 5000m and B) the marathon. The orange and blue lines are the results of an ordinary least squares regression, controlling for age and body mass index, for females and males, respectively. The bands show 95% confidence intervals and dots the raw extracted data. C) Weekly running distance versus predicted yearly bone stress injury (BSI) rate. Lines show a Poisson regression model predicting the yearly BSI rate as a function of weekly distance, controlling for age, body mass index, and observation duration (i.e., total days of training included for a participant). D) Predicted BSI rate and speed changes if females increased their weekly distance by 20km.

Joint Kinematic Comparison of Telemark and Alpine Skiing Turns in Fully Certified Instructors: A Statistical Parametric Mapping Analysis

M.S. Alique Malakian[1], B.S. Tobin Arden[1], B.S. Tom Koto[2], Ph.D. John Seifert[1]

[1]Montana State University, Bozeman, Montana, United States. [2]Bogus Basin Ski Area, Boise, Idaho, United States

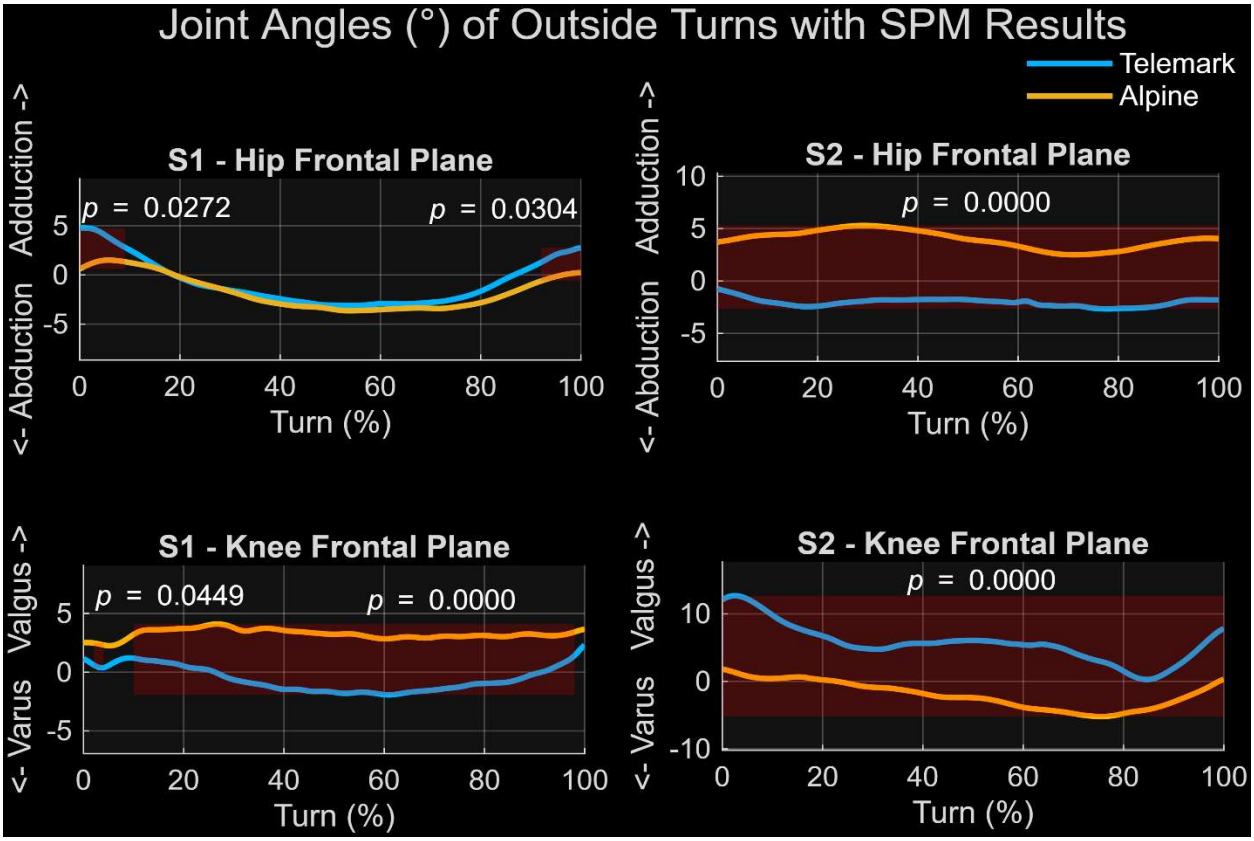
Introduction

Telemark turns (TT) are an alternative form of skiing characterized by the free movement of the heel compared to alpine skiing. Turns are initiated by lunging forward and differ from alpine turns (AT) due to the increased knee and hip ROM. General sagittal plane kinematics have been described previously, but specific outside and inside leg turn differences and frontal plane kinematics are not well understood. Therefore, the purpose of this study was to evaluate the kinematic differences of the hip and knee joints of a ski turn.

Methods

Two subjects (female, age: 60, male, age: 69), fully PSIA certified in both disciplines, completed four runs for each discipline. Gate distances were set to ski radius. Full-body 3D kinematics were collected using the Xsens Link IMU body suit at 240 Hz. 67 and 69 total outside and inside leg turns were selected and normalized to 100%. Kinematics were calculated using a YXZ Cardan sequence. Statistical parametric mapping paired t-tests were conducted between each subject's AT and TT.

Results



Skiers' outside leg turns were characterized by significantly increased hip and knee flexion during TT. S1 displayed significantly increased hip adduction at turn initiation and completion and significantly increased knee varus during TT. S2 displayed significantly increased hip abduction and knee valgus during TT. For the inside leg turns, both skiers displayed significantly increased hip and knee flexion during TT. S1 displayed significantly increased hip adduction and knee varus during TT. S2 displayed significantly increased hip abduction and knee valgus at turn initiation and completion during TT.

Discussion

The sagittal plane kinematic results were similar to previous TT studies; however, differentiating the outside and inside leg turns revealed contrasting frontal plane turning

strategies for each skier. Despite comparable technical expertise in both disciplines, the results indicate that complex activities, such as telemark skiing, produce great individual variability in movement execution. These data indicate that although these skiers are of expert technical level, they achieved this level by differing movement patterns. The results emphasize that a variety of strategies are possible to perform complex movements.

Neuromuscular signatures of fatigue precede kinematic changes in constant-speed treadmill running

M.A.Sc. Candidate Zachary A. Flahaut[1,2], Post-Doctoral Fellow Nicholas S. Ryan[3], Professor Pär Halje[3], Professor Allison L. Clouthier[1,4], Professor Daniel L. Benoit[3]

[1]Ottawa-Carleton Institute for Biomedical Engineering, University of Ottawa, Ottawa, Ontario, Canada. [2]Department of Mechanical Engineering, University of Ottawa, Ottawa, Ontario, Canada. [3]MoRe-Lab, Department of Health Sciences, Faculty of Medicine, Lund University, Lund, Scania, Sweden. [4]School of Human Kinetics, University of Ottawa, Ottawa, Ontario, Canada

Introduction

Neuromuscular fatigue can modify muscle activation patterns before observable changes in movement mechanics. However, most fatigue research has focused on incremental or short-duration running, and EMG fatigue analyses are typically performed under isometric or controlled laboratory conditions. It remains unclear how prolonged, constant-speed running at high metabolic strain affects neuromuscular activation patterns when joint kinematics remain preserved. This study investigated how sustained high-intensity treadmill running influences lower-limb muscle activation and joint kinematics in young adults.

Methods

Seven recreationally trained young adults completed a 30-minute treadmill run at ~85% individual VO2max on a 1% incline. Three-dimensional kinematics (200 Hz), ground reaction forces (1000 Hz), and bilateral surface EMG (2000 Hz) were recorded at three intervals: pre-fatigue, mid-fatigue, and post-fatigue. EMG metrics—mean amplitude, median frequency, power, and integrated EMG (iEMG), were quantified for eight muscles (biceps femoris, semitendinosus, gluteus medius, rectus femoris, vastus lateralis, vastus medialis, lateral gastrocnemius, medial gastrocnemius). Physiological variables (VO2, heart rate, respiratory quotient (RQ), Borg scale) were averaged across 30-second windows. Statistical parametric mapping (SPM) assessed sagittal-plane hip, knee, and ankle joint angles across the gait cycle. Repeated-measures ANOVAs evaluated fatigue-related differences.

Results

Heart rate and Borg increased significantly across fatigue stages ($p<0.01$), confirming rising physiological strain, while VO2 and RQ plateaued. SPM revealed no significant differences

in sagittal-plane hip, knee, or ankle joint angles between stages, indicating preserved running mechanics.

In contrast, significant neuromuscular alterations emerged (Figure 1). Median frequency declined in posterior thigh and triceps surae muscles, while several knee extensors and hip stabilizers exhibited reductions in iEMG across fatigue stages. These changes reflect decreased recruitment efficiency during sustained running despite unchanged kinematics.

Discussion

Despite stable kinematics, participants showed neuromuscular and physiological drift, demonstrating that fatigue alters motor unit recruitment under steady-state metabolic conditions. Unlike most fatigue studies, which rely on incremental protocols or EMG fatigue under isometric conditions, this work shows that prolonged constant-speed running induces substantial EMG-based fatigue signatures without accompanying biomechanical changes. These findings highlight the limitations of using joint kinematics alone to infer fatigue and underscore the importance of integrating neuromuscular measures for monitoring load and guiding training and injury-prevention strategies in endurance-based sports.

Evaluation of Fatiguing Effects on Grip Strength Due To Dismounted Litter Transport With and Without the Use of Assistive Devices

Mrs. Allison Robinette MS

U.S. Army Aeromedical Research Laboratory, Fort Rucker, AL, United States. Chenega Services and Federal Solutions, LLC, Chesapeake, VA, United States

Introduction

Dismounted litter transport is a physically strenuous task that is compounded by terrain, combat, and distance from the next point of care. Previously, we investigated litter carry assistive devices (LCAD) during simulated, prolonged dismounted litter transport to reduce post-carry fatiguing effects [1,2]. Our findings indicated that LCAD (shoulder harness and wrist hooks) could have many benefits to litter bearers, but further testing was needed in mass casualty (MASCAL) scenarios. As a result, we conducted field testing with the LCAD to evaluate litter carriage performance and post-carry fatigue effects in a simulated MASCAL scenario [3]. Our objective was to investigate relationships of fatigue between dominant hand and bilateral grip strength.

Methods

Following a counterbalanced design, sixteen U.S. Army Soldiers evaluated all litter carry conditions: unassisted carry (UA), shoulder harness carry (SH), wrist hooks carry (WH). For each condition, participants in two-person teams picked up, carried (50 meters), and set down a weighted litter, simulated a return to the point of injury (starting location), and repeated this process for 20 minutes. Immediately before and after each carry condition, grip strength was recorded using a VALD Dynamo Plus dynamometer with a grip strength attachment. Grip strength assessments were recorded three times for each hand, alternating between left and right. A pairwise t-tailed test was used to investigate the relationship between dominant and non-dominant grip strength. Repeated measures ANOVAs were computed for grip strength on carry condition for average change (post-carry minus pre-carry) in dominant, non-dominant, and bilateral grip strength groups ($p < 0.05$ was significant).

Results

Results did not show any significance between dominant and non-dominant hand average grip strength (p=0.697). Post-hoc analyses revealed significance in grip strength groups between UA and SH (a), SH and WH (b), and WH and UA (c) (Table).

Discussion

While all grip strength measurements were found to be acceptable measures of post-carry fatigue, variance obscured some statistical differences, but not the trends, between carry conditions. Consistent with previous findings [1,2], LCAD lessen grip strength decrements in MASCAL scenarios.

Images (Optional)

Table. Average Change in Grip Strength (Newtons) Between Carry Conditions

Grip Strength Group	UA, n=15	SH, n=16	WH, n=15
Dominant Hand	-117.2[a]	-35.7[a,b]	-67.1[b]
Non-Dominant Hand	-125.6[a,c]	-30.1[a]	-54.0[c]
Bilateral Hands	-121.7[a]	-32.7[a,b]	-60.4[b]

Quantifying Slip Events Using Foot Center-of-Mass (COM) Kinematics During Cutting Maneuvers in Collegiate Soccer Players

Ms. Allyson Ford[1], Dr. Brett Pexa[1], Mr. Noah Rauch[1], Mr. Garrett Hess[1], Dr. Jeffrey Taylor[1], Mr. Joseph Helseth[2], Dr. Kevin Ford[1]

[1]High Point University, High Point, NC, United States. [2]Nike Sport Research Lab, Beaverton, OR, United States

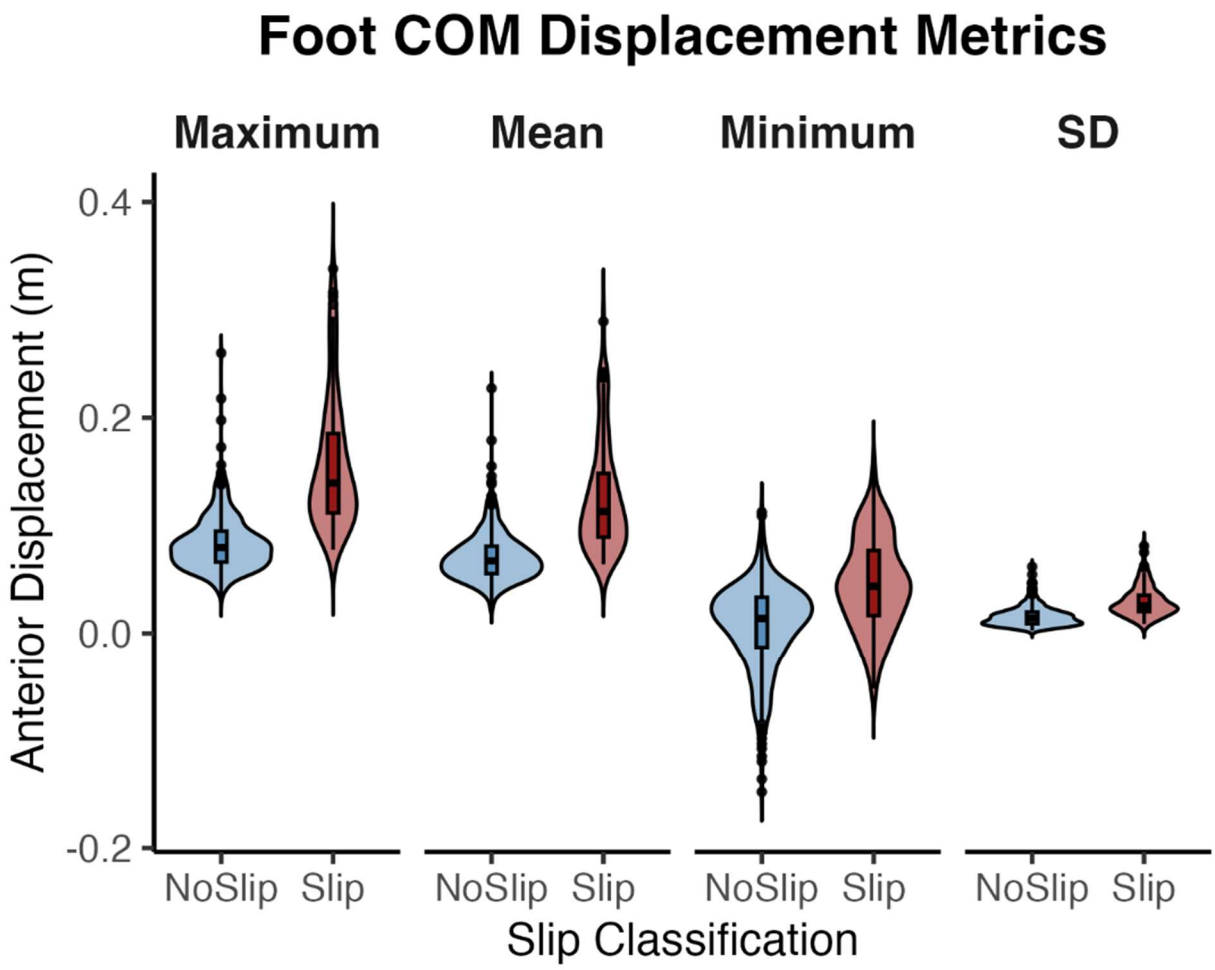
Introduction

Cleated footwear traction testing on turf surfaces often involves translational foot motion (slip events). These slip events may contribute to injury, especially if they increase joint kinetics. The purpose of this study was to develop a simplified method for objectively quantifying slip events in collegiate soccer athletes.

Methods

30 competitive soccer players (age: 20.7 ± 1.2 yrs; mass: 71.5 ± 9.9 kg; height: 171.9 ± 8.1cm, 15 male, 15 female) participated in a footwear traction study. A total of 20 trials (5 per condition) were collected from each participant performing maximum effort 180-degree cutting maneuvers across two cleated footwear conditions and two turf surface conditions. Kinematic data were collected (200Hz) on a three-dimensional motion analysis system consisting of 14 digital high-resolution cameras positioned throughout the laboratory (Qualisys AB, Göteborg, Sweden). Foot COM anterior displacement metrics (relative to running approach direction in lab coordinate system, Figure 1: minimum, maximum, mean, standard deviation) were normalized to the initial contact position and calculated through toe off. Logistic regressions were used to predict visually classified slip events. Model performance (pseudo-R^2 and AIC) and classification (accuracy, sensitivity, and specificity) were evaluated.

Results



595 trials were visually reviewed by one of the authors and classified as a slip (89, 15.0%) or non-slip (506, 85.0%) based on the observed anterior translation (relative to the running direction) of the cleat during the cutting step. Logistic regression with foot COM variables predicted 91.6% of the observed slip classifications (97.8 % specificity, 56.2% sensitivity, McFadden's pseudo-R^2 = 0.48). Receiver operating characteristic (ROC) (AUC 0.946) and optimal probability threshold analyses determined Youden's index (0.13) with slightly lower

specificity (86.8%) and higher sensitivity (92.1%), resulting in correctly identifying 36% more visually observed slips. Generalization was assessed by training on 70% and testing on 30% of the sample (AUC 0.931, 88.2 % specificity, 88.9% sensitivity). A five-fold cross-validation indicated model stability (AUC 0.943 +/- 0.037).

Discussion

The optimized and validated model demonstrated high specificity and sensitivity in identifying slip and non-slip events during high-speed 180-degree cutting. This approach may reduce the need for subjective and time-sensitive visual classification of slip events.

The Power to Win: The Influence of Power and Playing Time as Measures of Physical Workload on Performance Error by Match Outcome and Opponent Rank in Elite Women's Rugby Sevens

Dr Amarah Epp-Stobbe[1], Dr Ming-Chang Tsai[1], Dr Marc Klimstra[2,1]

[1]Canadian Sport Institute Pacific, Victoria, BC, Canada. [2]University of Victoria, Victoria, BC, Canada

Introduction

In rugby sevens outscoring the opposition ensures a win which is influenced by individual and collective strategies and tactics[1,2]. System errors, which are deviations from strategy and tactics, reduce success[3]. While athlete physical workload affects strategic and tactical execution, the magnitude of the effect in sevens remains unclear[4]. This study investigates the influence of power and playing time as indicators of physical workload, on system errors, examining how this relationship varies according to match outcome and opponent rank.

Methods

22 female athletes (26.5±4.20years,169.5±5.90cm,70.5±6.43kg) participated in 103 international sevens matches. Athlete-worn GNSS monitors collected distance(m), speed(m/s), and playing time(mins) from which acceleration(m/s^2) was derived. Total power(W) was calculated as the cumulative sum of instantaneous absolute power (product of mass, acceleration, and velocity). Match outcome(win/loss) was recorded, and opponent rank(top-4, midrange, bottom-4) was calculated relative to the team-of-study using pre-match international rankings. System errors-per-athlete were identified using notational analysis by the team's performance analyst. A linear mixed model evaluated the relationship between fixed (power, time) and random effects (outcome, opponent) on errors by athlete.

Results

The model demonstrated a significant interaction between outcome and time, $t(997)=2.01, p<0.05$, and between power, outcome, and time, $t(997)=-2.04, p<0.05$. No other main effects or interactions reached significance. The model accounted for 18.1% of the variability in errors ($R^2_{adjusted}=0.181$).

Discussion

Errors are related to time and outcome. In wins, errors increased over time at a lower rate than losses. Further, the relationship with power, time, and errors differed depending on outcome. Higher power in wins reduced errors, suggesting a protective effect as players were highly focused, appropriately making decisions and executing team strategies[5]. Errors are equivalent across opponent, agnostic of power, inferring that additional variables such as psychological state must be considered in parallel to physical outputs when monitoring athlete workload.

Shivering Magnitude Is Strongly Correlated With Temperature Recovery Following Cold Water Immersion in the Field

Dr. Amy Schwartz[1,2], Dr. Douglas Jones[1], Ms. Rebecca Weller[1,2], Ms. Rebecca McClintock[1,2], Dr. Matthew Peterson[1], Mr. Tony Duong[1,2], Dr. Amy Silder[1]

[1]Naval Health Research Center, San Diego, CA, United States. [2]Leidos Inc., San Diego, CA, United States

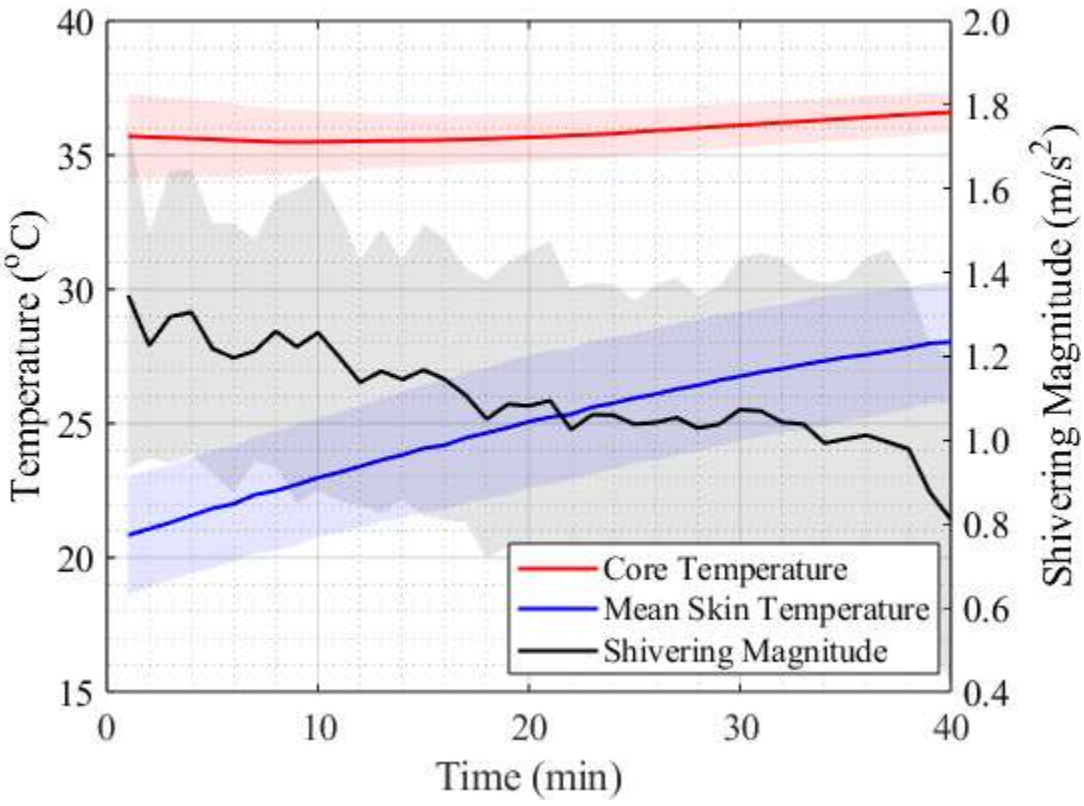
Introduction

After cold-water immersion (CWI), core temperature may continue to drop during early rewarming. The timing of this "afterdrop" is closely associated with shivering thermogenesis. Although core and skin temperature recovery have been well studied, their relationship to shivering cessation has not been quantified. Here, we assessed changes in shivering magnitude throughout rewarming and explored its time-dependent relationship with temperature recovery.

Methods

Active duty service members (17M; 30±7y; 163±41cm; 85.5±12.6kg) were immersed to the neck in a near-frozen outdoor pond for 10 minutes during a training exercise (water: 1.3ºC; air: -4.2ºC). After immersion, participants changed into dry clothes and began active rewarming by stair stepping in place at a predetermined frequency for 40 minutes. Shivering magnitude was estimated from an Xsens DOT accelerometer on the pectoralis. Core temperature was recorded using BodyCAP ingestible capsules. Mean skin temperature (MST) was calculated [1] from iButtons on the pectoralis, thigh, and shoulder. Data were time synchronized, with shivering magnitude averaged into 1-minute epochs to align with temperature data. Pearson's coefficient and canonical correlation analysis via statistical parametric mapping vector field analysis were used to assess the strength of correlations between variables.

Results



Shivering magnitude decreased from 1.35±0.41 m/s^2 to 0.81±0.39 m/s^2 across the 40-minute rewarming (Figure 1). These reductions were very strongly correlated with increasing MST ($r=-0.93$, $p<.001$) and strongly correlated with increasing core temperature ($r=-0.79$, $p<.001$). Canonical correlation revealed the rate of change in shivering magnitude was correlated with MST and core temperature from minutes 13-40 of rewarming ($p=.033$). Post hoc Pearson's correlation further revealed the rate of change in shivering magnitude

was moderately correlated with MST from 0-27 minutes (r=-0.65 to -0.50, p=.022) but not significantly correlated with core temperature.

Discussion

Shivering magnitude was strongly correlated with increasing MST and core temperature while actively rewarming following outdoor, whole-body, CWI. This association emerged shortly after minimum core temperature (minute 11.9±9.2 of rewarming), aligning with previous work relating shivering thermogenesis to afterdrop. Our findings quantify the time course of shivering cessation dynamics and may inform targeted rewarming protocols to optimize thermoregulation and reduce afterdrop risk.

Investigating The Relationship between Maximal Isometric Strength and Measures of Dynamic Performance in Collegiate Female Basketball Athletes

Mr Anaikh Randhawa

McMaster University, Hamilton, Ontario, Canada

Introduction

Lower body strength is crucial for basketball performance, impacting sprinting ability, jump height, and injury risk. Traditional assessments such as one-repetition maximum testing have limitations regarding safety, fatigue, and force-time characteristics. The isometric mid-thigh pull (IMTP) is a validated alternative, providing a safer and more efficient measure of maximal isometric strength. Although IMTP-performance relationships are well established in male athletes, evidence in female basketball athletes remains limited.

Methods

The objective of this study was to determine whether IMTP-derived strength metrics correlate with dynamic performance in female basketball athletes, and to evaluate how the magnitude of these associations compares with recreational athletes. Collegiate female basketball athletes (n = 11) and recreational athletes (n = 9) completed two IMTP's on a portable force plate system to assess peak force (PF) and rate of force development (RFD). Dynamic performance was evaluated using countermovement jump (CMJ) concentric mean power (W/kg) and jump height (in), and 10-meter sprint time (s). Pearson correlations were computed within each group to examine associations between IMTP-derived strength metrics and dynamic performance outcomes.

Results

Female basketball athletes demonstrated significant correlations between RFD 0–50 ms and both jump height and sprint time, as well as between sprint time and RFD 0–150 ms and RFD 0–200 ms. Conversely, recreational athletes exhibited significant correlations between peak vertical force / BM (N/kg) and both jump height and concentric mean power, along with similar relationships using net peak vertical force (N). Detailed correlations between IMTP metrics and CMJ/sprint performance are presented in Table 1.

Discussion

These findings highlight the value of the IMTP for performance profiling in female basketball athletes, particularly through early-phase RFD, which was associated with dynamic outcomes despite no relationships with peak force. In contrast, peak force values were more strongly related to performance in recreational athletes, with no significant relationships observed for RFD, potentially reflecting reduced ability to generate rapid force. Overall, the IMTP appears useful for guiding individualized training program design. However, metric selection should be population-specific, as force expression differs across athlete groups.

Assessing Deep Learning Techniques for Ice Hockey Human Activity Recognition fromGame Simulated Inertial Measurement Unit Data

Mr Andrew Phillips MSc, Mr Philippe Renaud MSc, Dr Shawn Robbins PhD

McGill University, Montreal, Quebec, Canada

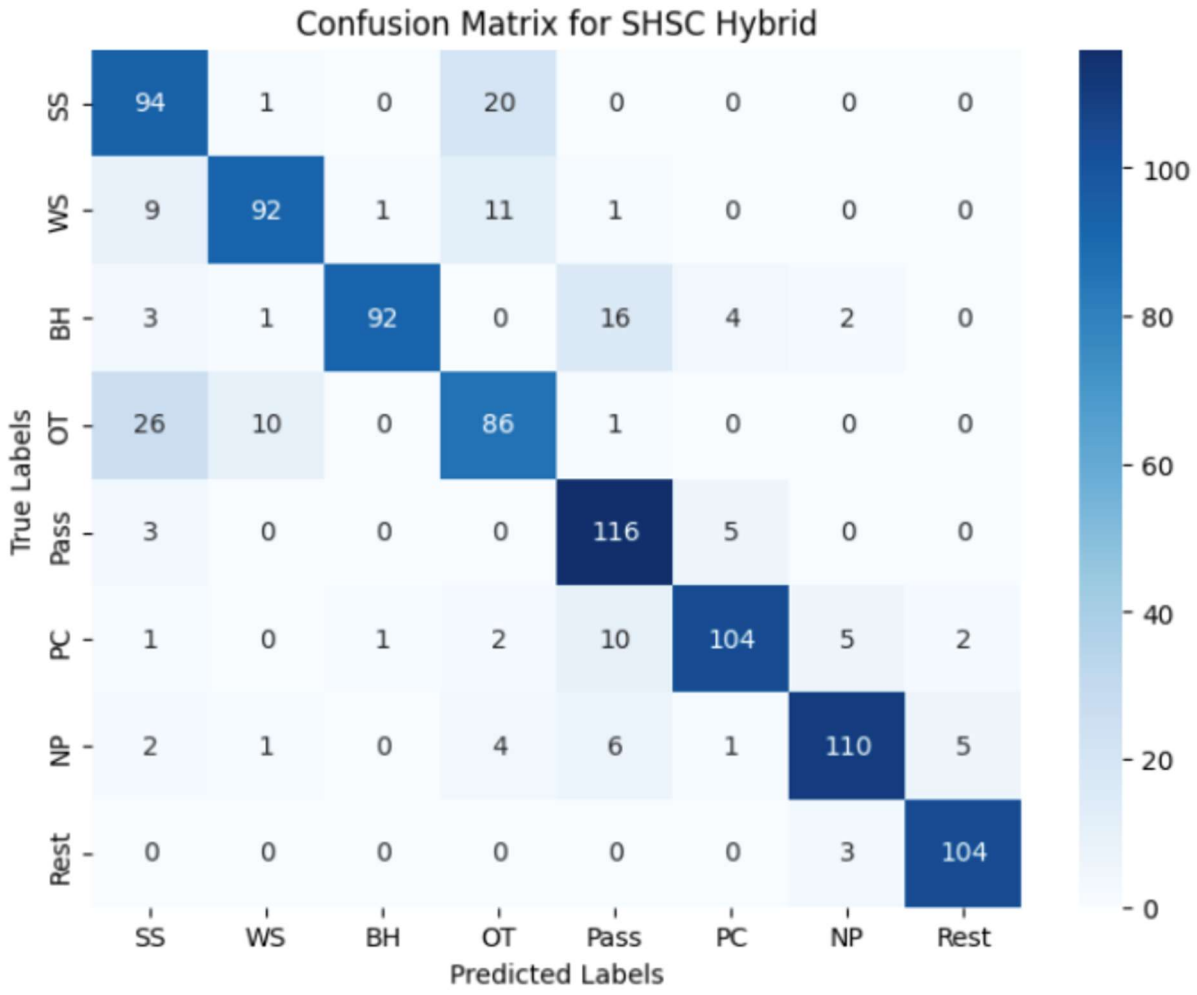
Introduction

The introduction of artificial intelligence (AI) has revolutionized the way sports data is collected and analyzed, opening new possibilities for what can be achieved in sports science research and performance. Human activity recognition (HAR) in ice hockey had traditionally relied on manual annotation and analysis from humans, a time-consuming task prone to error and bias. By partnering AI algorithms with movement data from wearable sensors, HAR models can be developed and implemented to provide deeper, more efficient, and more meaningful insights into hockey data. The objectives of this research were to compare three distinct deep learning neural networks in their abilities to classify eight ice hockey player events using wearable accelerometer data and to determine the optimal sensor configuration for this task.

Methods

48 hockey players performed shots and other hockey events in a game-simulated environment using 17 wearable inertial measurement units (IMU). Video footage of the participant trials was used as ground truth for labelling the IMU data. The segmented and labelled acceleration data were used to train and test three deep-learning model architectures: a traditional approach (Convolutional Neural Network (CNN)), a modern approach (Transformer Network), and a hybrid approach combining the benefits of both models (CNN-Transformer Hybrid), with three different sensors configurations (all 17 sensors (ASC), 3 sensors on the sternum and hands (SHSC), and 2 hands only sensors (HSC)).

Results



The hybrid models achieved the highest mean F1 score across all three sensor configurations (81.9%), followed by the CNN models (79.5%) and the Transformer models (74.4%). The highest-performing individual model was the 3-sensor Hybrid model, reaching an F1 score of 83.7%. The models all demonstrated their ability to differentiate between

tasks with different movements (e.g. slap shot vs pass) but struggled to differentiate between tasks with similar movement patterns (e.g., slap shot vs one-timer).

Discussion

Findings from this study can have a positive impact on the advancement of how movement data is detected and analyzed in real-game environments. These advancements have important implications for coaches, players, and analysts by supporting the development of AI technology for injury detection and rehabilitation, real-time performance tracking, and technique optimization to enhance player performance.

Neuromuscular Coherence Patterning in Female High School Soccer Athletes

Ms. Yara Izhiman[1], Ms. Annika Schaeffer[1], Dr. Vesna Novak[1,2], Dr. Michael Riley[3], Dr. Brian Grawe[4], Dr. Eric Nauman[1]

[1]Department of Biomedical Engineering, University of Cincinnati, Cincinnati, Ohio, United States. [2]Department of Electrical Engineering and Computer Science, University of Cincinnati, Cincinnati, Ohio, United States. [3]Department of Rehabilitation, Exercise, & Nutrition Sciences, University of Cincinnati, Cincinnati, Ohio, United States. [4]Orthopaedics and Sports Medicine University of Cincinnati, College of Medicine, Cincinnati, Ohio, United States

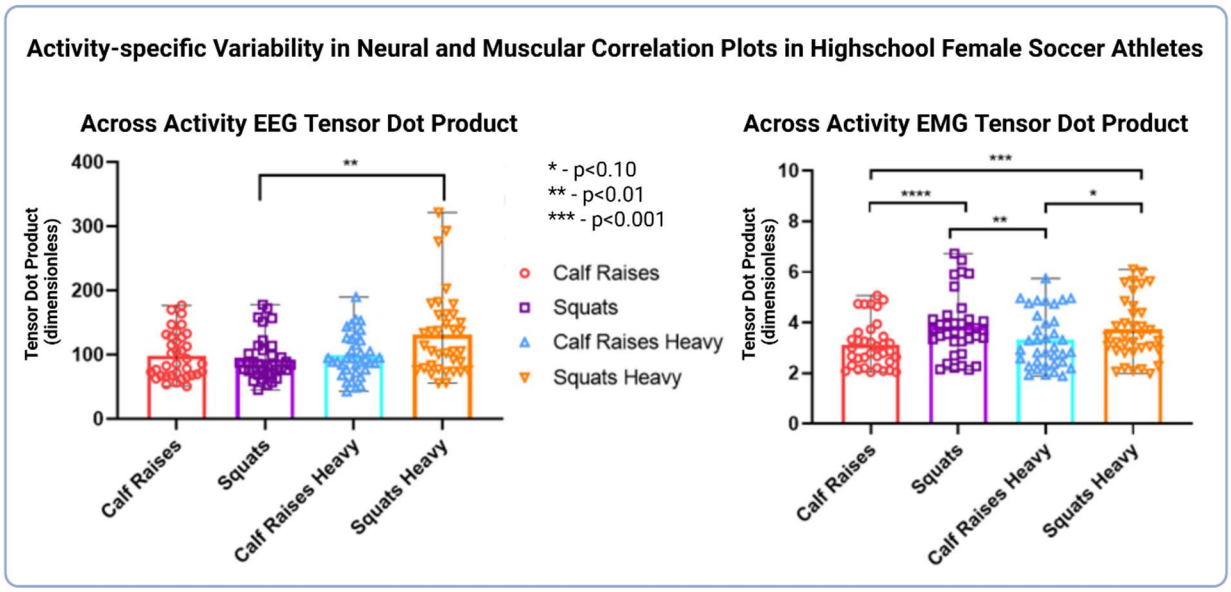
Introduction

The integration of cognitive command signals and muscle activation as biomarkers for functional performance remains under-researched yet holds potential for advancing rehabilitation strategies and enhancing athletic performance. This study aims to advance the understanding of cortico-muscular communication across functional performance in pre-professional teams such as high school soccer. To achieve this, we compared cortical and muscular correlation and coherence across different functional movements in six female high school soccer athletes. By comparing these interactions, our study aims to offer a baseline for future directions, especially in identifying indicators of injury, muscular fatigue, as well as recovery.

Methods

Data acquisition was conducted across six repetitions of two activities: calf raises and two-legged squats under a loaded and unloaded condition. Electromyography (EMG), electroencephalography (EEG), and motion capture signals were recorded concurrently to ensure synchronized multimodal datasets. The raw datasets were processed using a custom MATLAB pipeline that expanded on standardized signal processing procedures for cross-modal comparative analysis. Correlation and coherence maps describing neural, muscular, and cortico-muscular dynamics were generated for EMG, EEG, and EEG-EMG data, respectively.

Results



Our preliminary findings highlight statistically significant difference between functional movement, calf raises and squats, which suggests movement-dependent cortico-muscular dynamics. Furthermore, squats, which are considered complex movement as compared to calf raises, exhibited significant increases in both cortical and muscular

dynamics when loaded sets were compared to non-loaded. The increased neuromuscular dynamics in loaded squats may signify increased neuromuscular recruitment that required stabilization. In addition, the increased neural dynamics may reflect enhanced cortical drive under the loaded condition, likely required by the recruitment of higher motor strategies for neuromuscular control.

Discussion

Our preliminary results revealed that the repeatability of cortico-muscular dynamic characterization allows for utilizing cortical and muscular dynamics as markers for neuromuscular communication across functional performance in athletes. In addition, the reported activity-specific cortico-muscular dynamic variability highlights the promise of this integrated investigation in personalizing comprehensive functional performance. These findings further invite the expanded investigation of the role of athletic training in enhancing neuromuscular efficiency in functional movement. In addition, this proposed approach may allow for injury prediction, and in parallel, return-to-sport readiness following an injury.

Impact of Shoulder Fatigue on Motor Learning During High-Velocity Athletic Wheelchair Propulsion

Mr. Anthony Tremblay[1,2], Ms. Sara Havashinezhadian[1,2], Mr. Abdellah Hassar[1,2], Mr. Jason Bouffard[1,2]

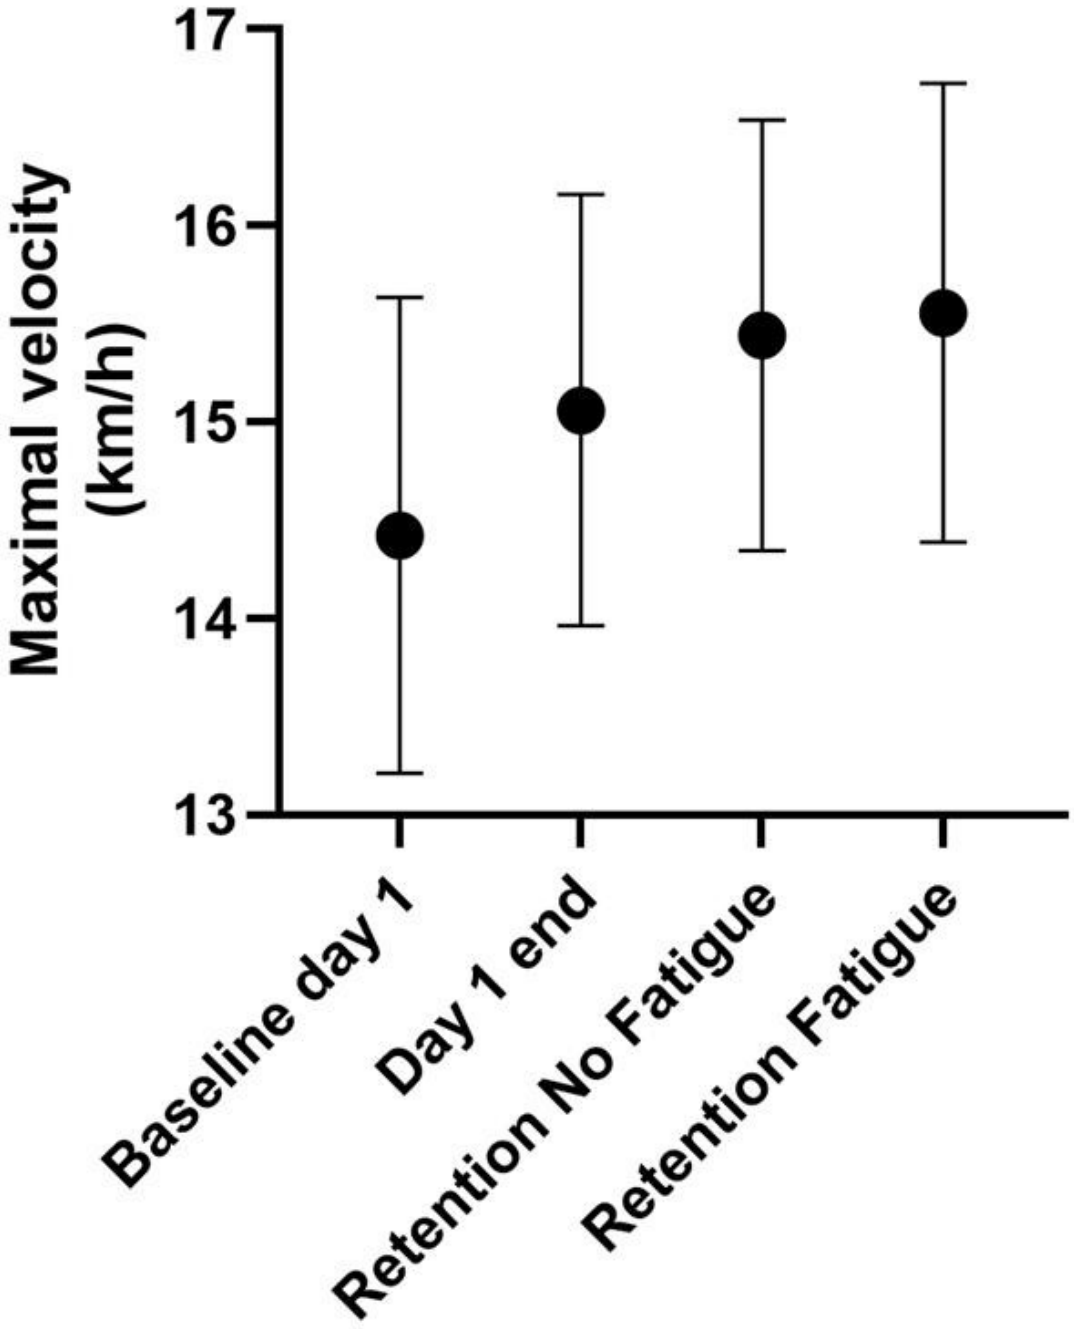
[1]Université Laval, Quebec, Quebec, Canada. [2]Center for Interdisciplinary Research in Rehabilitation and Social Integration, Quebec, Quebec, Canada

Introduction

Neuromuscular fatigue emerges from sustained physical exertions and leads to diminished performance and heightened perceived effort. In the context of motor learning, it can disrupt practice quality and skill acquisition. Previous studies have shown that training under conditions of fatigue can affect motor learning, especially during precision motor tasks. However, very few studies evaluated its effects on motor learning of skills requiring important power production such as high velocity wheelchair propulsion. The objective of the study is to analyze the effects of neuromuscular fatigue on motor learning in athletic wheelchair propulsion. Fatigue is expected to impair performance and learning.

Methods

Forty healthy participants will be evaluated during three laboratory sessions. During the first session, they will complete a total of 7 blocks of 3 wheelchair propulsion trials (2 submaximal + 1 maximal). Each block will be separated by 5 minutes of fatiguing or non-fatiguing shoulder movements, depending on group assignment. Retention will be assessed in Sessions 2 and 3 during two blocks performed either with or without fatigue in randomized order. Multiple spatiotemporal (i.e. cycle frequency), velocity (average speed, within-cycle speed gains and loss) and acceleration (i.e. maximal acceleration and deceleration) metrics will be computed for each propulsion cycle and compared between blocks and groups. Subjective and objective signs of fatigue will also be assessed.



Results

Preliminary results (Control group: n=6; Fatigue group: n=4) showed a trend for improvement in maximal velocity over time when considering both groups together (Figure 1; one-way ANOVA: $p = 0.064$). Participants perceived significantly more fatigue following fatiguing (>6.5/10) than non-fatiguing contractions (<3.5 / 10), as expected. However, maximal velocity wheelchair propulsion induced significant objective (>15% decreased in maximal force) and subjective (up to 7.8 / 10) signs of fatigue in all conditions, reducing the contrast in the fatigue experienced by each group.

Discussion

Preliminary results partially confirm the validity of the protocol aiming to assess the effects of neuromuscular fatigue on motor learning. Still, results highlight challenges in finding the best balance between movement repetition and rest time to allow motor learning and prevent fatigue to advance the research field, especially in motor skills requiring important power production.

Efficacy of a Frugal Inertial Sensor-based Motion Capture System in Quantifying Ankle Kinematics during Badminton Lunge

Mr. Apoorv Shrivastava PhD Student[1], Ms. Saranya Navratnarajah[2], Mr. Jeevaraaj N. Vivekanandan[3], Dr. Siew Li Goh[4], Dr. Darshan S. Shah[1]

[1]BiOME Lab, Department of Mechanical Engineering, Indian Institute of Technology Bombay, Mumbai, Maharashtra, India. [2]Institute for Advanced Studies, Universiti Malaya, Kuala Lumpur, Federal Territory of Kuala Lumpur, Malaysia. [3]Department of Biomedical Engineering, Faculty of Engineering, Universiti Malaya, Kuala Lumpur, Federal Territory of Kuala Lumpur, Malaysia. [4]Sports Medicine Unit, Faculty of Medicine, Universiti Malaya, Kuala Lumpur, Federal Territory of Kuala Lumpur, Malaysia

Introduction

Inertial sensors are an ubiquitous alternative to optical motion capture (OMC) in characterizing movement biomechanics in field applications [1]. However, issues related to measurement noise, signal distortion, sensor drift, coupled with the premium and discreet software packages of commercial sensors limit their adoption to a narrower user-base. A modular frugal inertial measurement unit (IMU)-based motion capture system was therefore, developed for more accessible, transparent and customizable biomechanical analyses. To validate this custom IMU system for high-impact, high-frequency on-field sporting tasks, this study aimed to assess the efficacy of the system in capturing ankle kinematics during badminton lunge.

Methods

The custom-IMU system consisted of a low-cost IMU (MPU9250, InvenSense, USA), a microcontroller, wireless data transmission module and on-board data storage. Data handling included signal processing, drift compensation, a Madgwick filter-based sensor fusion algorithm and a functional calibration-based sensor-to-segment alignment procedure [1]. Following institute ethics approval, 18 recreational badminton players (7F, 29±7yrs) performed three trials of forward lunges. Ankle kinematics – plantar-dorsiflexion (PDF), inversion-eversion (InvEv), internal-external rotation (IErot) – were captured using custom IMUs attached to the foot and shank segments, and an eight-camera OMC system (Qualisys, Sweden), which tracked markers attached to these segments following ISB recommendations [2]. Root mean square error (RMSE), maximum error, error in range of

motion (ROM) and paired-t test ($p<0.05$) were used to compare the accuracy of IMU-derived ankle kinematics against benchmark OMC results.

Results

RMSE and maximum error were lower for PDF (RMSE=0.89°, max. error=3.31°, ROM error=5.51%) and InvEv (RMSE=1.35°, max. error=3.76°, ROM error=15.00%) as compared to IErot (RMSE=3.62°, max. error=7.19°, ROM error=95.48%).

Discussion

RMSE results revealed 'good' accuracy of the custom-IMU system for PDF and InvEv, and 'acceptable' for IErot [3], despite higher errors near the heel-strike and foot-off events anticipated due to impact-driven movement artefacts. Large maximum and ROM errors observed for IER displayed the inefficacy of custom IMUs to track the tertiary degree of freedom. Overall, these findings for the dynamic high-impact activity showed potential of the custom-IMU system for tracking sports-related motions.

A Machine Learning Pipeline to Evaluate Dive Performance

Ms. Athena Constantinou-Simek[1], Professor Jill McNitt-Gray[2], Professor Nidhi Seethapathi[1]

[1]Massachusetts Institute of Technology, Cambridge, Massachusetts, United States. [2]University of Southern California, Los Angeles, California, United States

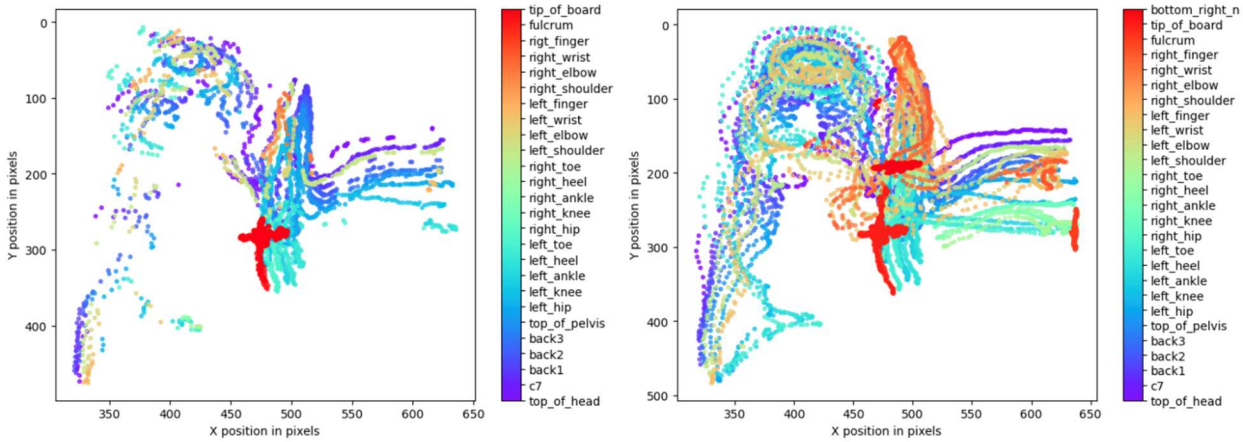
Introduction

Several sports use automated judging systems to provide metrics of an athlete's movement or to assist referees with qualitative judgements. Springboard diving has implemented AI to measure low-dimensional features like dive height or number of revolutions, to aid judges with scoring. However, technology to automatically analyze dives directly from video is missing. Here, we create and evaluate a machine learning pipeline to track athlete movements, determining minimum labels for accurate tracking.

Methods

Our dataset consists of 126 sagittal videos from the Men's 3M Diving Preliminaries during the 2012 London Olympics. These videos were analyzed using pose estimation software (DeepLabCut (DLC)), extracting 27 keypoints using supervised learning. DLC requires several pre-labelled frames for each video, and we tested different numbers of labels to determine an optimal number for an accurately tracked video. Then, we created a Long Short-Term Memory Machine Learning (LSTM ML) model, whose inputs are the x,y coordinates of an individual video, and whose output is a single overall score, as given by the Olympic judges.

Results



DLC generates accurate labeling on a test dataset if ~8% of the input frames are labelled. Using DLC's automatic kmeans frame extraction algorithm gives 31.99 pixels root mean squared error (rmse). When we manually extract 69 frames from the same video, the rmse is 4.6 pixels. The software performs better if the labelled frames are manually selected and concentrated around periods when the diver's position changes rapidly. We trained our LSTM ML model with 23 videos of pike dives and tested the model on 6 videos, and the rmse of the predicted judge scores is 15.2%.

Discussion

Our study clarifies the ideal method of frame selection and the number of frames needed to track a complex whole-body movement like diving. We provide preliminary evidence that such pose tracking can be used to predict the overall dive score. Going forward, we will

adjust our input movement data to determine the minimum information necessary for accurate predictions of the dive score. Overall, this data-driven approach will help advance automated scoring of sports and understand which movement features are most score-relevant.

Images (Optional)

Plots generated by DLC, graphed are x,y coordinates of 27 keypoints across all frames. Left: 20 labelled frames (2.5% of total), extracted using DLC kmeans algorithm. Right: 69 labelled frames (8.6% of total), extracted using manual selection.

Effect of Effective Mass in Lower Limb Strikes in Martial Arts Between Experience Levels

Ms. Avery Moe, Dr. Ross Miller

University of Maryland, College Park, MD, United States

Introduction

High rates of force development and deceleration just before impact are integral to martial arts striking performance. Effective mass is a measure that reflects the martial artist's ability to strike with both of these characteristics as observed in highly experienced individuals. There is little evidence on how training affects a person's ability to achieve high effective masses in the striking, or impact, leg and standing, or plant, leg upon impact. This study seeks to quantify effective mass in the impact and plant legs of a front leg round kick, and to compare effective mass between martial artists of different experience levels.

Methods

Three beginner (24±3 years old, 1±1 years of experience) and five advanced (21±2 years, 13±2 years of experience) martial artists performed five maximal effort front leg round kicks with each leg, targeting a standing 100-lb foam bag. Ground reaction forces of the participant and the target were collected. Acceleration of the participant's center of mass was calculated from the ground reaction forces, and effective mass was calculated for the striking leg and the plant leg as the ratios between the peaks of these forces and the accompanying acceleration of the center of mass. Effective mass averages were reported as absolute values in kilograms and relative values when scaled by body mass. They were then compared between groups using unpaired t-tests.

Results

No significant differences were found between groups in absolute or relative effective mass of either leg (all $p > 0.1$). Further analysis revealed that beginners had greater variance values in all outcome measures and conditions except for effective mass in the plant leg and of the sum of the forces when kicking with the right leg. No statistical significance of variances between groups was found either (all $p > 0.1$).

Discussion

Contrary to our expectation, martial artists did not differ in effective mass, regardless of experience, suggesting this skill is developed early. Advanced martial artists demonstrated more consistency in the way that they perform the kick, especially in the striking leg. This

consistency is likely beneficial for traumatic knee injury prevention when striking at higher forces.

Effects of model personalisation on muscle and joint forces in powerlifting

Dr Basilio Goncalves[1,2], Dr Alexander Pürzel[1,2], Dr Ekaterina Stansfield[3], Dr Willi Koller[1,2], Prof Arnold Baca[1], Ass Prof Hans Kainz[1,2]

[1]Centre for Sport Science and University Sports, University of Vienna, Vienna, Vienna, Austria. [2]Neuromechanics Research Group, University of Vienna, Vienna, ViennaResearch Group, University of Vienna, Austria. [3]Department of Evolutionary Biology, University of Vienna, Austria, Vienna, Vienna, Austria

Introduction

In powerlifting squats, increasing lifting load results in heterogeneous muscle force increases particular for hip and knee muscles [1]. Powerlifting athletes have different femoral geometry compared with normal population [2] which might influence muscle and joint contact forces (JCF) [3]. Furthermore, muscle coordination strategy during squats might not aim to minimize activations, which is a common approach to calculate muscle forces [1]. We investigated how model personalisation influences muscle and JCF and hypothesised that individual bone geometry would decrease muscle and JCF while accounting for the athletes' muscle coordination would increase said forces.

Methods

Magnetic resonance image (MRI) scans of the lower limb and 3D motion capture data from seven powerlifters were collected. Generic musculoskeletal models were personalised using either marker data (linearly scaled) or using MRI derived morphology [4]. Joint kinematics and net joint moments were calculated using OpenSim and muscle forces were calculated using either Static Optimisation (SO) or a calibrated electromyography-informed neuromusculoskeletal model (CEINMS) [5]. Muscle and JCF obtained from four different simulation approaches (SO-Scaled, SO-MRI, CEINMS-Scaled, CEINMS-MRI) were compared across three different tasks (walking, bodyweight squatting, and loaded squatting).

Results

So far, data of one athlete was analysed. Personalisation of bone geometry increases knee JCF by 2% to 12% during squatting but not during walking (-8% to 19%) (Figure 1). Compared to the simplest model (SO-scaled) the most personalised model (CEINMS-MRI) resulted in similar muscle forces during walking (< 9%) but larger hip muscle forces during squatting (24 to 31%). Knee and ankle muscle forces during squatting vary largely between models.

Discussion

Personalising bone geometry and muscle coordination substantially altered muscle forces and JCF. Bone morphology increased knee JCF during squatting, while CEINMS revealed higher hip muscle forces than SO. These findings show that simplified models may underestimate key loads, highlighting the necessity of personalised musculoskeletal models for powerlifters.

Images (Optional)

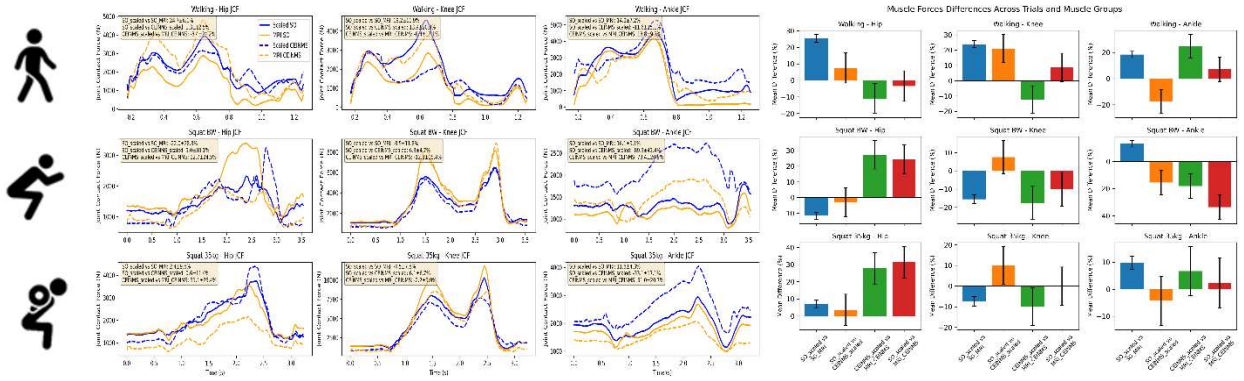

Figure 1. Effects of model personalisation on (left) joint contact forces and (right) muscle force differences between models during (top) walking, (middle) bodyweight squat,and (bottom) weighted squat in one elite powerlifter. Ensamble waveforms and standard deviations for joint contact forces were compared between a linearly scaled model (blue), an MRI-derived model (yellow), using static optimisation (solid lines) and an electromyography informed optimisation (dashed lines). Muscles forces differences are shown as mean differences (%) between the simulation approaches with standard deviation error bars. Muscles groups are shown as those crossing hip, knee, and ankle joints.

P1-271

Midsole Rocker Geometry of Advanced Footwear Technology Affects Biomechanics but Not Running Economy or Perception in Female Runners

Mr. Ben Hazelwood, Dr. Jamie Ferris, Dr. Samuel Cheuvront, Dr. Jinger Gottschall

New Balance Sports Research Lab, Boston, MA, United States

Introduction

Midsole rocker geometry is a key feature of advanced footwear technology (AFT) and is thought to enhance endurance running performance [1]; however, its isolated effects within AFT are not well understood. This study aimed to examine effects of midsole forefoot rocker onset on running economy (RE), biomechanics, and perception in AFT.

Methods

Ten experienced female runners completed 5-minute bouts of instrumented treadmill running in three prototypes based on the New Balance FuelCell SuperComp Elite v4 of equal mass with varying midsole forefoot rocker onsets: ~50% (Early), ~60% (Mid), and ~70% (Late) of stick length. Nylon plates mirroring each prototype's rocker shape were embedded in the midsoles. RE and lower-limb biomechanics were analyzed via RMANOVA and Tukey's HSD (α=0.05). Perceived footwear attributes were rated on 7-point scales [2] and compared using Friedman tests and Dunn's post hoc pairwise comparisons.

Results

Rocker onset had non-significant effects on RE (p=0.55). Biomechanical differences occurred primarily in force, spatiotemporal, and ankle kinematic measures. These included increased peak braking force with later rocker onset and increased peak propulsion force in Late (Figure 1), as well as increased ankle sagittal range of motion in Mid (p=0.021 vs. Early; p=0.010 vs. Late). Perceived energy return (p = 0.029), ground feel (p = 0.022), and speed (p = 0.024) were different among footwear, though no pairwise differences were significant. Median values differed by less than 1 scale point out of 7.

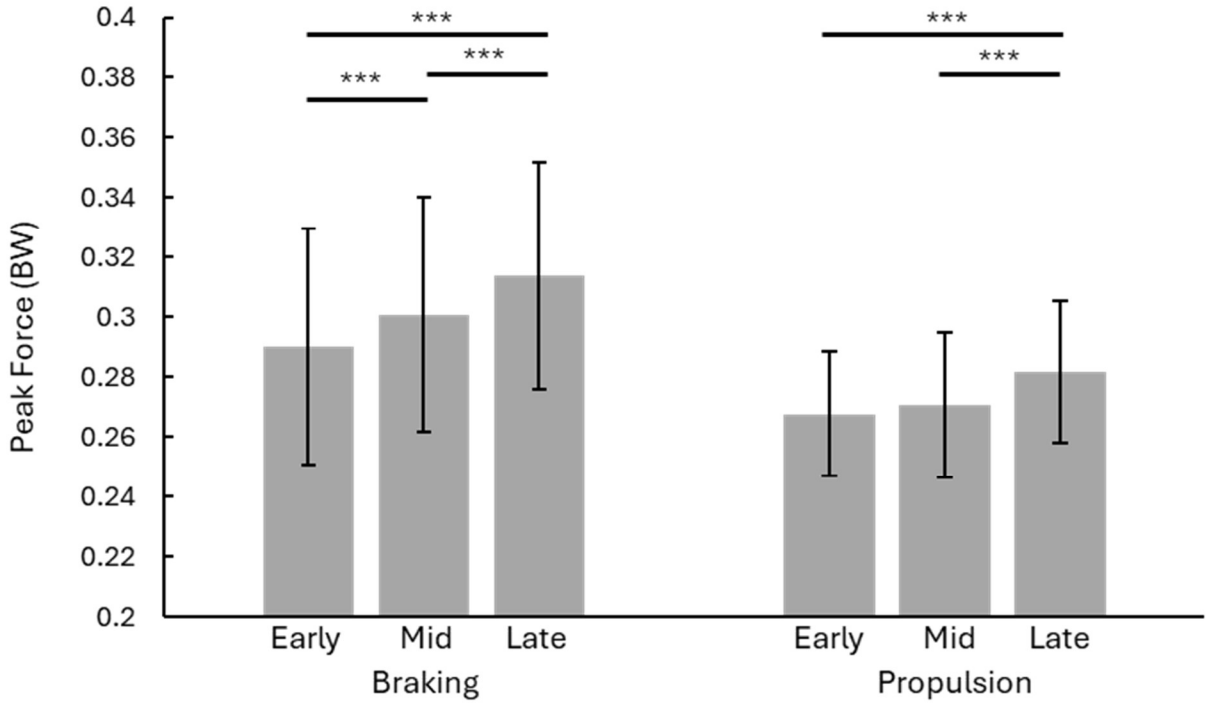

Figure 1. Average peak braking and propulsion forces across footwear conditions. ***p < 0.001

Discussion

While forefoot rocker onset in AFT affects running gait, these changes did not lead to differences in whole-body energy expenditure or footwear perception. Rocker onset in AFT

can be altered within 50-70% of stick length without impacting endurance performance or runner experience.

Swinging Arms Helps Gluteus Maximus Generate More Work in the Standing Long Jump

Dr. Blake Ashby Ph.D., P.E.[1], Ms. Abigail Douglas M.S.E.[1,2]

[1]Grand Valley State University, Grand Rapids, MI, United States. [2]Thompson Surgical Instruments, Traverse City, MI, United States

Dr. Blake Ashby

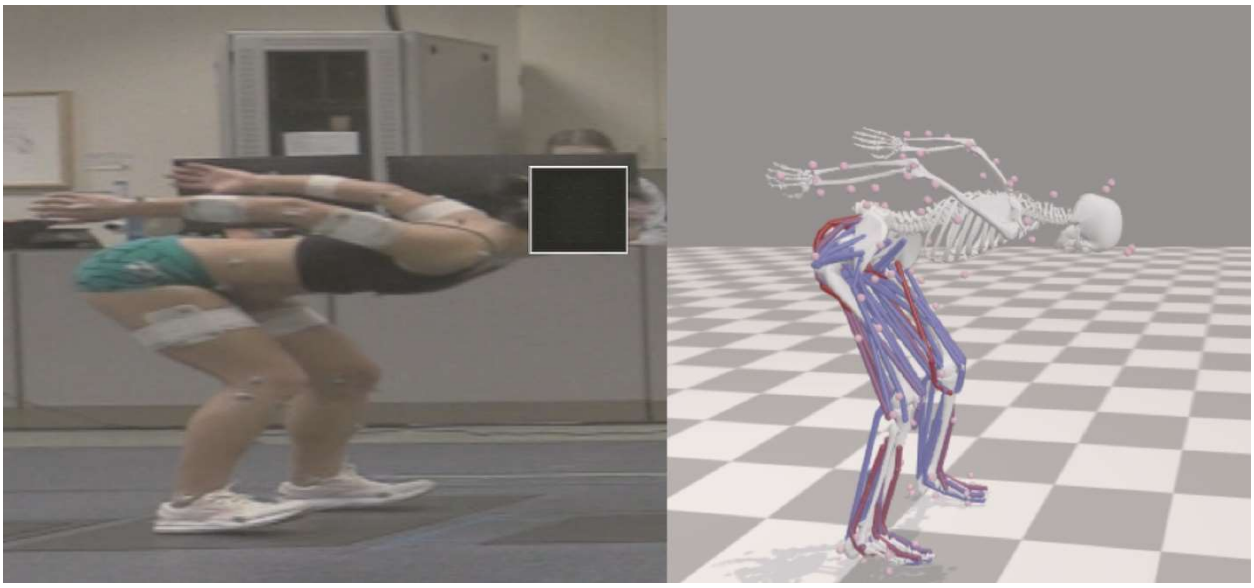
Introduction

The standing long jump is a fundamental movement found in numerous sports. Prior studies using joint torque actuated models have demonstrated that arm motion improves performance in part by allowing the lower body muscles to generate more work during the takeoff phase of the movement. The purpose of the present study was to further explore this principle using muscle-actuated models to determine individual muscle contributions to performance in jumps with and without arm motion.

Methods

Three male and three female participants executed maximum effort standing long jumps: three with free arm motion and three with restricted arm motion. The motion of passive reflective markers was recorded using a 16-camera motion capture system, and ground reaction force data were recorded with two in-ground force platforms. Scaled, full-body models with 17 upper body joint torque actuators and 80 lower-body musculotendon actuators were used to analyze the longest jumps with and without arm motion for each participant. OpenSim was used to conduct inverse kinematics, inverse dynamics, residual reduction algorithm, static optimization, and muscle analyses. Muscle forces and lengths from the muscle analyses were used to calculate power and work for the takeoff phase of all jumps. Paired t-tests were performed with muscle work differences presented as mean ± standard deviation.

Results



Lower body muscles generated 37.2 ± 28.2 J more work ($p = 0.02$) during the takeoff phase of jumps with free arm movement when compared to jumps with restricted arms. Over half (53%) of that work difference was due to the gluteus maximus muscles (19.7 ± 12.7 J, p =

0.01). The soleus muscles also generated significantly more work (5.0 ± 3.6 J, p = 0.02) with free arm motion.

Discussion

The largest differences in work were demonstrated by the gluteus maximus muscles, which are major hip extensors. This is consistent with the joint torque augmentation theory, which states that swinging the arms exerts downward forces at the shoulder that slow the extension of the hip allowing the hip extensor muscles to generate larger forces consistent with the force-velocity dependence of muscles. This preliminary work will be extended to include the analysis of more participant jumps.

Center-of-Mass Inclination Angle and Ski Edge Angle Influence Glide Length on Roller Skis

Mr Brandon Cabaniss, Mr Isaac Burgess MS, Mr Ethan Livingood, Dr. James Becker PhD

Montana State University, Bozeman, MT, United States

Introduction

Glide length is a critical determinant of cross-country skiing performance, with longer glide length consistently linked to faster V2 ski speed. On-snow studies show mediolateral plantar-pressure balance but not ski edge angle are strongly correlated with glide time. However this relationship has not been examined on rollerskis despite rollerskiing accounting for over half of yearly training volume. In addition to pressure balances, maintaining a stacked body position on the ski might be essential for longer glide lengths. Thus, the purpose of this study was to investigate the relationship between glide length and plantar-pressure balance, ski edge angle, and mediolateral center-of-mass inclination angles during rollerskiing.

Methods

Twenty-nine elite biathletes (15M/14F, 24±5 years) skied on a roller ski treadmill at race intensities. Ski, pole, and whole body kinematics were collected using hybrid markerless motion capture while forces applied to the ski were measured using plantar-pressure system insoles. Glide length (*GL*), mean mediolateral center-of-mass inclination angle (θ_{ML}), mean asymmetry in mediolateral pressure balance as an asymmetry index (*ASI*), and average ski edging angle (θ_{ski}) during the gliding phase were then calculated. Multiple linear regression was used to evaluate how well $\theta_{ML,}$ *ASI*, and θ_{ski} predicted *GL*

Results

Multiple regression showed that *ASI*, θ_{ski}, and θ_{ML} accounted for 30% of variance in glide length ($F_{3,52} = 7.393$, $p < 0.001$), however *ASI* was not significant ($p = 0.155$, Table 1).

Discussion

While *ASI,* not θ_{ski}, is a strong predictor of *GL* on snow, our finding suggest this is not true on rollerskis. This may be due to the differences between gliding on snow and roller skis. Less balanced *ASI* on-snow may increase ski friction and thus decrease *GL*. However, the same may not be true on a roller ski, as changing ski orientation does not have as large an impact

on the rolling speed of the ski. On a roller ski, a skiers ability to dynamically balance on the wheels, as measured by θ_{ski} and θ_{ML}, appears to be more influential than plantar-pressure balance. Skiers that maintain a more stacked body position and flatter ski across gliding phase may glide further on the skiing treadmill.

Images (Optional)

Table 1. Mean data for glide length *(GL)*, ski edge angle *(θ_{ski})*, mediolateral center-of-mass inclination angle (θ_{ML}), and mediolateral plantar-pressure balance *(ASI)* across the glide phase. Beta-coefficients *(β)* and significance for each variable in the multiple regression are shown.

Variable	Mean ± SD	*β*	*p-value*
GL (m)	3.1 ± 0.7	4.16	< 0.001
ASI (%)	4.0 ± 2.9	-0.02	0.155
θ_{ski} (°)	12.9 ± 8.2	-0.07	0.025
θ_{ML} (°)	5.7 ± 1.8	-0.05	0.049

P1-274

Rate of Force Development as a Key Performance Indicator for Collegiate Golfers

Mr. Cameron Jensen MS, Dr. David Kingston PhD, Dr. Samuel Wilkins PHD, ATC, Dr. Adam Rosen PhD, ATC, Dr. Brian Knarr PhD

University of Nebraska Omaha, Omaha, NE, United States

Introduction

Peak rate of force development (RFD) is an important kinetic performance indicator for many athletic movements [1]; however, it remains unexplored during the golf swing. This study's purpose is to investigate the relationship between peak RFD during a golf driver swing with performance metrics and strength and flexibility measurements assessed by the Titleist Performance Institute (TPI) Level 1 Screen.

Methods

Twenty-six collegiate golfers (Male: 17, Right-Handed: 24, Age: 20.5 ± 1.3 years, Height: 176.7 ± 8.5 cm, Mass: 73.5 ± 10.0 kg, Handicap: +2.6 ± 1.1) completed the TPI screen and three driver swings on two force plates (AMTI, Watertown, MA, USA) in an indoor environment. Force-time and moment-time curves were derived, and the maximums and minimums were identified to determine the peak positive and negative linear and angular RFDs (angular RFD: rate of torque development), respectively. A golf launch monitor (Rapsodo, Chesterfield, MO, USA) collected clubhead speed (CHS). Spearman correlations examined relationships between average peak RFD and average CHS. Separate PCAs reduced dimensionality for TPI and kinetic variables, and a linear regression model assessed relationships between TPI-derived and kinetic-derived principal components (PC).

Results

Twenty-two RFD values had significant correlations stronger than rho = ± 0.50, with the two strongest being Back Foot Peak Angular RFD Magnitude (rho = 0.81, $p < 0.01$) and Front Foot Peak AP Angular RFD (rho = 0.78, $p < 0.01$) (Figure 1). For males, the RFD PC had a significant negative relationship ($\beta = -1.17$, $p = 0.03$) with the mobility/flexibility TPI PC.

Discussion

Golfers who can rapidly generate side-bending torque by driving the lead side downward and toward the target tend to achieve greater CHS [2]. This movement emphasizes effective weight transfer [3]. In males, peak RFD was negatively affected by mobility and flexibility, suggesting that greater flexibility may reduce the ability to generate force rapidly

[4]. Because several peak RFD measures were strongly associated with CHS, peak RFD may represent an important key performance indicator for golf performance.

Images (Optional)

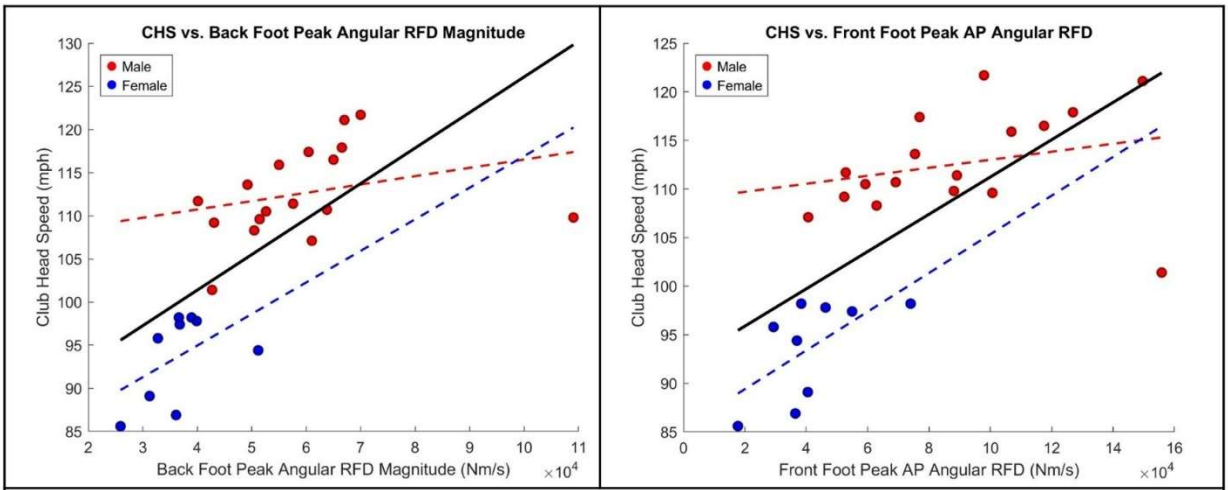

Figure 1: Correlation Plots of Back Foot Peak Angular RFD Magnitude (Left) and Front Foot peak AP Angular RFD (Right) with Clubhead Speed (CHS). Each variable has a moderate positive relationship with CHS (rho = 0.81, 0.78), with greater peak angular RFD being associated with greater CHS for both males and females, separately and combined.

Comparison of Traditional Kinematics and Bidimensional Variables for Classifying Lead Leg Effectiveness in Baseball Pitchers

Mr. Brandon Doehne MS, Mr. Cameron Jensen MS, Dr. Samuel Wilkins Ph D, ATC, Dr. Adam Rosen Ph D, ATC, Dr. Brian Knarr Ph D

University of Nebraska at Omaha, Omaha, Nebraska, United States

Introduction

Previous baseball literature defines the role of a pitcher's lead leg to reduce their body's linear momentum to create a stable base for upper body rotation. While the change in lead knee angle (from stride foot contact (SFC) to ball release (BR)) and lead knee extension velocity at BR are commonly used to classify a pitcher's lead leg effectiveness, they only consider a pitcher's kinematics and lack contextual kinetic intricacies of different pitchers. This introduces the need for variables that involve kinematics and kinetics, such as joint power and work. The purpose of this study is to determine which set of variables has a greater relationship with a reduction of linear momentum.

Methods

Ninety-seven baseball pitchers (Age: 18 ± 2.1 years, Height: 183.6 ± 7.1 cm, Mass: 84.3 ± 10.1 kg) were extracted from the UNO Pitching Lab registry for preliminary analysis. Each pitcher performed maximal intent pitches on a force-instrumented mound (960-1280 Hz) while wearing a full-body marker set (240–320 Hz). The lead leg joint power, joint work, and change in linear momentum were investigated between SFC and BR. Power was calculated by taking the dot product of the proximal and distal joint angular velocities and torques. The maximum, minimum, and deltas were extracted for statistical analysis. Spearman correlation coefficients ($p<0.05$) were calculated to assess the change of linear momentum in relation to lead knee/hip power and work, along with the change in lead knee angle and extension velocity at BR.

Results

Our analysis found that traditional and bidimensional variables were significantly correlated with a pitcher's reduction of linear momentum from SFC to BR, as seen in **Table 1**. However, lead knee/hip power and work variables displayed greater correlation coefficients than the traditional ones.

Discussion

Due to the greater correlation coefficients that the joint power and work variables demonstrated, they may be potential alternative variables to traditional kinematics for quantifying the effectiveness of the lead leg. While additional research is necessary, they may serve as a standard in the future for assessing biomechanics, which could optimize a pitcher's lead leg mechanics to increase their overall performance.

Images (Optional)

Table 1. Spearman Correlation Results

Variables	Correlation Coefficient	p-value
Lead Hip Work and Change in Linear Momentum	-0.453	p<0.001
Lead Knee Angular Velocity at BR and Change in Linear Momentum	0.322	p<0.01
Max Lead Hip Power and Change in Linear Momentum	-0.322	p<0.01
Lead Knee Work and Change in Linear Momentum	-0.289	p<0.01
Max Lead Knee Power and Change in Linear Momentum	-0.267	0.013
Change in Lead Knee Angle and Change in Linear Momentum	0.247	0.022

Non-Dominant Limb Asymmetries Associate With Lower Landing Performance in Professional Soccer Players

Ms. Camilla Antognini[1], Mr. Henry Eilen[2], Mr. Matthew Varano[2], Dr. Felipe Gonzalez[1], Ms. Brittany Dowling[2], Dr. Markus Wimmer[1], Dr. Brian Forsythe[2]

[1]Rush University Medical Center, Chicago, Illinois, United States. [2]Midwest Orthopaedics at Rush, Chicago, Ilinois, United States

Introduction

Soccer requires frequent jumping and rapid directional changes that generate high lower-limb loads, making landing biomechanics central to both performance and injury risk. Although asymmetrical landing patterns have been linked to decreased performance and greater injury risk, the specific role of limb dominance in shaping performance-related landing mechanics in soccer players is not well defined. This study investigated how limb dominance and interlimb asymmetry relate to landing performance in professional male soccer players.

Methods

Twenty-six professional male players (27.1 ± 5.3 yrs, 1.83 ± 0.06 m, 80.9 ± 7.6 kg) completed pre-season testing in 2020–2021. Dominance was based on preferred kicking leg (20 right, 6 left). Only drop jumps were analyzed. Movement was recorded using marker-based motion capture (Optitrack) and dual force plates (Bertec), with kinematic and kinetic variables computed in Visual3D (HAS-Motion). Joint angles and external moments of the trunk, hip, knee, and ankle were extracted at maximal knee flexion. Performance was defined by average jump height (mean of three trials), and players were split into high- (n=13) and low-performance (n=13) groups using the sample median (49.8 cm). Analyses compared: (1) dominant-limb biomechanics between groups, (2) non-dominant-limb biomechanics between groups, and (3) dominant vs. non-dominant limbs within each group, using statistical t-tests (α=0.05).

Results

Performance groups did not differ on dominant-limb landing mechanics (Table 1). However, low-performing players showed significantly higher non-dominant knee external rotation moment (p=0.005) and ankle adduction moment (p=0.004). Within-group analyses indicated high performers displayed reduced hip abduction on the non-dominant limb relative to the dominant limb (p=0.046), whereas low performers demonstrated greater non-dominant knee external rotation and ankle adduction moments (p=0.045, p=0.05).

Discussion

Higher-performing players exhibited more symmetrical landing mechanics, while lower-performing athletes showed marked non-dominant limb asymmetries, particularly elevated frontal and transverse plane joint moments. Because such asymmetries may elevate injury risk, assessing interlimb differences can help identify athletes who may benefit from targeted neuromuscular or strength interventions.

Images (Optional)

	Dominant Side			Non-dominant Side			Dominant vs Non-dominant Sides	
	High performance (Mean ± SD)	Low performance (Mean ± SD)	p-value	High performance (Mean ± SD)	Low performance (Mean ± SD)	p-value	High performance (p-value)	Low performance (p-value)
Hip abduction angle [°]	-5.6 ± 3.6	-6.8 ± 6.6	0.585	-8,3 ± 4.1	-8.4 ± 3.7	0.907	**0.046****	0.356
Knee internal rotation moment [%BW*m]	-2.0 ± 6.9	-2.3 ± 8.5	0.758	-0.08 ± 8.3	-11.1 ± 9.7	**0.005****	0.475	**0.045****

Intervertebral Lateral Bending Moments in the Lumbar Spine of Baseball Pitchers Across Throwing Velocities

Mr. Justin Humenay, Dr. Michael McClure, Dr. Carrie Peterson

Virginia Commonwealth University, Richmond, VA, United States

Introduction

Baseball pitching imposes substantial mechanical demands on the lumbar spine, a crucial link in the kinetic chain responsible for transferring energy from the lower body to the upper extremity. While increased pitch velocity is associated with greater trunk forces, the specific intervertebral loading patterns during high-velocity pitching remain unclear. This study investigates differences in lateral bending moments across lumbar spinal segments between collegiate pitchers throwing at high versus low velocities.

Methods

Twenty right-handed collegiate pitchers were divided into two groups: high-velocity (n = 10, 90.3 ± 1.6 mph) and low-velocity (n = 10, 81.6 ± 1.1 mph). Motion capture and external ground reaction forces from an open-access pitching dataset (Driveline Baseball [1]) were processed. A thoracolumbar model [2] and inverse dynamics analysis was used to compute lateral bending moments at six intervertebral joints. Statistical parametric mapping (SPM) was used to compare moment waveforms between groups across a time-normalized window centered at maximum shoulder external rotation. To compare the lateral bending moments of the lumbar spine between high- and low-velocity pitchers, time-series data were aligned based on the timing of maximum shoulder external rotation.

Results

We observed significant group differences at L5/S1 ($p = 0.014$) and L3/L4 ($p = 0.009$), with high-velocity pitchers showing average peak moments approximately 28% higher at L5/S1, and 24% higher at L3/L4. Additionally, the T12/L1 segment showed multiple significant intervals ($p = 0.025–0.016$) of increased loading in the high-velocity. These peaks occurred primarily during late-cocking and early acceleration.

Discussion

These findings identified high-velocity pitchers experience greater and more temporally concentrated lateral bending moments at key lumbar and thoracolumbar junctions. Our

findings may indicate enhanced spinal engagement plays a central role in generating higher pitching velocities. From a performance standpoint, these insights highlight the importance of trunk control and spinal stability in energy transfer. From an injury prevention perspective, the increased and localized loading observed in high-velocity throwers may support the emphasis on targeted strength, mobility, and recovery strategies to optimize the lumbar spine for loading.

Inter-joint Coordination Differences While Skiing Across Development Levels of Biathletes

Ms Charlotte Whitcomb, Mr Isaac Burgess MS, Dr. James Becker PhD

Montana State University, Bozeman, MT, United States

Introduction

Skate cross-country skiing is a complex full-body movement requiring coordinated motion across multiple joints and segments. Although previous studies have used relative timing to quantify coordination differences across development levels, this approach does not capture the continuous nature of joint interactions throughout the ski cycle. Therefore, the purpose of this study was to use a dynamical-systems approach to compare inter-joint coordination between junior (JN), national-caliber (NC), and world-class (WC) athletes during V2 skate skiing

Methods

Nine JN (18 ± 1.06 years; 4M/4F), seven NC (26 ± 3.95 years; 4M/3F), and eight WC biathletes (27.63 ± 4.50 years; 5M/3F) roller skied on a treadmill at race intensity while whole-body kinematics were recorded using markerless motion capture. A modified vector-coding approach quantified three sagittal-plane joint couplings relevant to skiing performance: torso–pole, shoulder–elbow, and hip–knee. Kinematics were time-normalized to 100% of the ski cycle, and bin counts were used in a 3x4 mixed ANOVA to determine the proportion of in-phase, anti-phase, distal-phase, and proximal-phase coordination. Statistical parametric mapping (SPM) was applied to compare differences in coordination variability (CAV) across groups.

Results

Torso-pole coordination showed a significant phase x group interaction ($F_{6,63} = 3.12$, $p = .01$) with NC athletes having more antiphase motion than either JN or WC athletes, and JN athletes having less in-phase motion than NC or WC athletes (Figure 1). SPM showed that JN athletes has less coordination variability than NC or WC athletes during the pole recovery phase for shoulder-elbow coordination ($p < .05$)

Discussion

Skill level in biathlon appears to influence both coordination of movement as well as variability of movement during V2 skate skiing. The increased antiphase movement in NC and decreased in-phase movement of JN biathletes may be indicative of inefficiency in applying force to pole and skis compared to WC biathletes. Additionally, the reduced CAV in JN athletes might show limited movement strategies to achieve efficient body positions. Future research should target whether addressing coordination patterns is one potential method for improving performance as JN athletes progress to NC and WC ranks.

Images (Optional)

Ankle Strains During Ipsilateral and Contralateral Change of Direction

MSc Chi-Hsien Chen[1], PhD Timothy Derrick[1], MSc Yan-Jer Tseng[2], MSc Sung-Ting Lu[3,4], PhD Chiang Liu[2]

[1]Department of Kinesiology, Iowa State University, Ames, Iowa, United States. [2]Graduate Institute of Sports Equip-ment Technology, University of Taipei, Taipei, Taipei, Taiwan. [3]Taiwan Institute of Sports Science, Kaohsiung City, Kaohsiung City, Taiwan. [4]Graduate Institute of Athletics and Coaching Science, National Taiwan Sport University, Taoyuan, Taoyuan, Taiwan

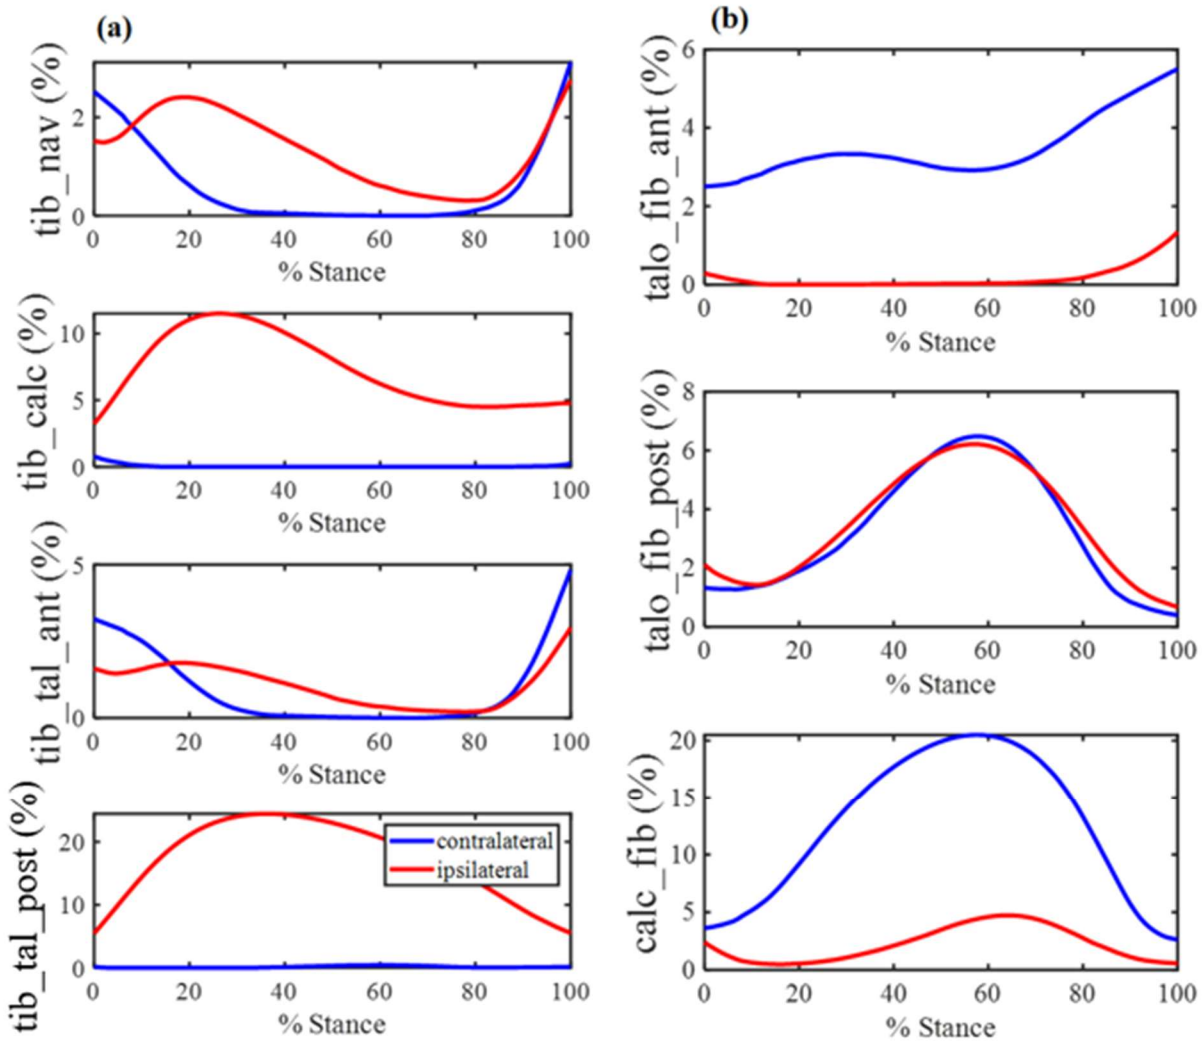
MSc Chi-Hsien Chen

Introduction

The rapid change of direction (COD) can lead to an increase in ankle ligament strain during the ground contact phase, which may predispose an athlete to a sprained ankle. Our previous work (1) found that COD of ipsilateral direction (ipsi-COD) and contralateral direction (contra-COD) showed asymmetrical mechanisms. However, the previous study only reported the ankle joint loading in contra-COD (2). Therefore, it is necessary to confirm the differences in ankle joint ligament strain between ipsi-COD and contra-COD for understanding the risk of injuries.

Methods

Thirty-four recreational athletes (height: 176.0 ± 7.0 cm, weight: 74.8 ± 11.2 kg, age: 23.5 ± 2.7 years) performed ipsi-COD and contra-COD tasks in 60° with their non-dominant leg. A 3-D motion capture system and photocells were used to collect kinematic data. A low-pass filter with a cut-off of 6 Hz was applied to the coordinate data. Helical tibiotalar, subtalar and midfoot angles were calculated. A 3-segment musculoskeletal foot model (3) was used to estimate strain in four medial and three lateral ankle ligaments. It was assumed that there was zero strain in the ligaments while standing in the T-pose position.



Results

The approaching speed between ipsi-COD and contra-COD showed non-significant difference. The ipsi-COD showed a significantly higher tibiocalcaneal strain (ips: 16.6 ± 6.4, contra: 1.1 ± 2.3) and higher posterior tibiotalar strain (ips: 34.4 ± 6.2, contra: 1.2 ± 3.0) compared to contra-COD. The contra-COD led to a significantly higher anterior talofibular strain (ips: 2.0 ± 1.8, contra: 7.8 ± 3.1) and higher calcaneofibular strain (ips: 8.9 ± 9.2, contra: 27.3 ± 4.9) than ipsi-COD.

Discussion

The contra-COD caused inversion at the tibiotalar and subtalar joints, while the ipsi-COD caused eversion. Inversion increased strain in the lateral ligaments, while eversion caused strain in the medial ligaments. Strains were modulated by the sagittal plane motion during midstance of the cutting motion. Dorsiflexion increased strain in the posterior ligaments while reducing strain in the anterior ligaments. Overall, the posterior tibiotalar and the calcaneofibular ligaments showed the greatest amount of stress.

An Evaluation of the Functional Movement Screen and a Golf-Specific Movement Screen in Identifying Physical Limitations Related to Golf Performance

Mr. Christopher Wendt, Dr. Emma White, Dr. Courtney Crews, Dr. Brittany Gallagher, Dr. Jonathan Lind, Dr. Ellsworth Parham, Dr. William Holland, Dr. Elizabeth Nail, Dr. Mona Sajjad, Dr. Timothy Wooton, Dr. Brianna O'Connor, Dr. Sidney Rhodes, Dr. Angie Rodriguez, Dr. Landon Ward

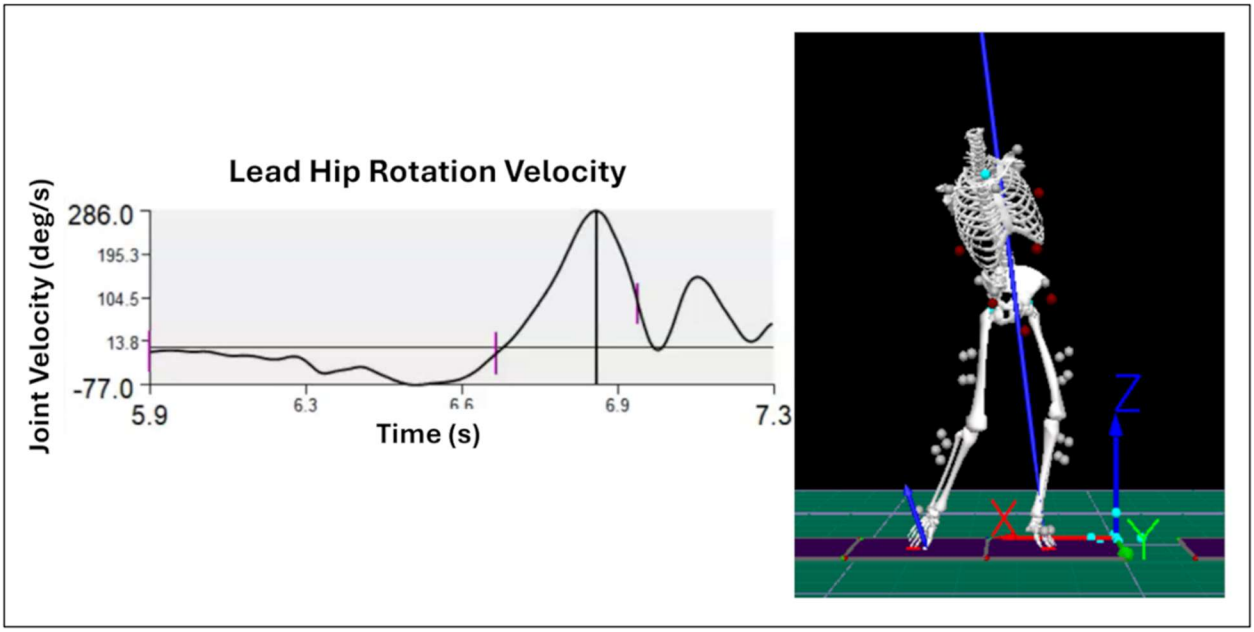
Winston-Salem State University, Winston-Salem, NC, United States

Introduction

Over 56% of amateur golfers are at risk of sustaining a musculoskeletal injury during their lifetime, commonly due to poor swing mechanics. An effective and quick way to identify the cause of such deficits is by performing a movement screen. The Functional Movement Screen (FMS) and the golf-specific Titleist Performance Institute (TPI) Movement Screen have differing levels of evidence in the assessment of amateur golfers. The purpose of this study was to evaluate the relationship between golf swing biomechanical movement characteristics and test scores from both the TPI Movement Screen and the Functional Movement Screen, respectively.

Methods

Twenty-four amateur golfers (between ages 18-65) completed two separate sessions consisting of golf swing biomechanical analysis on one day, with FMS and TPI movement screenings on another day. Motion capture and force platform measurements provided golf swing kinematic/kinetic outcomes, such as hip rotation velocity (as shown in Figure 1), trunk/pelvis range of motion, and ground reaction force. Statistical analysis was performed to determine if there were statistically significant correlations ($p \leq .05$) between subject demographics and screening/golf swing outcomes, as well as associations between each of the TPI and FMS screening tests vs. golf swing biomechanical characteristics.



Results

Eight different TPI movement tests (50%) demonstrated a total of 11 moderate, statistically significant correlations with golf swing movement outcomes. A total of 4 significant correlations were found between 3 individual FMS movement tests (43%) and golf swing characteristics. TPI and FMS total screening scores were moderately associated ($r=.531$, $p=.008$).

Discussion

The golf-specific Titleist Performance Institute Movement Screen was positively associated with the Functional Movement Screen, suggesting agreement between the two movement screening methods. However, more statistically significant relationships were discovered between golf swing biomechanical variables and physical limitations identified using the golf-specific movement screen (TPI) vs. the Functional Movement Screen (FMS). Therefore, the golf-specific movement screen may be more useful for clinicians to assess a golfer's physical limitations, which could impact golf swing mechanics and/or risk of injury.

Whole Body Assessment of Exercise Proficiency Using a Single Camera: Application to a Sub-Academy Rugby Cohort and an Academy Gaelic Football Team

Ms Clara Mercadal MAI[1,2], Mr Robert McCarthy MAI[1], Mr Jorge Gonzalez MSc[2], Mr Leo Peyton Acct[1,2], Prof Aljosa Smolic PhD[1,3], Mr Garreth Farrell Physio[4], Mr Mark Kenneally Physio[4], Mr Des Ryan Sports Sci[5], Ms Lara Coyne PhD physio[6], Ms Giang Lam Nguyen BAI[2], Prof Ciaran Simms BA BAI PhD[1,2]

[1]Trinity College Dublin, Dublin, Leinster, Ireland. [2]KineMo, Dublin, Leinster, Ireland. [3]HLSU, Lucerne, Lucerne, Switzerland. [4]Leinster Rugby, Dublin, Leinster, Ireland. [5]Uni Galway, Galway, Connaught, Ireland. [6]Unafiliated, Galway, Connaught, Ireland

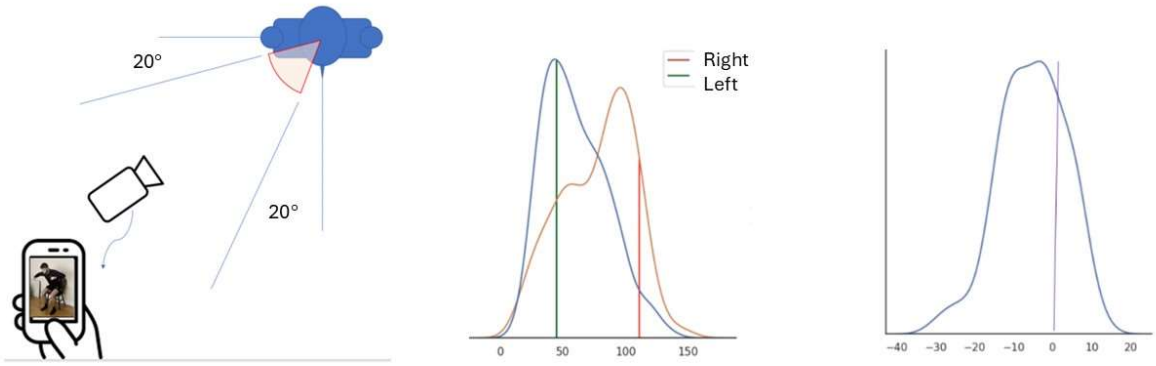
Introduction

Assessment of exercise form in large cohorts is complex and difficult. Calibrated cameras and sensors are challenging, and by-eye observation is low accuracy [1]. The single camera recording platform KineMo addresses this challenge. However, although the accuracy has been assessed [2] and the tool is available (app stores), its practical application in a large cohort has not been studied. Accordingly, we aimed to assess the practical utility of using KineMo to assess movement screening of youth athletes.

Methods

Following ethical approval, cohorts of male sub-academy male rugby and academy Gaelic football players (both mostly under 18 years old) were recorded. Rugby players performed single leg squats, overhead squats and drop jumps in two sessions. There were 109 participants in session 1 and 59 in session 2 (8 weeks later), due to logistics associated with participation. Separately, a cohort of 80 GAA football players performed single leg Romanian deadlifts and overhead squats in one session. Recording was done using mobile devices on tripods in regular gym lighting conditions, and athletes wore standard sports clothing, Figure 1a.

Results



Data capture required about one minute for five repetitions of an exercise per athlete/recording station, such that whole cohorts (>30 athletes) can be readily recorded in a one-hour session in a regular gym environment. A practical requirement is that only a single athlete is visible in the camera view. Whole-body metrics such as sagittal plane ankle, knee and hip joint angles, pelvic tilt, spine flexion and shoulder flexion were

available, as well as frontal plane knee angle. These metrics were used to assess overall movement form at baseline (Figure 1b) and changes over time, for example Figure 1c.

Discussion

The results of these user trials demonstrate high throughput capabilities due to the simple nature of video data capture, and significant actionable data can be extracted. For example, the distribution across a cohort of individual metrics associated with different exercises (such as knee flexion in a squat), or the changes for large groups of individuals performing the same exercise at different time points.

Influence of Stroke Rate and Static vs. Dynamic Rowing on Joint Kinematics Among Female Collegiate Sweep Rowers

Ms. Claudia Poehlmann, Ms. Julia Tamai, Dr. Stephanie Jones

Smith College, Northampton, Massachusetts, United States

Introduction

Training among competitive rowers includes on-land rowing using ergometers. High ergometer training loads are associated with a greater incidence of low back pain but dynamic ergometers are associated with reduced injury risk that could result from altered kinematic patterns. Understanding how stroke rate and ergometer dynamics interact to shape joint motions, could explain this discrepancy. The purpose of this study was to investigate joint kinematics in collegiate sweep rowers to determine how ergometer dynamics and pacing interact to shape rowing technique.

Methods

Ten female collegiate rowers rowed on an ergometer for 30 minutes, performing two randomized blocks of trials: Static vs. ergometer placed on slides (Dynamic). Within each block participants rowed three minutes at self-selected pace, followed by two 5 minute bouts at Low (20 strokes per minute [SPM]) and High (30 SPM) stroke rates. Ten high speed digital video cameras tracked 13 body segments to quantify 3D joint kinematics. Cycle parameters, sagittal joint ranges of motion (ROM) and peak angular velocities of lower limbs and trunk were assessed using two-way repeated measures ANOVAs (ergometer, stroke rate); significance set at $P<0.05$.

Results

Dynamic ergometry was associated with shorter cycles and drive phases, with longer recovery phases compared to static. Ankle and Knee ROM were greater in dynamic than static, while hip and trunk ROMs were unchanged across conditions. Angular motions were more invariant in dynamic, with little effect of stroke rate on ankle and knee ROM; in static, ankle and knee ROMs decreased at High stroke rate relative to Low. Knee and hip extension velocities increased at High, with similar ankle velocity across conditions. Knee and trunk flexion velocities increased during the recovery phase of dynamic rowing.

Discussion

These findings indicate that dynamic rowing consists of constant ROMs across stroke rates with reduced cycle time and drive phases. These alterations suggest rowers are leveraging

the inertia of the ergometer to assist in their transition between phases. Elevated knee and trunk velocities at higher stroke rates highlight increased mechanical demands that may affect technique and loading. Ongoing analyses will assess lower limb joint asymmetries, trunk frontal/transverse rotations and joint coordination.

Coordinated Hip, Pelvis, and Trunk Biomechanics Associated With Stride Length In Baseball Pitching

Professor Daniel Ramsey PhD[1], Dr Ryan CBaseball Consulting Services Ryan Crotin PhD[2]

[1]D'Youville University, Buffalo, New York, United States. [2]ArmCare.com, RC13 Baseball Consulting Services, LLC, Farm System Network, LLC, USA, Indialantic, Florida, United States

Professor Daniel Ramsey

Introduction

Hip and lumbopelvic coordination in pitching delivery are essential, yet frontal plane hip, pelvis and trunk biomechanics during baseball pitching in relation to stride length remans under explored.

Methods

- Nineteen collegiate baseball pitchers threw 2 randomized 80-pitch games at ±25% from desired stride length, (over-stride (OS) and under-stride (US)) then crossed over to the alternate condition after a 72-hour washout period. Conventional motion capture recorded the pitching sequence [1-3].
- Pitching cycle time normalized to 100%, from peak knee height (PKH) to ball release (BR). Hallmark events included stride foot contact (SFC) and maximal external rotation (MER) and phases were linked between hallmark events; Generation (GEN) from PKH to SFC; Brace-Transfer (BT) from SFC to MER; and Acceleration (ACC) from MER to BR.
- Paired t-tests were used for comparative analysis of joint kinematics, moments, and powers between the two stride conditions at hallmark events and phases. Statistical significance was set at $p \leq 0.05$.

Results

Figure 1: frontal plane hip and lumbopelvic dynamics.

1. OS saw drive-hip more abducted during GEN ($p < .001$) with higher adductor power generation during ACC ($p < .001$). US yielded greater negative drive-hip abductor

moments during GEN ($p < 0.001$) through eccentric work that absorbed energy and the hip more adducted during ACC ($p < .001$) that absorbed power.

2. With OS, significantly higher stride-hip adductor angular velocities concomitant with greater abductor joint power absorption during ACC ($p < .001$).
3. OS saw significantly greater upward pelvic rotation (leading hip) during GEN ($p < 0.001$), greater upward rotational velocities during BT ($p < 0.05$), but lower pelvic angle during ACC ($p < 0.001$). With US, upward (counterclockwise) pelvic rotation was higher during ACC ($p < 0.001$). Lateral trunk bending trunk displacement profiles were similar between stride conditions except at SFC ($p < 0.001$), where contralateral (non-dominant) trunk flexion was observed with OS as opposed to ipsilateral trunk flexion with US.

Discussion

Further research on optimal sequencing in response to changes in stride length for throwing arm health is warranted.

The Effect of Sport and Sex on Quadratus Lumborum Musculature in Varsity Athletes

Mr Daniel Sheffield MSc, Mr Sam Vasilounis MSc, Dr Dan Desroches PhD, Dr Janessa Drake PhD

York University, Toronto, Ontario, Canada

Introduction

Asymmetry in lumbopelvic musculature and reduced lumbopelvic control have been linked to altered trunk mechanics, performance deficits, and injury risk in athletes. The quadratus lumborum (QL), a key stabilizer of the lumbar spine and pelvis, may develop side-specific differences due to repeated unilateral sport demands. This study examined QL cross-sectional area (CSA) asymmetry in varsity athletes and explored whether sex or sport influenced asymmetry magnitude, as well as whether QL CSA relates to single-leg jump performance.

Methods

Ultrasound measures of QL were collected from 116 varsity athletes (58 males, 58 females) across five sports: basketball, track and field, hockey, volleyball, and wrestling. Images were processed to quantify bilateral CSA (mm^2), and an asymmetry index assessed dominant vs. non-dominant sides. Paired t-tests examined side-to-side differences across groups. Linear regression assessed relationships between QL CSA or asymmetry and single-leg jump height.

Results

Across all athletes, the dominant QL was significantly larger than the non-dominant QL ($p < 0.001$). Significant asymmetry was present in both females ($p < 0.001$) and males ($p < 0.001$). Overall, 79 athletes (68.1%) demonstrated >10% asymmetry. All five sports showed significant side-to-side differences ($p < 0.001$).

Asymmetry was not significantly associated with single-leg jump height. However, unilateral QL CSA showed a significant contralateral relationship, with larger left QL CSA predicting greater right-leg single-leg jump height ($R^2=0.104$, $F(1,114)=13.291$, $p=0.0004$; Figure 1). No relationship was observed between right QL CSA and left-leg jump height ($R^2=0.00178$, $F(1,114)=0.2034$, $p=0.6528$).

Discussion

Varsity athletes demonstrated prevalent QL asymmetry, with over two-thirds exceeding a 10%. The presence of significant asymmetry in both sexes, and across all sports tested, suggests that unilateral adaptations in trunk musculature are a common characteristic of competitive athletic participation rather than being sport or sex-specific. This universal pattern may reflect common sport-specific unilateral loading patterns, such as repeated cutting, shooting, or skating mechanics.

Establishing normative patterns of lumbopelvic muscular asymmetry in varsity athletes provides a valuable reference for clinicians and coaches. Such benchmarks may help identify atypical asymmetry that may contribute to lumbopelvic dysfunction, performance limitations, or elevated injury risk.

How Do Head Impacts in Youth Ice Hockey Vary Based on Player Position, On-Ice Location, Score Differential, and Penalty Kills?

Mr Marco Sladoje, Mr Andrew Kotevski, Dr David Andrews

University of Windsor, Windsor, Ontario, Canada

Introduction

Concussion rates in ice hockey are nearly double those experienced in other contact sports [1], and concussions in youth athletes tend to be more severe than in adults. The frequency, mechanism of head impact, and head impact location during youth hockey games has been quantified [2], however, the effect that player position, on-ice location, score differential, and penalty kill status has on these variables has not been analyzed to date.

Methods

Seven GoPro Hero9 cameras (47° fixed lenses) captured play of U15 and U16 (13-16 years of age) boys ice hockey teams over 21 games (one season). The cameras were powered by rechargeable portable power packs. The occurrence and mechanism of 674 head impacts identified in the videos [2] were analyzed by trained observers based on player position, on-ice location, and the score differential and penalty kill (PK) status at the time of impact.

Results

61% (n=414) of head impacts were experienced by forwards and 39% (n=260) by defensemen. In terms of ice location, 62% (n=418) of impacts were board contacts and 38% (n=256) were open-ice. Nearly half the impacts occurred in the offensive zone (46%; n=308), followed by the defensive zone (36%; n=241), and then neutral zone (19%; n=125). More than 77% and 87% of the impacts occurred when the score differential was ≤ 2 points, and during even strength play, respectively. 70% (n=471) of the impacts occurred between the head and body (n=260) and head and boards (n=211).

Discussion

This analysis confirmed that the number and mechanism of head impacts varied based on player position, ice location, score differential, and PK status. More head impacts to forwards is consistent with more impacts occurring in the offensive zones. Closer scoring games resulted in more head impacts, reflecting more aggressive player interactions when the chance of winning is greater. Fewer head impacts during PK reflects more conservative

play by the PK team. Analysis of hockey games for girls and across a wider range of ages would inform age- and gender-specific interventions.

A Descriptive Analysis of Tackling Techniques in Youth Football

Ms Vanessa Bechard[1], Ms Claudia Graham[2], Dr Danielle Gyemi[1], Dr David Andrews[1]

[1]University of Windsor, Windsor, ON, Canada. [2]University of Waterloo, Waterloo, ON, Canada

Introduction

There is limited understanding of how youth football players respond to head impacts. Improper tackling techniques, such as leading with the head or using poor body alignment, are major contributors to the high rates of head injuries, including concussions [3]. This study aims to describe the tackling techniques used by youth football players across three age groups (9-12, 13-14 and 15-16 years).

Methods

Tackling events from video records of football games of players from three age groups [9-12 years: ATOM (A), 13-14 years: Bantam (B), and 15-16 years: Junior Varsity (JV)] were evaluated [2] based on categories including contact method, head position, balance, rib protection and anticipation. Comprehensive multi-angle views of tackling events were captured using an 11-camera GoPro system [2]. Tackling techniques were evaluated by two raters using validated frameworks [1,4].

Results

Forty-nine tackles were analyzed across the age groups [A(5), B(33), JV(11)]. Over 80% of tackles across the three age groups were in a head-up position. A head-across-the-bow technique was observed in 20.0%, 15.2%, and 45.5% of A, B, and JV tackles, respectively. There were no significant differences for any of the tackle grading categories between age groups ($p>0.05$). Interrater reliability for tackle categories ranged from fair [Cohens Kappa (k) = 0.275] for Posture Striker, to very good (k = 1.000) for Player Motion Struck [mean k = 0.668 (good)].

Discussion

Positive tackling technique execution was present across all three age levels. However, the use of the head-across-the-bow technique by all age groups is a concern, as it is associated with more frequent and severe head impacts [3]. Despite the lack of significant differences between age groups for all tackling categories, the results provide useful descriptive insights into youth tackling technique. Investigations of additional tackling

events across different ages of youth players are needed to advance this important area of inquiry.

Biomechanical Comparison of Deep and Shallow Squatters

Dr David Hudson PT, PhD

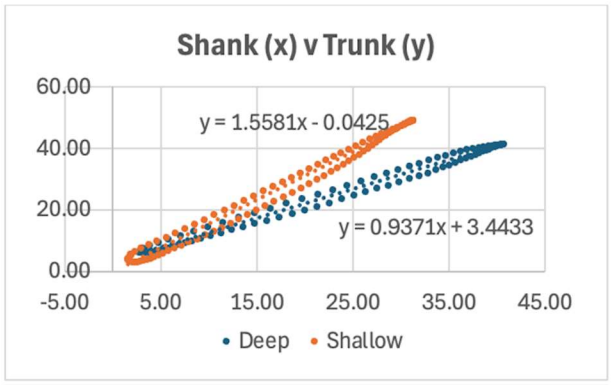
Western Carolina University, Cullowhee, NC, United States

Introduction

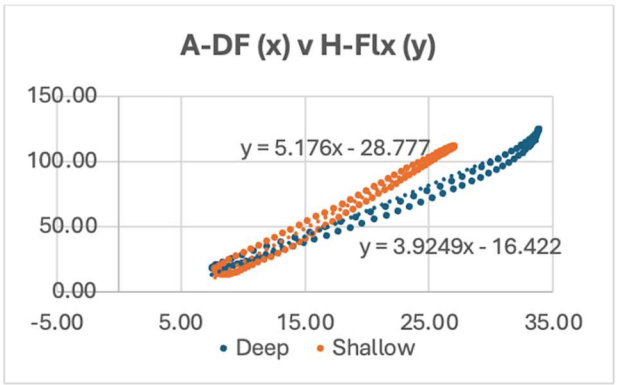
Squatting is a compound movement commonly used as a screening tool to identify deficits in mobility, force production, and motor coordination. This study seeks to improve the utility of the squat as a screening tool by understanding differences in joint coupling, kinematics and lower extremity joint mobility.

Methods

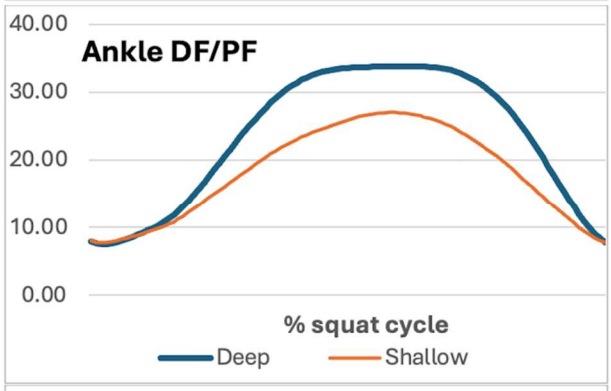
Twenty-six healthy adult subjects (12 males) were measured for maximal hip and knee flexion, and ankle dorsiflexion (weight bearing / knee flexed) using a goniometer. Squat depth and sagittal plane motions of the trunk and (right) hip, knee, ankle joints were then recorded while double limb squatting using a 14-camera motion analysis system where 6 successive squats were performed as deeply as able in preferred stance. Subjects were ranked according to normalized squat depth to form deep and shallow groups. The accompanying image shows cyclograms and their slopes of averaged group data showing movement coordination across joints and segments (trunk-shank and hip-ankle). Independent t-tests were performed to determine the presence of group differences in maximal hip, knee, ankle joint mobility (goniometer), maximal flexion angles of the trunk, hip, knee, and ankle (kinematic data), and slopes of the (individual subjects) cyclograms. Bonferoni correction was used to account for multiple comparisons and a was adjusted to 0.0056.



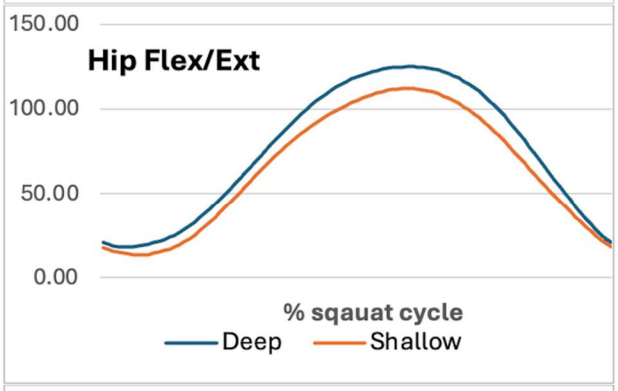
Results



There was no significant difference in mobility of the hip, knee, and ankle measured with the goniometer. Maximal flexion angles (kinematics) were significantly different between deep v. shallow squatters; respectively: Trunk (41.5°±13.3° v. 49.3°±6.9°; $p < .004$) and Ankle (33.9°±5.2° v. 27.0°±2.3°; $p < .003$). Slopes of the shallow squatters cyclograms were significantly higher (see image for equation); Trunk-Shank ($p < .001$) and Hip-Ankle ($p < .001$).



Discussion



The cyclograms show shallow squatters are dominant in hip and trunk movements where deep squatters utilize greater knee and ankle movement. Despite no significant difference in goniometric mobility of the hip, knee, and ankle, there were differences in maximal kinematic angles and movement coordination between segments. This study is ongoing, the differences seen in these and additional kinematic waveforms and cyclograms will be further explored and reported on using a Statistical Parametric Mapping (SPM) approach.

P1-288

Reliability, Agreement and Waveform Differences Regarding Separate Mathematical Calculations of Knee Valgus Angles During a Land-Cut Task

Dr. Derek Dewig PhD, ATC[1], Ms. Tricia Lemasters[1], Ms. Lindsey Ulring[1], Dr. Taylor Oldfather PhD[2]

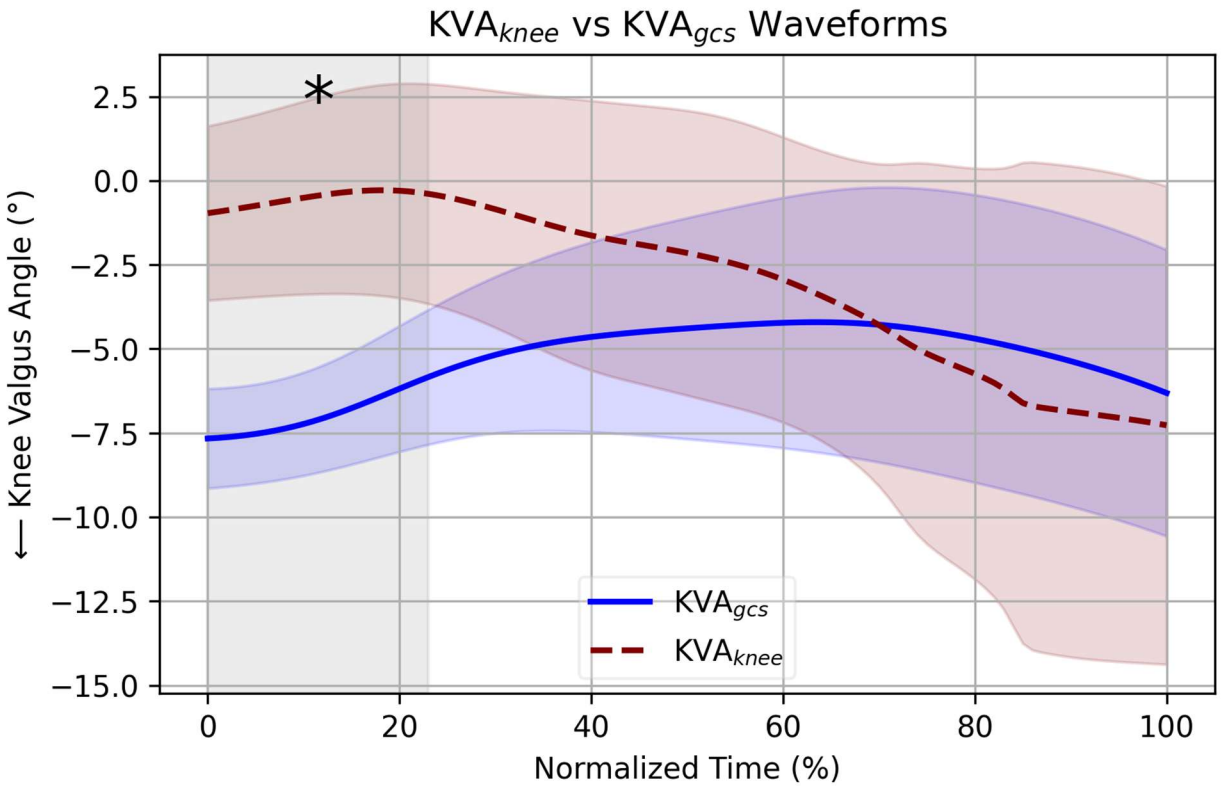
[1]Fairmont State University, Fairmont, WV, United States. [2]Auburn University, Auburn, AL, United States

Introduction

Knee valgus angles (KVAs) are frequently assessed in biomechanics research as they are associated with lower-extremity injury occurrence.[1] However, ambiguity in reported KVA calculations and definition inconsistency renders direct comparison of kinematic outcomes between studies difficult or obfuscate.[2] This ongoing study aims to evaluate the reliability, agreement and waveform differences between two mathematical methods of calculating KVAs during a single-leg, land-cut task.

Methods

Kinematics and kinetics (8-camera motion capture and forceplates sampling at 200 and 2000Hz, respectively) of 6 participants were assessed as they dropped off a 30-cm box, landed on a force-plate with their dominant leg, and cut 45-degrees towards the non-dominant leg. Two KVAs were calculated: 1) the orientation of the shank relative to thigh in the frontal plane defined by the thigh coordinate system (KVA_{knee}) and 2) the orientation of the shank relative to the vertical global axis in the frontal plane of the global coordinate system (KVA_{gcs}). Angles were evaluated from initial contact (vGRF >20N) to peak knee flexion angle. Intrasession reliability for both peak KVA measures was evaluated via Intraclass Correlation Coefficients (ICC(3,k)), and agreement between peak measurements was assessed via a repeated measures correlation and Bland-Altman Limits of Agreement (LOA)/bias. Statistical Parameter Mapping paired t-test was conducted on both ensemble waveforms to identify temporal differences in measurements.



Results

Both peak KVA_{knee} (ICC=0.993) and KVA_{gcs} (ICC=0.934) had excellent intrasession reliability. The bias of difference (KVA_{knee}-KVA_{gcs}) was 1.1°, LOA were between -13.0° and 15.2° and there was no significant correlation between measures ($r = 0.218$, $P = 0.47$). KVA_{gcs} was significantly greater than KVA_{knee} during the first 23% stance (t_{max}= -6.3, t*= ±4.1).

Discussion

KVA_{knee} and KVA_{gcs} are not correlated with each other and have large LOA despite within session reliability, indicating problematic comparisons between differently calculated definitions of KVAs. Additionally, early stance rends the largest difference between measurements, which could have implications for injury risk evaluation as most non-contact injuries occur within 50ms of landing.[3]

P1-289

The Role of Minimum Pelvis Velocity in Kinematic Sequencing and Performance in Baseball Pitchers

Mr. Dimitri Haan MS

University of Nebraska at Omaha, Omaha, NE, United States

Introduction

The kinematic sequence suggests that pitchers reach peak rotational velocity of their segments in a proximal-to-distal fashion, with each subsequent segment achieving a higher velocity.[1–3] Research shows the strongest predictor of pitch velocity is trunk maximum velocity, and a strong predictor of trunk velocity is pelvis velocity.[4] Little research has investigated the effect of minimum pelvis velocity (MinPV) on trunk velocity (MTV) and pitch velocity. The segmental interaction principle states that distal segment acceleration increases when the proximal segment decelerates, resulting in a faster, whip-like motion due to the transfer of momentum.[5] For a baseball pitch, this may present as the trunk reaching a higher rotational velocity due to the pelvis reaching a lower minimum velocity. Therefore, the purpose of this study was to investigate the effect of MinPV on MTV and pitch velocity. We hypothesized that MinPV would have an inverse relationship with trunk and pitch velocity.

Methods

100 pitchers were included in this study (Age: 18.5±2.83 years, Height: 1.82±0.099 m, Mass: 82.67±14.12, Right-Handed: 74, Left-Handed: 26). Pitchers were excluded if they missed competition due to injury within the last 6 months. Pitchers threw fastballs, and motion capture data were collected (240 Hz-333 Hz). The fastest three fastballs were exported to Visual3D for analysis. Maximum and minimum pelvis velocity, maximum trunk velocity, and associated timing were exported to RStudio for analysis. Pitch velocity was collected using a Stalker Radar Gun.

A linear mixed-effects model was used to measure the effect of MinPV and time of MinPV on MTV. A second model measured the effect of MinPV and time of MinPV on pitch velocity. Significance (†) was set at t=2.00.

Results

Results of the model show that MinPV has a moderate significant effect on MTV and small, significant effect on pitch velocity. The results suggest that for every 100°/s slower a pitcher's MinPV is, MTV increases by 15.2°/s, and pitch velocity increases by 0.6mph.

Discussion

These results expand the scope of the kinematic sequence, offering more information to coaches and players on how to move in a way that optimizes segmental interaction and performance.

Images (Optional)

Table 1.

Model Design	β_{MinPV}	t_{MinPV}	β_{Time_MinPV}	t_{Time_MinPV}
MTV ~ MinPV + Time_MinPV + (1 | Subjects)	-0.152	-3.99 †	-2.33	-1.34
Pitch Velocity ~ MinPV + Time_MinPV + (1 | Subjects)	-0.0063	-3.21 †	-0.118	-1.38

The Relationship Between Energy Flow, Ball Velocity, and Upper Extremity Joint Loading in High School Baseball Pitchers

Mr. Brandon Muczynski BS, Dr. Adam B. Rosen Ph.D, Dr. Samuel J. Wilkins Ph.D, Dr. Brian A. Knarr Ph.D, Mr. Dimitri Haan M.S

University of Nebraska Omaha, Omaha, NE, United States

Introduction

In 2024/2025, over 8.2 million U.S. high school athletes participated in sports, with baseball ranked third in popularity at 472,598 participants. Among male pitchers, 46–57% experience shoulder or elbow injuries, accounting for 39.6% of shoulder and 56.9% of elbow injuries. A comprehensive energy flow analysis will be performed across multiple pitch types, measuring joint forces, torques, power, and work in the lower extremities (LE) , trunk, and upper extremities (UE). We hypothesize that different pitch types will show distinct patterns of segmental energy flow, with inefficient transfer linked to increased joint stress and decreased velocity.

Methods

Six male high-school baseball pitchers (16.6 ± 1.47 yrs, 186.94 ± 4.59 cm., 84.38± 8.02 kg) were extracted from the UNO Pitching Lab database. Kinetics and kinematics were collected using three in-mound force plates (AMTI, 320 Hz) and a 16-camera motion capture system (Qualisys, 320 Hz) using a 41-marker full-body model. Joint forces, torques and velocities were computed using inverse dynamics in Visual 3D software v2024.10.4 (Germantown, MD). Custom MATLAB code calculated torque power, work and Energy-Transfer Efficiency (ETE). ETE is defined as the ratio of distal (UE) to proximal (LE+ trunk) positive work. Data were normalized to the pitch cycle (Setup→Ball Release). Spearman/Pearson correlation ($p<0.05$) was used to evaluate relationships between ETE, work, and joint kinetics.

Results

Clear proximal-to-distal sequencing of joint kinetics was observed. The LE accounted for 75%–85% of all positive work, with sliders producing the most. The UE exhibited greater positive work than negative work, with curveballs generating the highest. Elbow varus torque was greatest in fastballs and curveballs, change-ups and sliders producing the lowest. A moderate positive correlation was found between UE positive work and shoulder torque ($r_s = 0.42$, $p = 0.05$), and a weak trend for elbow varus torque ($r_s = 0.39$, $p = 0.076$).

Discussion

High school and youth pitchers are especially vulnerable due to inadequate training and instruction as well as underdeveloped pitching mechanics. Different pitch types place varying demands on the body, emphasizing the need for efficient energy transfer to reduce arm stress and injury risk.

Images (Optional)

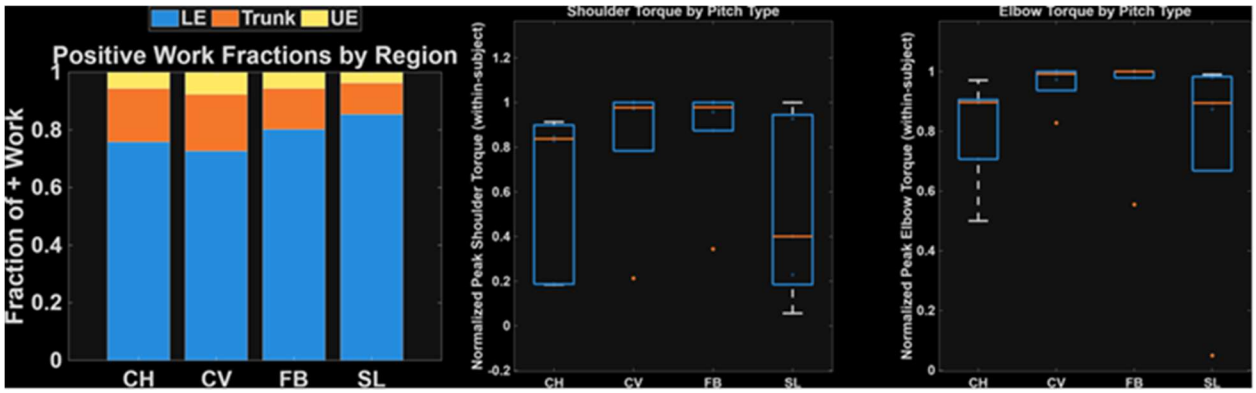

Figure 1. Positive joint work fractions for the lower extremity (LE), trunk, and upper extremity (UE) across pitch types (left). Normalized peak shoulder and elbow torques by pitch type (right).

P1-291

Maximal Sprint Acceleration: Is it Better to be More Grounded?

Mr. Dominic Crisostomo, Mr. Gouresh Powar, Dr. Peter Weyand

Texas Christian University, Fort Worth, Texas, United States

Introduction

The maximal accelerations of the fastest sprinters on earth are typically substantially less than the earth's rate of gravitational acceleration of 9.81m/s^2. What factors might set this relatively modest limit? Unlike automobiles and other forms of wheeled transportation, human sprinters accelerate in a pulsatile fashion, where the body's velocity is increased during each push of the foot on the ground but remains unchanged during the aerial periods between steps. Between-step aerial periods are obviously necessary for limb repositioning, but they also introduce periods of zero force application that limit maximal rates of acceleration. Here, we hypothesized that humans minimize aerial times between steps to maximize sprint running acceleration. We tested this idea using torso weighting as an experimental tool, predicting that aerial times during maximal sprint accelerations would be unchanged in the weighted condition.

Methods

Two sprint-trained males ran five maximal sprint acceleration trials each from starting blocks under unweighted and torso-weighted conditions (+15% of bodyweight). The participants accelerated across a 5.3-meter force platform-runway system (Bertec, 1000Hz). Contact and aerial times were determined by analyzing the periods above and below a vertical force of 30N, respectively. Means were determined across the first five contact and four aerial periods. Step-by-step means were also determined for each participant

Results

Mean contact times across the first five steps were longer (1.17 vs. 1.05s) and aerial times were shorter (0.16 vs. 0.25s) in the weighted vs. unweighted condition, respectively. Corresponding percent differences were: T_c: +11.4%; T_{air}: -36%. Mean velocities were 4.0% slower in the weighted vs. unweighted condition (3.60 vs. 3.75 m/s).

Discussion

Contrary to expectation, runners decreased aerial times by more than a third in the weighted vs. unweighted condition. This occurred, at least in part, due to an elongation of the contact length (=tc•velocity) and contact times utilized to meet the additional vertical

force requirement in the torso-loaded condition. These data do not discount the possibility that the runners utilize limb repositioning strategies that maximize the time of propulsive force application when accelerating maximally.

A Biomechanical Investigation of Strike Kinematics in the Filipino Martial Art of Arnis: Use of Segmental Timing and Proximal-to-Distal Energy and Momentum Transfer to Generate Powerful Stick Strikes

Dr. Elaine Serina PhD[1,2], Dr. Eric Mockensturm PhD[1], Mr. Noah Schneider BS[1], Mr. Ellis Chiang[1,2]

[1]Talas Engineering, Hayward, CA, United States. [2]Legacy Filipino Martial Arts, Daly City, CA, United States

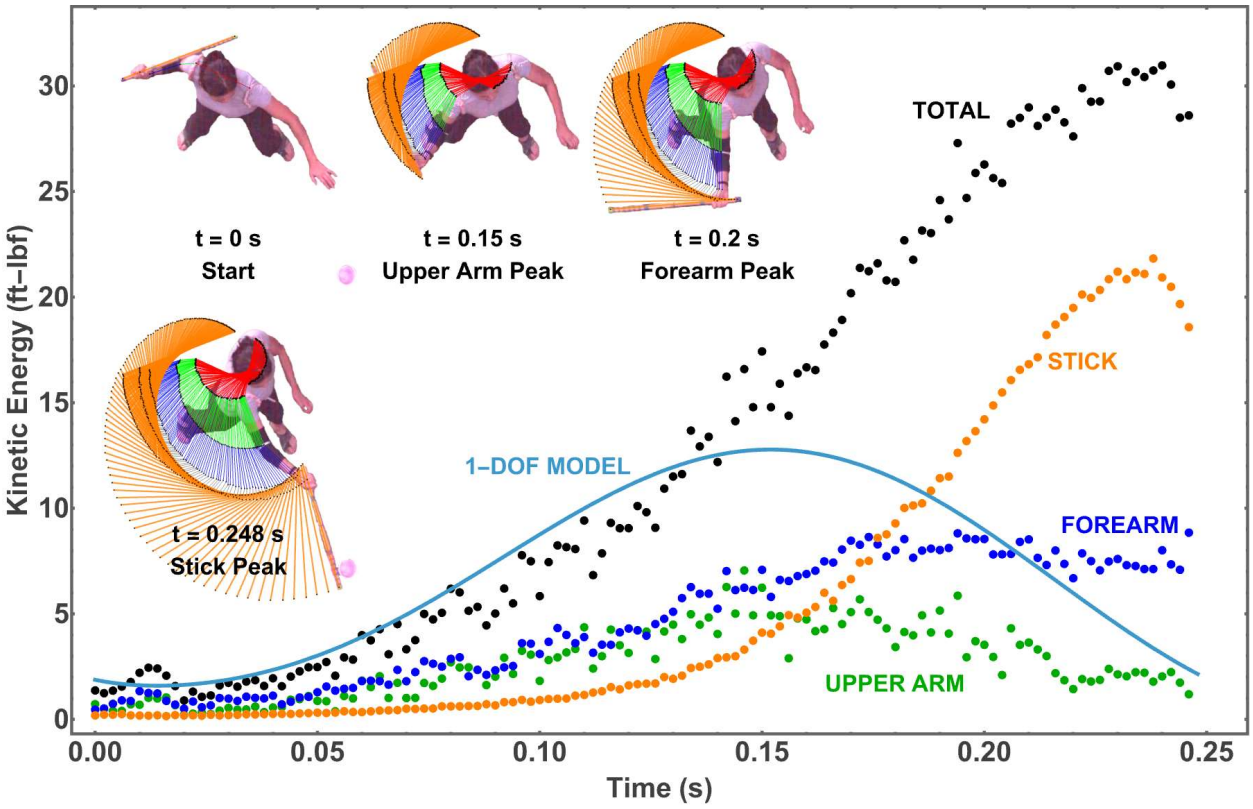
Introduction

The Filipino martial art of Arnis is a weapons-based defensive system where powerful, injury-producing strikes are executed using a long, lightweight rattan stick. Arnis techniques optimize stick dynamics so that even small-sized individuals can generate excessive force; however, the mechanism has not been scientifically studied. Research on limb dynamics in badminton forehand shots and baseball throws identified a proximal-to-distal sequencing that optimized energy transfer down the linkage system, enhancing distal speed. Effective execution depended on multi-joint coordination rather than isolated strength. This study investigated the applicability of this movement pattern to Arnis strikes.

Methods

Strikes by two elite Arnis practitioners were conducted in the horizontal plane using a standard 26-inch Arnis stick (1-inch diameter, ½ lbf). Overhead high-speed video (500Hz) was captured, and anatomical joint markers on the upper extremities were digitized to determine torso, upper arm, forearm, hand, and stick trajectories. Using subject anthropometric data, mass moments of inertia were calculated, adjusted to account for out-of-plane segment orientation over time. Kinematic parameters—limb velocities, angular momentum about a central-body axis, and energy—of each segment were calculated. Total momentum and energy data were compared to a simple 1-DOF model that assumes a fully extended arm/stick system with fixed joints.

Results



Overall, joint movements between subjects were generally consistent. Stick velocities reached 80mph over a 180-250ms duration. Kinematic parameters of the proximal body segments peaked sequentially earlier than distal segments. Torso rotation contributed

significantly to the momentum and energy due to its much greater mass moment, despite its lower speeds.

Discussion

Arnis striking techniques optimize the generation of peak momentum and kinetic energy at impact to maximize the impulse and energy transfer to the target. Coordinated sequencing within the linked-segment system was observed, where velocity, energy, and momentum are transferred from proximal to adjacent distal segments. For horizontal strikes, the elbow-joint orientation was out of plane; thus, the elbow joint primarily extends the arm, increasing the inertia of the system to impact. In comparison, kinematic values of the 1-DOF model peaked earlier in the swing at less than half the magnitude and were only a fraction of their values at impact.

The Interaction Effect of Sex and Cleat Design on the 180-Degree Cut

Mr. Garrett Hess[1], Dr. Brett Pexa[1], Dr. Jeffrey Taylor[1], Mr. Joseph Helseth[2], Dr. Kevin Ford[1]

[1]High Point University, High Point, NC, United States. [2]Nike Sport Research Lab, Beaverton, OR, United States

Introduction

Athletes' performance and injury risk are influenced by several factors. These factors include inherent biological differences and the modifiable tools used in sport, which may influence an athlete's movement both independently and collectively. Further research is still needed to understand how the interaction between biological sex and cleated footwear influences lower extremity biomechanics.

Methods

30 collegiate soccer players (15 male: age: 21.0 ± 1.2 yrs; mass: 78.5 ± 7.1 kg; height: 177.9 ± 5.5 cm; 15 female: age: 20.5 ± 1.2 yrs; mass: 64.5 ± 8.9 kg; height: 165.9 ± 5.4 cm), completed five maximal effort 180-degree cuts with a 6-meter approach in two different cleats (Nike Phantom GX II Elite Artificial Grass (AG) & Nike Phantom GX II Elite Firm Ground (FG)), in a randomized order on a slit film fiber turf, infilled with a mixture of crumb rubber and sand. A 14-camera motion capture system (200Hz, Qualisys AB, Göteborg, Sweden) synchronized with in-ground force platforms (1200Hz, Advanced Mechanical Technology Inc., Watertown, MA, USA) were used to assess the movement.

Results

There was a sex and cleat interaction effect for normalized peak knee internal rotation moment (p=.007) with both a main effect of sex (p<.001) and cleat (p=.023). Post-hoc analysis indicated that males had a greater normalized peak knee internal rotation moment in both cleat conditions (p<.01) than females. Additionally, males had a reduction in the knee internal rotation moment in FG (0.58 ± 0.16 Nm/kg) compared to AG (0.66 ± 0.16 Nm/kg; p=.008, d=0.8), while females did not differ between cleated conditions (p=.61). There was also a main effect of sex for peak knee abduction angle with females demonstrating greater peak knee abduction in both cleated conditions (p=.011).

Discussion

Both biological sex and footwear influence knee biomechanics during the 180-degree cut. The sex differences in knee moment and angle showed that individuals may perform the task differently. The firm ground cleat reduced internal knee moments in males but not females compared to the artificial grass cleat, which differed in stud configuration and shape. This is an important factor to acknowledge for both cleat design and selection.

High-Frequency Plantar TENS Enhances Jump Performance, Landing Biomechanics, and Dynamic Balance: Preliminary Evidence for Sensory-Driven Modulation of Athletic Movement

Ms. Gina Garcia MA[1,2], Dr. Jae Shim PhD[1]

[1]University of Maryland - College Park, College Park, Maryland, United States. [2]Exos Human Performance Lab, Phoenix, Arizona, United States

Introduction

Plantar sensory input directly influences motor output by modulating excitability within sensorimotor pathways. Mechanoreceptors in the foot sole provide afferent feedback to the central nervous system, shaping movement planning, force production, and joint-level loading through spinal and supraspinal integration. Transcutaneous electrical nerve stimulation (TENS) provides a practical method to augment sensory input by lowering mechanoreceptor firing thresholds and amplifying afferent signaling. Pacinian corpuscles are highly sensitive to electrical stimulation, especially >100 Hz, making them an ideal target for influencing motor output. This study examined whether high-frequency plantar TENS improves countermovement jump (CMJ) performance, jump-landing biomechanics, dynamic balance, and fatigue resistance compared with low-frequency stimulation and no-stimulation.

Methods

Five jump-trained adults (22.4 ± 3.3 y) completed three randomized conditions: no stimulation, 50 Hz TENS, and 150 Hz TENS applied bilaterally to the heel and lateral forefoot at 90% of sensory threshold (Figure 1). CMJ performance and landing biomechanics were assessed using 3D motion capture (200 Hz) and force plates (1000 Hz). Joint kinematics, kinetics, and concentric/eccentric work were calculated via inverse dynamics. Dynamic balance was assessed using the Y-Balance Test (YBT) before and immediately after a fatiguing continuous jumping protocol. Fatigue was quantified from 30 s repeated CMJs using fatigue index.

Results

Three participants achieved their greatest CMJ height in the 150 Hz condition (mean improvement: +0.65 cm vs no stimulation; +1.08 cm vs 50 Hz). High-frequency stimulation increased the proportion of ankle concentric work in four participants and reduced knee

concentric contribution in three. During landing, ankle eccentric work was greatest in the 150 Hz condition for three participants, while relative knee contribution was lowest in three. Dynamic balance favored 150 Hz for posteromedial, posterolateral, and composite YBT scores in most participants. Under fatigue, three participants demonstrated lower fatigue index values with 150 Hz stimulation.

Discussion

These preliminary findings suggest that enhancing plantar sensory input can positively influence motor output, movement strategy, and balance performance, and may help preserve performance under fatigue. Individual responses varied, indicating possible responder heterogeneity. Ongoing data collection ($n \leq 30$) will evaluate whether high-frequency TENS consistently modifies performance, landing biomechanics, and balance outcomes at the group level

The Influence of Sample and Filter Frequencies on Baseball Pitching Data

Dr. Glenn Fleisig[1], Ms. Brittany Dowling[2], Dr. Jonathan Slowik[1]

[1]American Sports Medicine Institute, Birmingham, AL, United States. [2]Midwest Orthopaedics at Rush, Chicago, IL, United States

Introduction

The throwing motion in baseball pitching is the fastest recorded human motion, demanding higher sample frequencies than most human movements. Previous studies have used sample frequencies from 240-500 Hz and a wide range of low-pass filter frequencies, although 13.4 and 18.0 Hz are the most common. This study examined the effects of two common sample frequencies (240 and 480 Hz) and three filter frequencies (13.4, 18.0, and 27.2 Hz) on pitching data.

Methods

Fastballs from 28 professional baseball pitchers were collected at 480 with marker motion capture, then down-sampled to 240 Hz; each data set was filtered at the three filter frequencies. Twenty-six common kinematic, temporal, and kinetic variables were computed for each pitcher across all sample-filter frequency combinations and compared using two-way repeated measures ANOVA. Differences were interpreted relative to minimal clinically important differences (MCID). Based upon recent studies,[1,2] MCID for stride length, joint angles, arm angular velocities, lower body angular velocities, torques and forces were set as 1% height, 2°, 100°/s, 20°/s, 3 Nm and 30 N, respectively.

Results

Differences for kinematic and kinetic variables are shown in Table 1. There were numerous statistically significant differences in pitching biomechanics associated with sample and/or filter frequency. However, many of these differences were less than MCID and therefore have limited clinical value.

Discussion

Pitching data were more sensitive to filter frequency (significant differences above MCID in 13 of 26 variables) than to sample frequency (4 of 26 variables). Velocity and kinetic variables were most impacted by sample and filer frequency, as sensitivity to sample and filter frequency increases with each level of numerical differentiation.[3,4] Based upon these findings and time-series inspection, we recommend a minimum sample frequency of

240 Hz and a Butterworth low-pass filter of 18.0 Hz for with marker-based motion capture pitching mechanics.

Comparison of Baseball Infielder and Pitcher Throwing Biomechanics

Dr. Glenn Fleisig, Dr. Jonathan Slowik

American Sports Medicine Institute, Birmingham, AL, United States

Introduction

While numerous studies have quantified baseball throwing biomechanics, these studies have almost exclusively focused on pitching. Establishing infielder throwing biomechanics could provide valuable, lacking information for biomechanists, coaches, and players. Furthermore, infielders in youth through collegiate baseball often pitch too, raising questions and concerns whether playing infield in addition to pitching increases risk of arm injury. Thus, the purpose of this study was to compare infield throwing and pitching biomechanics.

Methods

Throwing biomechanics were captured for 11 baseball players in a laboratory setting with a 12-camera marker-based motion capture system at 240 Hz. Each player was both a pitcher and an infielder on a youth, high school, college, or professional baseball team. After warming up, each player threw ten fastballs from a pitching mound to a strike zone over a home plate 18.44 m away. After the mound was removed, the player fielded ten groundballs rolled to him and threw the ball to a first base target. For each throw, 31 biomechanical parameters were calculated from tracking the 47 markers on the athlete as previously described. Ball velocity was captured with a radar gun. Differences between pitching and infield throwing biomechanics were analyzed with paired t-tests ($p<0.05$).

Results

Only four of the 16 upper extremity biomechanical parameters showed statistical differences. Angular velocities of shoulder internal rotation (mean 6955 vs 6613 °/s) and elbow extension (2757 vs 2676 °/s) were greater when pitching. There were no significant differences in elbow varus torque (63.9 vs 63.7 Nm) or any other elbow and shoulder kinetics.

Nearly all (13 of 16) trunk and lower extremity parameters showed significant differences. The athletes demonstrated greater lead knee height (60.4 vs 23.3 % body height), stride length (81.0 vs 72.1 % body height), lead knee extension from foot contact to ball release (8.7° extension vs 1.5° flexion), and lateral trunk tilt to the glove side at ball release (26.8 vs 11.5 °) when pitching.

Discussion

While elbow and shoulder kinetics are similar for infield throwing and pitching, full-body kinematics are significantly different. Thus, pitching and infield throws create similar elbow and shoulder stress, but different mechanics are utilized.

Mechanical Basis of Maximal Speed in World-Class Sprinters

Mr. Gouresh Powar, Dr. Peter Weyand

Texas Christian University, Fort Worth, Texas, United States

Introduction

The maximal speeds of sprint runners are determined primarily by the application of large mass-specific ground forces [1, 2]. The relationship between stance average mass-specific ground forces and velocity can be expressed as:

$V_{max} = [(F_{avg}/M_b)*L_C]*Freq_{Step}$

Where:

V_{max} = Maximum Sprinting Velocity,

F_{avg}/M_b = Average mass-specific force,

L_C = contact length,

$Freq_{step}$ = Step Frequency.

Within the heterogeneous runners the positive relationship between Average mass-specific force and maximal velocity is known [1, 2], but which of these variables differentiate performance among the world-class sprinters is not known. We hypothesize that the Average mass-specific force and contact length will have a positive relationship with maximal velocity.

Methods

We acquired running performance and body size data for 48 national and international caliber male sprinters. The maximum instantaneous velocities for two over-ground sprinting steps at international competitions (World-champs, U.S. nationals 100m final) were recorded with a high speed video (≥ 200 Hz). The minimum speed required for inclusion was 10.5 m/s.

Results

The observed mean ± standard deviation and ranges for the variables are as follows: Maximum Sprinting Velocity (V_{max}): mean ± SD = 11.42 ± 0.37 m/s; Average mass-specific force (F_{avg}/M_b): mean ± SD = 2.38 ± 0.15 W_b; Contact length (L_C): mean ± SD = 1.02 ± 0.07

meters; Step Frequency ($Freq_{step}$): mean ± SD = 4.74 ± 0.19 Hz; Leg length (L_O): mean ± SD = 0.98 ± 0.03 meters. Our analysis showed that V_{max} is not significantly related to $Favg/M_b$ or step Frequency, but it was significantly related to L_C and L_C/L_O ($R^2 = 0.1$, $p = 0.02$).

Discussion

Although all sprinters ran with high step frequency and applied large mass specific ground forces (mean of nearly 2.5 times body weight). However frequency and force application did not differentiate between faster and slower world class sprinters. Among variables examined only contact length was significantly related to max velocity. Our results imply that the maximum velocities of the world's fastest sprinters are partially attributable to an ability to sprint with relatively long contact lengths.

Images (Optional)

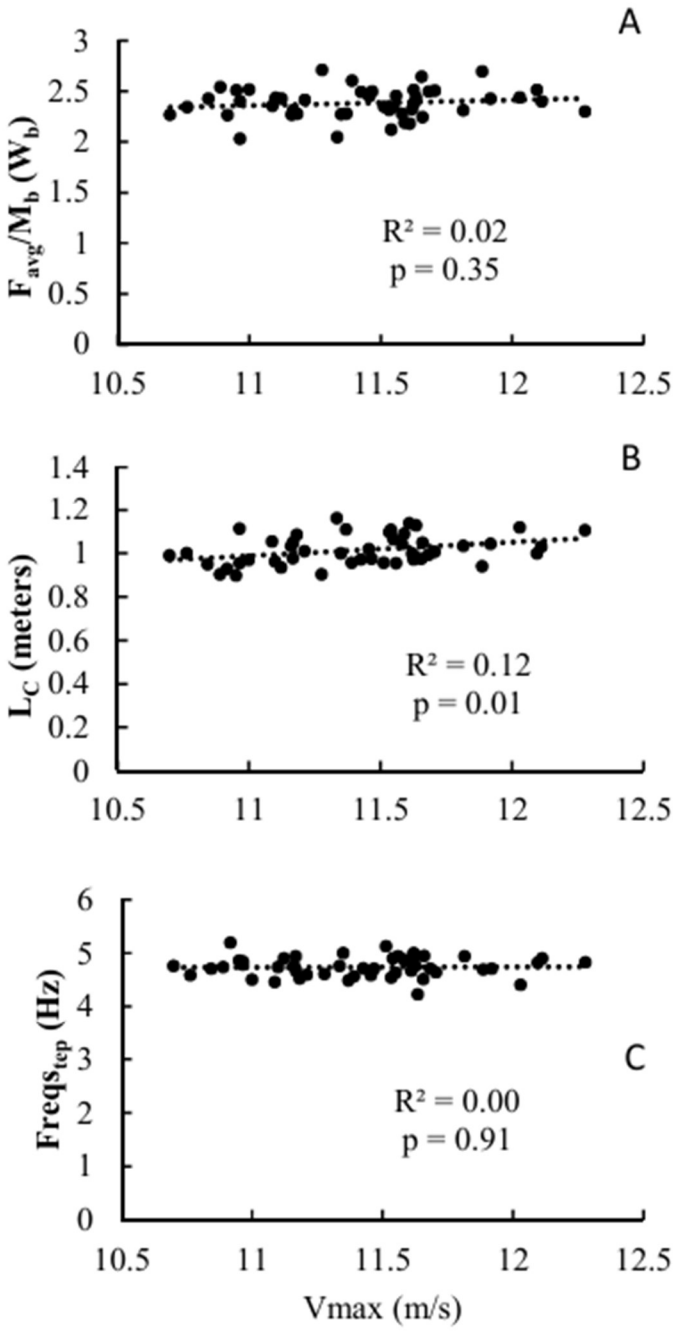

Figure 1: Average mass-specific force (Favg/M_b), Contact length (L_C), Step Frequency ($Freq_{step}$), as a function of maximum velocity (V_{max}). A: F_{avg}/M_bVs V_{max}. B: L_CVs V_{max} C: $Freq_{step}$ Vs V_{max}

Can a Smartwatch Learn My Practice Swing? IMU-Only Golf Swing Estimation via Supervised Learning Using Consumer Grade Video Labels

Ms. Guena Park Ph.D. Student, Prof. Sukyung Park Ph.D.

Korea Advanced Institute of Science and Technology, Yuseong-gu, Daejeon, Korea, Republic of

Ms. Guena Park

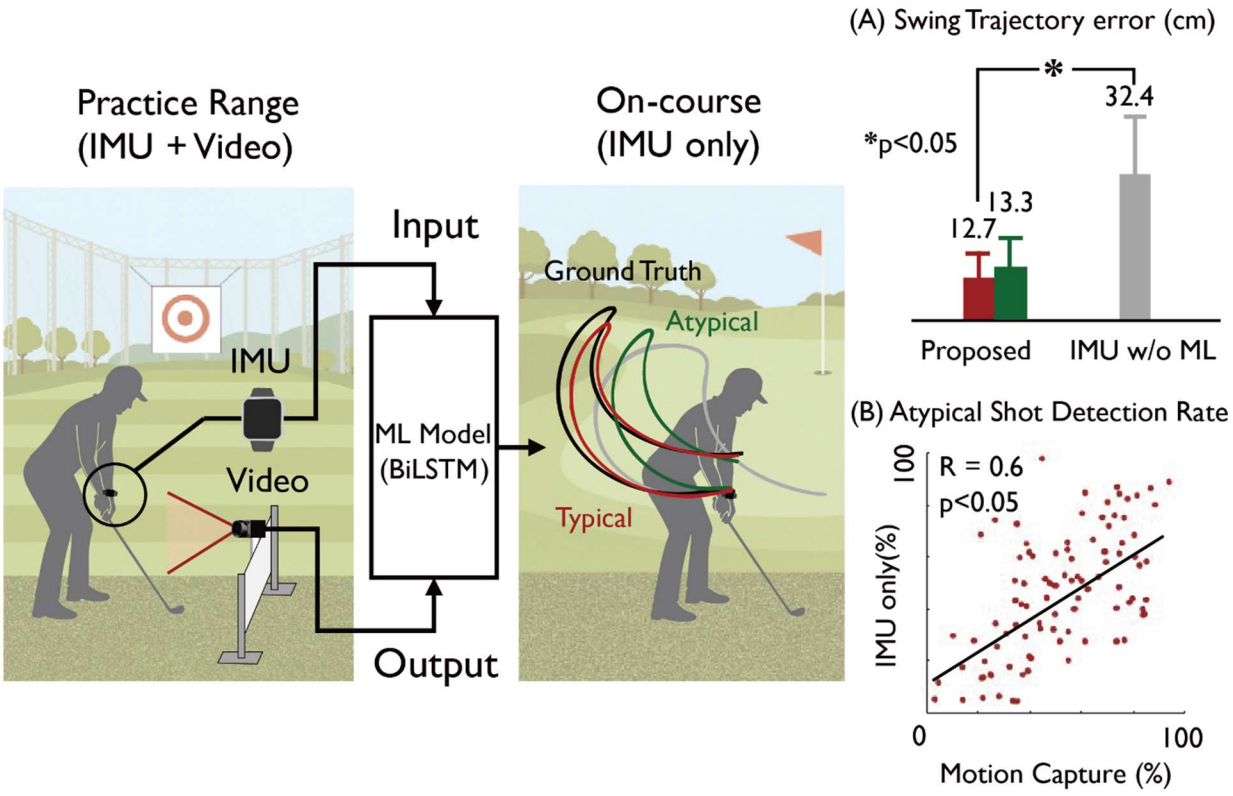
Introduction

Wearable devices using smartwatches and inertial measurement units (IMUs) are widely adopted in sports and rehabilitation. In golf, these devices typically provide simple low-dimensional metrics such as swing tempo or wrist angle. However, accurate 3D wrist trajectory monitoring is essential for improving swing performance. A single IMU alone struggles to estimate sensor orientation and control cumulative drift errors. A previous study [1] addressed this using machine learning with motion capture-based labels, but this approach requires large scale motion capture data and offers limited model interpretability. Recently, consumer-grade video from smartphones has become ubiquitous, facilitating synchronized IMU–video collection. This study aims to develop a supervised learning method that corrects IMU drift using video-based anchors and estimates swing trajectories from a single IMU without motion capture.

Methods

Ten amateur golfers (mean score: 87.5 ± 4.2) performed 400 driver swings. A 9-axis IMU on the left wrist was synchronized with consumer-grade video, with motion capture providing 3D wrist trajectories as ground truth. Initial sensor orientation was estimated from IMU alone at address, and displacement correction was applied, combining a prior velocity drift correction [2] with video-extracted wrist position anchors. Supervised learning models were trained on labeled IMU–video datasets and evaluated for 3D trajectory and pattern estimation using single-IMU input only.

Results



The proposed video-labeling correction reduced wrist position error by over 50% compared to raw IMU integration without machine learning. The final mean average error was 12.7 ±

3.9 cm, comparable to motion capture based supervised learning [2]. Additionally, atypical shot detection rates predicted by the model showed a positive correlation (R = 0.6) with motion capture ground truth, confirming the feasibility of single-IMU-based atypical shot detection.

Discussion

This study demonstrates that IMU-based swing trajectory estimation and supervised learning are achievable using consumer-grade video labels alone, without motion capture. The proposed method reduces data acquisition burden while achieving performance comparable to motion capture-based approaches. With long-term data accumulation, this framework could extend to personalized swing monitoring and feedback systems using a single IMU and video-labeled models.

Differences in Muscle Synergy Pattern between Satisfactory and Unsatisfactory Golf Swing: Pilot study

Prof. Hae Dong Lee PhD[1], Mr. Yoon Hyung Cho MSc[1], Mr. Jun Hyun Han BSc[1], Ms Song Yi Choi PhD[1,2]

[1]Yonsei Univeristy, Seoul, Seodaemun-gu, Korea, Republic of. [2]Yonsei Golf Science, Seoul, Jung-gu, Korea, Republic of

Prof. Hae Dong Lee

Mr. Yoon Hyung Cho

Mr. Jun Hyun Han

Introduction

To better understand the complexity of the golf swing, this study investigated how the muscle synergy pattern differs between satisfactory and unsatisfactory golf swings using a non-negative matrix factorization model [1]. Within the framework of dynamic motor control theory [2], the spatial and temporal muscle synergies were investigated during drive swing.

Methods

Young and healthy male volunteers (n = 3, handicap 15~20) performed drive swings until five bad (BS) and five good (GS) swings were collected, with classification based on both the subject's own evaluations and objective data from a ball tracker. This approach aimed to ensure consistent and reliable categorization of swing quality. For the selected swings, 3D joint kinematics and surface electromyography (sEMG) from 13 muscles across the body were obtained. During the downswing phase, using non-negative matrix factorization (NMF), the muscle synergy matrix weight (W) and a neural recruitment coefficient (C) were estimated. Within-subject comparisons of W and C between the conditions were performed using the Mann-Whitney U test and SPM1D, respectively, with a significance level of .05.

Results

For all participants, 3 synergies were found, including BS and GS. The subject-specific synergy weights are shown in Fig. 1A: in Subject 1, RRA in Synergy 1 was larger in good swings, whereas RRF in Synergy 2 was smaller in good swings; in Subject 2, RLD in Synergy 1 was lower in good swings, while RRA in Synergy 3 was higher; in Subject 3, RRA in Synergy 1 and LTB and RTB in Synergy 3 were all higher in good swings. The temporal activation coefficients (C) did not show any significant differences between BS and GS (Fig. 1B).

Discussion

In a driver golf swing, a non-repetitive, goal-directed task, differences between GS and BS were primarily expressed in the synergy weight (W) rather than in the time-varying synergies (C). Notably, all participants showed higher weighting of the right rectus abdominis during GS, suggesting that enhanced trunk stabilization may be a key component of the synergy architecture underpinning successful golf swings.

Exploring Modeled Muscle Activation Profiles of Ballet Dancers With Different Jump Landing Techniques

Ms Hailey Wrona[1], Dr Glenna Clifton[2], Dr Kathleen Bieryla[3], Dr Shawn Russell[1]

[1]University of Virginia, Charlottesville, VA, United States. [2]University of Portland, Portland, OR, United States. [3]Carnegie Mellon University, Pittsburgh, PA, United States

Introduction

Ballet dancers are required to exhibit exceptional strength and control while they train beyond typical joint ranges. The primary mechanism of injury in over 50% of time-loss injuries for ballet dancers is attributed to jumping and landing movements. In certain training techniques, they are encouraged to keep their weight forward and maintain a heel-lifted position, landing primarily on their forefoot. In other disciplines, forefoot jump landings and strikes have been linked to increased musculotendon injury risk factors. Therefore, the purpose of this study was to investigate how ballet dance training style influences muscle activation profiles in forefoot (FR) landing and full-foot (FL) landing strategies.

Methods

Thirteen preprofessional dancers performed three sets of jumps in first position (Fig.1A), hips externally rotated with their heels touching, in the two landing styles: FR and FL. The Rizzoli marker set with Optitrak motion capture cameras (100 Hz) and a Bertec force plate (1000 Hz) covered with marley dance floor material was used for kinematics and kinetic data collection. In OpenSim 4.5, to best represent the muscles engaged in the turned-out position, the parameters of the short external rotator muscles of the hip were updated from the generic musculoskeletal (MSK) model based on updated anatomical measurements. With updated subject-specific MSK models, computed muscle control was used to estimate muscle activations.

Results

It was first established that the hip-updated MSK model produced significantly different ($p<0.05$) external rotator outputs. Statistical parametric mapping and heat map visualization (Fig.1B) then revealed that the FR condition exhibited larger muscle activations in the plantarflexion group during take-off compared to the FF condition. Simultaneously, the FF condition showed larger hip flexion muscle activation during take-off than the FR condition.

Discussion

The difference in muscle activation profiles, with the FR condition more significantly using their plantar flexor muscle groups compared to the FF condition, could be a compensation strategy. This strategy may help counteract the dancers' reduced ability to use their base of support to absorb forces through the lower extremity. The FR condition's overreliance of the plantar flexors without sufficient involvement of the hip muscles places them in a position of increased injury risk.

Images (Optional)

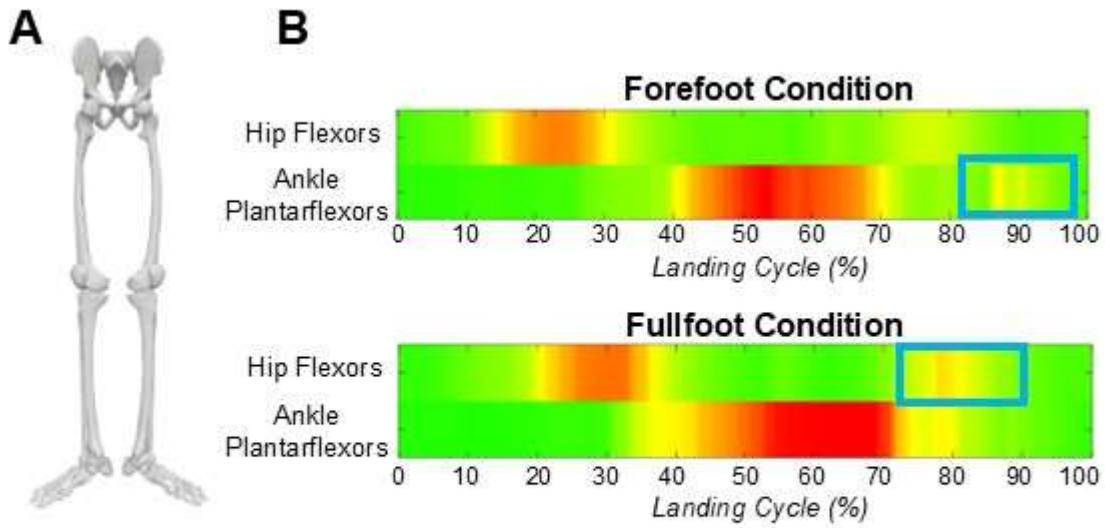

Figure 1. (A) OpenSim MSK model in ballet first position with the hips externally rotated, knees aligned in the direction of turnout, and heels touching with toes pointing outwards. (B) Heat map visualization of the muscle coordinate group activation profiles across the jump landing cycle for the forefoot (FR) and fullfoot (FF) conditions. The color intensity reflects normalized muscle activation with red (high, 1) and green (low, 0).

Comparison of Arm Positions During Double Leg Drop Landing and Their Impact on Lower Extremity Kinetics and Kinematics

Ms. Hallie Music, Ms. Madelyn LeGault, Mr. Jacob Vassar, Dr. Abbie Ferris

University of Northern Colorado, Greeley, Co, United States

Introduction

Drop landings have been used to study ACL injury mechanics [1], analyze performance metrics [2], and monitor athlete performance [3]. However, arm position has either been restricted (to standardize research protocols), unreported, or ignored [4]. Comparisons between arm placements and sport-specific arm positions have not been assessed. The purpose of this study is to determine if arm position during double leg drop landing alters lower extremity mechanics. We hypothesize lower extremity joint angles and vertical ground reaction force (GRFv) will be greater when restricting arm movement than over free arm conditions during double leg (DL) drop landing.

Methods

Four adults (2M/2F, 24±4.69 y) were asked to complete DL drop landing tasks from 30cm. Kinematic (VICON, Denver, CO) and kinetic (AMTI, Watertown, MA) data were measured during four arm conditions: free arm (FA), hands on hips (HH), arms across chest (AC), and arms overhead (AO). Peak joint angles, moments, and powers, and GRFvwere calculated during the initial landing phase. Given the small n in these preliminary data, no statistics were performed; trends are noted below and will be expanded upon in our poster as we add participants.

Results

GRF_V was reduced for AC and HH. In general, HH and AO conditions showed small, but notable differences at the ankle, knee and hip. The HH condition showed increased ankle plantarflexion and eversion and hip flexion, but reduced knee flexion and knee valgus. In contrast, the AO condition showed reduced ankle plantarflexion and hip flexion, and increased knee flexion. Further, reduced peak plantar flexor knee extensor, and hip abduction moments and less ankle power absorption were noted in the HH condition. AO consistently maintained a more extended trunk position than all other conditions.

Discussion

These preliminary data suggest that during DL landing, the lower extremity can successfully adjust to different arm positions. While we did note that HH and AO

conditions resulted in differences, they were generally not large. Coaches, practitioners, and researchers should be aware of these results to help them better direct their research goals. Although arm position does not affect DL landing, single leg landings may show different results.

Lower Extremity Mechanics are Impacted by Arm Position during Single Leg Drop Landings

Ms. Hallie Music, Ms. Madelyn LeGault, Mr. Jacob Vassar, Dr. Abbie Ferris

University of Northern Colorado, Greeley, Co, United States

Introduction

Single leg drop landings have been used to identify movement deficits of the ankle, knee, and hip [1] because it has an increased load on the lower extremity than other tasks [2]. However, arm position has either been restricted (to standardize research protocols) or sport specific [3], but the impact of these conditions on the lower extremity have not been evaluated. The purpose of this study is to determine if arm position during single leg drop landing alters lower extremity mechanics. We hypothesize lower extremity joint angles and vertical ground reaction force (GRFv) will be greater when restricting arm movement during single leg (SL) drop landing.

Methods

Four adults (2M/2F, 24±4.69 y) completed SL drop landing tasks from 30cm. Kinematic (VICON, Denver, CO) and kinetic (AMTI, Watertown, MA) data were measured during four arm conditions: free arm (FA), hands on hips (HH), arms across chest (AC), and arms overhead (AO). Peak joint angles and GRFv were calculated during the initial landing phase. Given the small n in these preliminary data, no statistics were performed; trends are noted below and will be expanded upon in our poster as we add participants.

Results

Initial trends suggest GRFv was greatest for AO and lowest for HH. Generally, we noted arms constrained conditions (HH and AC) differed from unconstrained conditions (AO and FA) with HH and AO showing greater differences. HH showed a more neutral ankle while the AO condition maintained a dorsiflexed position. The arm constrained conditions showed a reduction in knee flexion. HH increased hip flexion and AO reduced hip flexion. Most interestingly, overall limb position differs between the arm conditions. The HH showed a more upright limb position, whereas the FA and AO place the foot medially creating an increased adduction limb angle.

Discussion

These preliminary data suggest arm position changes lower extremity mechanics during SL landings. This is especially true at the knee where limb position can be affected by arm

placement thus altering measures such as Q angle. Therefore, if the goal of training or rehabilitation is to evaluate limb mechanics, athletes should use an unconstrained arm position.

Real-Time Markerless and Serverless Estimation of Dual-Foot Ground Reaction Forces during the Acceleration Phase of Baseball Pitching

Dr. Hiroki Tanioka[1], Mr. Masato Ueguri[2]

[1]Tokushima University, Tokushima, Tokushima, Japan. [2]Baseball Partners Tokushima Co., Ltd., Tokushima, Tokushima, Japan

Dr. Hiroki Tanioka

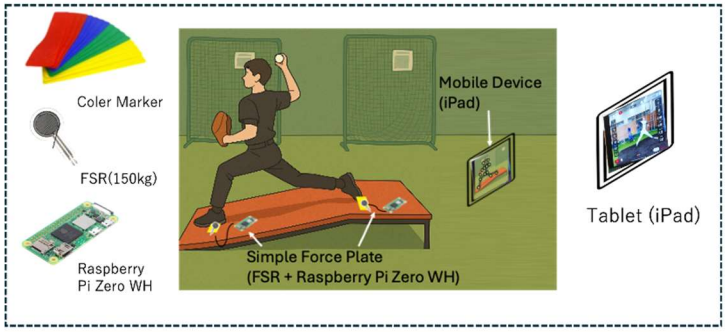
Introduction

Ground reaction forces (GRFs) are essential for generating pitching velocity and limiting joint loading [1][2], yet their measurement outside laboratories is difficult. Force plates are accurate but impractical, and markerless methods typically estimate only kinematics. Existing GRF models, developed for steady gait [5][6][8], do not capture pitching acceleration, especially the force distribution between both legs during double support. This study proposes a real-time, markerless, serverless method to estimate total and dual-leg GRFs [9].

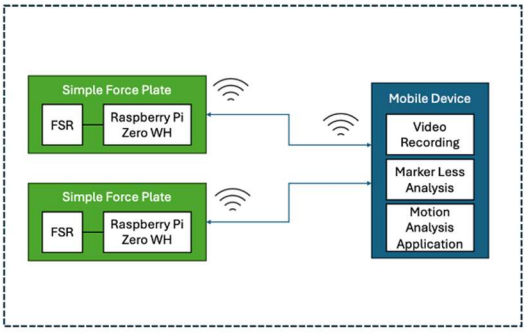
Methods

One collegiate pitcher threw three fastballs recorded with a smartphone (60 fps). MoveNet provided keypoints to compute center-of-mass acceleration and estimate total and dual-foot GRFs. Foot-load distribution was derived from the CoM-acceleration vector [3][4]. Estimates were validated against FSR plate measurements using basic error metrics.

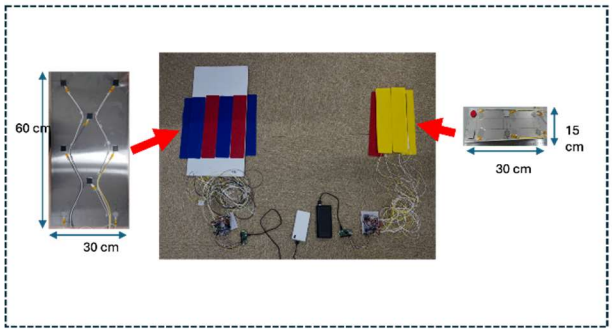
MoveNet keypoints → center-of-mass acceleration
Total and dual-foot GRFs estimated from CoM dynamics
Foot-load ratio from CoM-acceleration vector and foot positions
Validation against FSR plates using error metrics [7]



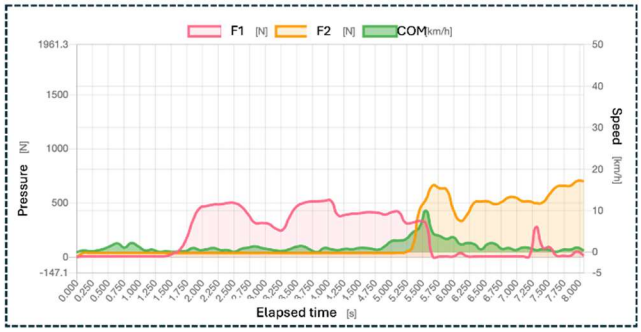
Results



Estimated GRFs closely matched measured forces. Total vertical GRF showed RMSE values of 8–13% of body weight, with peak-force errors under 12% and correlations above 0.90. The estimated drive-to-lead load-transfer pattern replicated the measured transition during acceleration, with loading-ratio errors of 9–15%. Timing errors for key loading events were under 20 ms.



Discussion



Results suggest dual-foot GRFs in acceleration phase can be estimated from markerless kinematics alone. Despite single-subject validation, the method shows on-field potential. Future work will test more pitchers and evaluate effects of handedness, camera angles, arm slots, and multi-view setups.

Laboratory Derived Biomechanical Predictors of Biathlon Ski Speed

Mr Isaac Burgess MS, Mr Ethan Livingood BS, Mr Brandon Cabaniss, Dr James Becker PhD

Montana State University, Bozeman, MT, United States

Introduction

Previous studies have shown that physiological performance measures during laboratory tests can predict ski speed during biathlon competitions. While numerous studies have shown gross-biomechanical measures such as cycle length influence ski speed, it is unclear whether kinematic and kinetic markers of ski technique during laboratory assessments also predict ski speed in races. Therefore, the purpose of this study was to evaluate whether laboratory based biomechanical assessments of ski technique predict ski speed in elite biathletes.

Methods

Twenty-eight elite biathletes (17M/11F, 24±5 years) skied on a rollerski treadmill while body, ski, and pole kinematics were captured with hybrid-markerless motion capture while forces applied to the ski were measured using plantar-pressure insoles. Biomechanical variables that may be important for achieving higher speeds during V2 skating were then calculated for different phases of the ski cycle, which included; Poling - mean anterior-posterior inclination angle (θ_{AP}), Gliding - mean mediolateral center-of-mass inclination angle (θ_{ML}) and mean asymmetry in mediolateral pressure balance (*ASI*), Pushing - peak force applied to the ski (F_{peak}) and peak knee angular velocity (ω_{knee}), Ski placement - step-out distance (d_{step}) and V-angle (V_{θ}) at ski contact. All athletes then participated in a biathlon sprint competition on rollerskis, where average ski speed was calculated. Pearson correlation coefficients quantified relationships between each variable and ski speed. Variables correlated with ski speed ($r \geq 0.5$) entered a multiple regression to evaluate whether they explained ski speed.

Results

θ_{ML}, θ_{AP}, F_{peak}, *ASI* , and d_{step} were weakly correlated with ski speed and not considered further (Table 1). The multiple regression with the remaining variables showed a model containing V_{θ} ($\beta = -0.09$, $p = 0.008$) and ω_{knee} ($\beta = 0.08$, $p = 0.024$) accounted for 46% of ski speed ($p < 0.001$).

Discussion

The greater ω_{knee} may allow athletes to pre-load the ski more effectively. Additionally, this finding may also reflect more effective use of a stretch-shortening cycle in the leg muscles for greater force production. A lower V_θ at ski-on may improve energy transfer from the pushing to gliding ski, as the gliding ski is more aligned with skiing direction. Future research should investigate whether improving these variables can increase ski speed.

Images (Optional)

Table 1. Mean ± standard deviation for biomechanical variables and Pearson product-moment correlation coefficients (r) for average ski speed in biathlon competition and selected laboratory-derived biomechanical variables.

		Average Competition Ski Speed	
Variable	**Mean ± SD**	***r***	***p-value***
V_θ (°)	7.9 ± 3.1	-0.62	<0.001
ω_{knee} (rad/s)	146.3 ± 30.1	0.60	<0.001
θ_{ML} (°)	5.7 ± 1.8	-0.45	0.003
ASI (%)	14.5 ± 7.9	-0.35	0.03
F_{peak} (BW)	1.26 ± 0.15	0.32	0.05
θ_{AP} (°)	7.5 ± 2.8	0.27	0.09
d_{step} (cm)	1.02 ± 0.50	-0.22	0.17

Note. Pearson product-moment correlation coefficients were evaluated as very weak (0.00-0.29), weak (0.30-0.49), moderate (0.50-0.69), and strong (>0.70).

The Turnout Control During Bipodal and Unipodal Ballet Jumps: Multi-Joint Strategies Across Landing Conditions

MSc., P.T. Luciana C. Manfrim[1], PhD. Maria Isabel V. Orselli[2,1,3], P.T. Bianca M. Portela[1], P.T. Matheus O. Moutinho[1], PhD Paolo Caravaggi[4], PhD Isabel C.N. Sacco[1]

MSc., P.T. Luciana C. Manfrim

PhD. Maria Isabel V. Orselli

P.T. Bianca M. Portela

P.T. Matheus O. Moutinho

PhD Paolo Caravaggi

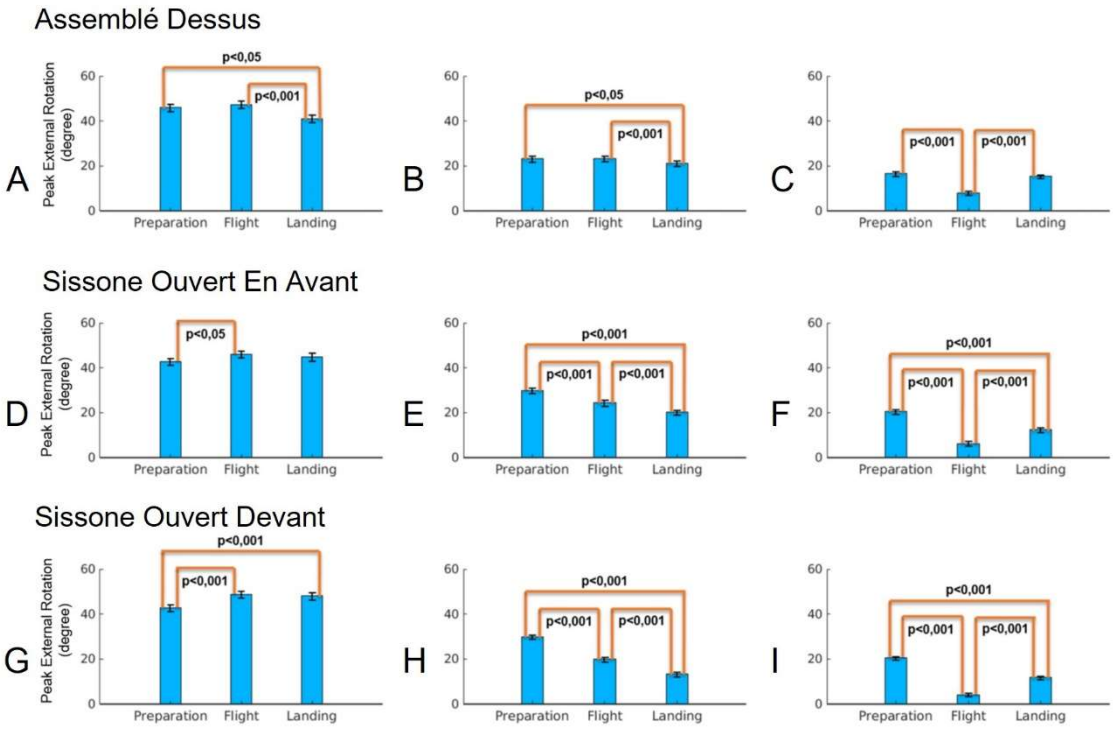
Introduction

The Turnout, or external rotation of the lower limbs, is a fundamental skill in ballet. While the hip is turnout's main contributor, the coordinated roles of the knee and ankle remain unclear under aerial skills, such as jumps. Despite the importance of turnout for ballet, its understanding and biomechanical investigation during aerial movements has been overlooked[1], especially in unipodal jumps. This study aimed at analyzing kinematic contributions of hip, knee, and ankle to turnout during 3 jumps from fifth position: Assemblé Dessus (bipodal, lateral aerial body displacement), Sissone Ouvert En Avant

(unipodal, anterior displacement), and Sissone Ouvert Devant (unipodal, lateral displacement).

Methods

We accessed 30 pre-professional dancers (20.1±2.6yrs; 11.7±4.1yrs ballet experience) with a 8-camera optoelectronic system (Vicon, @100Hz) using a rigid cluster-based marker protocol[2,3]. Kinematic profile of the hip, knee and ankle joints were calculated using a 6-DOF model implemented in Visual3D. Peak rotation and its timing were extracted and compared across joints and jump phases (preparation, flight, and landing) using repeated measures ANOVA, followed by Newman Keuls post hoc ($p<0.05$).



Results

The hip consistently exhibited the greatest external rotation across all jumps and phases (Fig.1, $p<0.001$). In both Sissones, hip rotation remained stable from flight to landing, whereas in Assemblé, hip and knee rotations decreased upon landing ($p<0.001$). Ankle rotation increased during landing ($p<0.001$) and was the lowest during flight. Timing of rotation peaks varied across joints: the hip peaked earlier, while the ankle reached its maximum in late flight and late landing. Fig.1:Mean (SE) external rotation peak in preparation, flight and landing of all jumps for hip (A,D,G), knee (B,E,H), ankle (C,F,I).

Discussion

The hip is the primary contributor to turnout in all jumps, whereas the knee and ankle act complementarily, with the knee reducing its contribution and the ankle increasing it from flight to landing. Jump type and landing support influence rotational contributions, reinforcing the need for training that optimises coordination and joint alignment.

Longitudinal Bending Stiffness affects Biomechanics but Not Running Economy or Perception in Advanced Footwear Technology

Dr. Jamie Ferris, Mr. Ben Hazelwood, Dr. Samuel Cheuvront, Dr. Jinger Gottschall

New Balance, Boston, MA, United States

Introduction

Evidence suggests longitudinal bending stiffness (LBS) does not independently affect running economy (RE) or ankle mechanics (Stephen, et al., 2025); however, the current data quality is limited by uncontrolled footwear differences and by methodology such as shoe-mounted markers. This study aimed to examine the effects of LBS on RE, biomechanics, and perception in advanced footwear technology (AFT) using controlled footwear and foot-mounted markers.

Methods

Twelve experienced runners (6 female; biomechanical data for 10) completed 5-minute bouts of treadmill running in four mass-adjusted prototypes based on the New Balance FuelCell SuperComp Elite v5 with carbon fiber plate variations: no plate, plate with medial-lateral cuts, lower-stiffness plate, and higher-stiffness plate. RE and lower-limb biomechanics were analyzed via RMANOVA and Tukey's HSD ($\alpha = 0.05$). Perceived footwear attributes were rated on 7-point scales and compared using Friedman tests with subsequent Dunn's pairwise comparisons.

Results

LBS had inconsistent and non-significant effects on RE ($p = 0.584$) and perception, including yield ($p = 0.822$), energy return ($p = 0.690$), and speed ($p = 0.575$) (Agresta, et al., 2020). Spatiotemporal variables were unaffected. Biomechanical changes occurred primarily at the metatarsophalangeal (MTP) joint, including reduced MTP negative work as LBS increased (Figure 1). Ankle mechanics were unchanged, and effects at the knee and hip were limited.

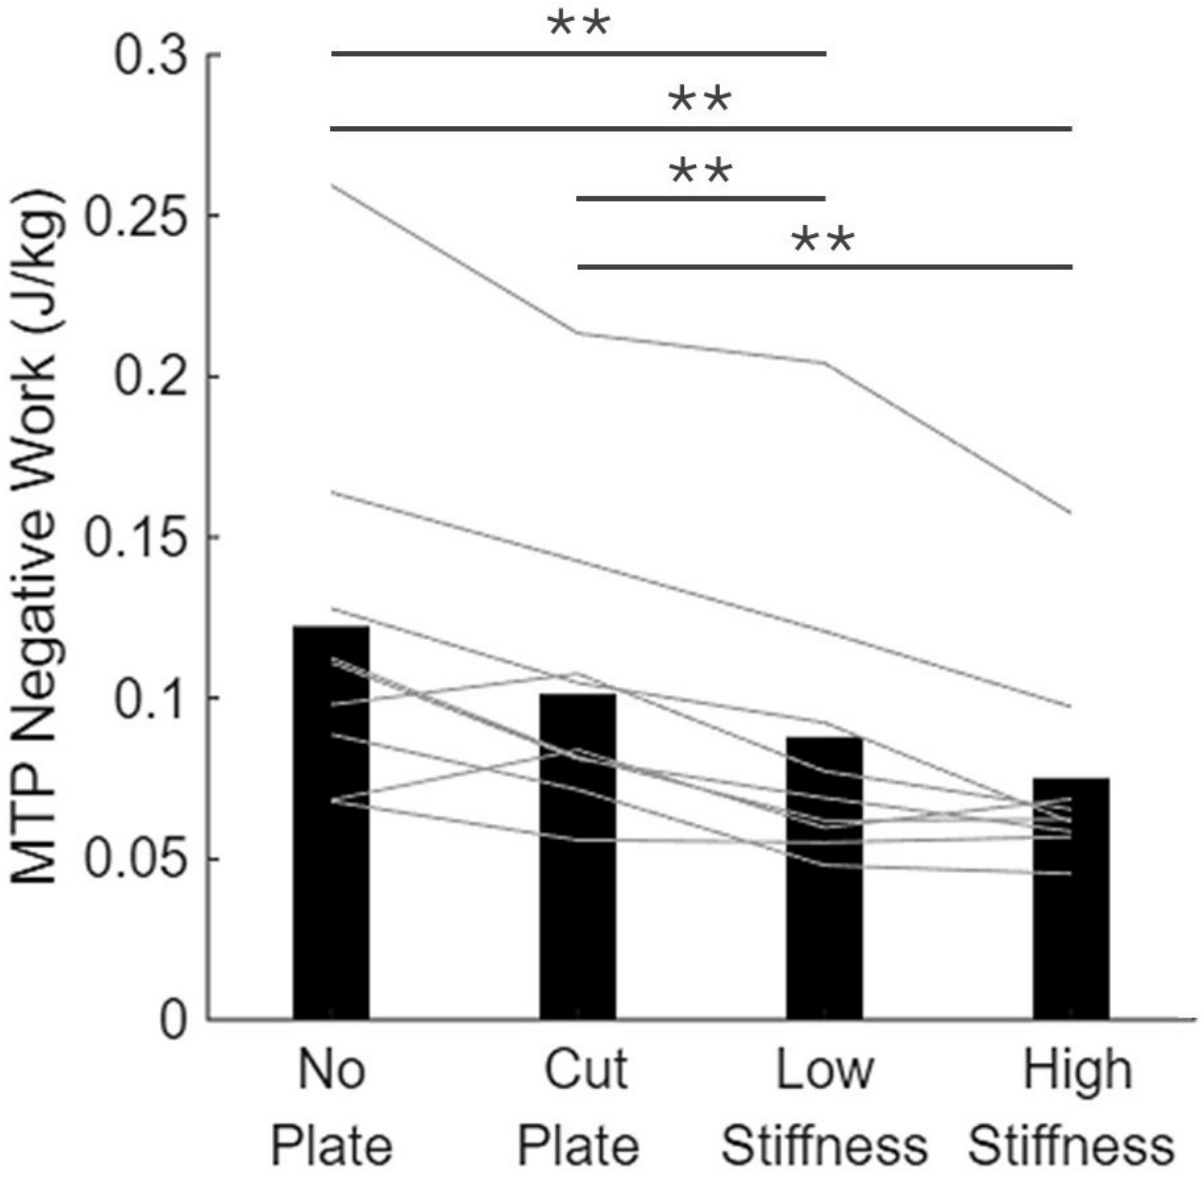

Figure 1. Average and individual MTP negative work across footwear conditions. ** $p < 0.01$

Discussion

Although lower negative work at the MTP joint may reduce local energy expenditure, this did not translate into measurable whole-body energy savings—likely due to the MTP joint's

small contribution to total energy expenditure. Racing footwear may therefore vary in LBS without performance or perceptual effects.

"Thinking Inside the Box": Ice Hockey Goaltender Glove Position Analysis

Ms. Jasmine Kwan BSc, Mr. Seth Daley MSc, Dr. Kathleen MacLean Ph.D.

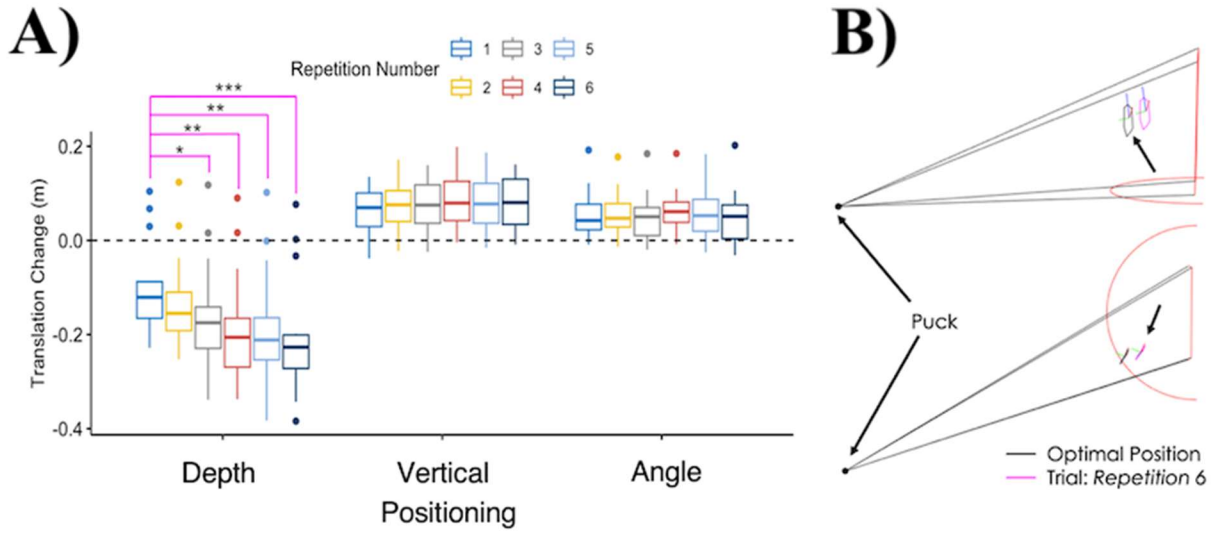
Dalhousie University, Halifax, Nova Scotia, Canada

Introduction

Optimal performance for ice hockey goaltenders requires dynamic positioning of their equipment within the net's frame, including the glove, to block shots. There is no criterion standard for goaltender glove positioning. However, "box control" is a concept to teach maximum net coverage and glove positioning, highlighting how net size dynamically changes based on puck shooting location. Whether goaltenders execute box control and what factors influence their ability to optimally cover the net is not known. This study examined goaltender box control performance by investigating how three-dimensional glove position changes based on duration of play, perceived fatigue, and gender.

Methods

Fourteen experienced goaltenders' (9 men, 5 women) completed three conditions: 1) baseline, 2) short trial, and 3) long trial, while glove position was tracked at four high-shooting puck locations using Optitrak motion capture (NaturalPoint Inc.; Corvallis, USA). Baseline trials captured the static optimal glove position at each puck location. Short and long trials tracked dynamic glove position as participants moved to each puck in pre-determined patterns. A rating of perceived exertion (RPE) was obtained after each trial. Short and long trial glove position at puck locations were compared to the baseline to compute three-dimensional translational and rotational errors in box control using two-way ANOVA's. Pearson's correlation determined the association between glove position error and RPE and gender.



Results

In the short trial, goaltenders had significantly more translational error for pucks located on the far left ($p<0.04$) and right ($p<0.045$) and significantly higher rotational error about the vertical axis ($p<0.001$). In the long trial, goaltenders drifted back into the net with increased trial duration ($p<0.001$) (Fig. 1). Error increased with increasing RPE. No league-identified gender differences were found in the short trial, but men's league goaltenders had greater error in the long trial.

Discussion

Experienced goaltenders struggled to maintain box control in short and long bouts of simulated play. Alternative, standardized coaching methods may be needed to improve off-center glove positioning for wide shots. Greater glove position errors with duration, drift into the net, and RPE indicate a need for targeted isometric training to mitigate potential muscular fatigue and improve net coverage.

The First Line of Defense Against Head Accelerations in Wrestling

Dr. Jeffrey S. Brooks PhD[1], Mr. Rashad J. Hussain[1], Dr. Ryan T. Schroeder PhD[1,2], Ms. Princess A. Uona MSc[1], Mr. Daniel C. Anzovino MSc[1], Ms. Emma J. Ratke BSc[1], Dr. Shawn M. Beaudette PhD[1], Dr. Amanda M. Black PhD, CAT(C)[1,3]

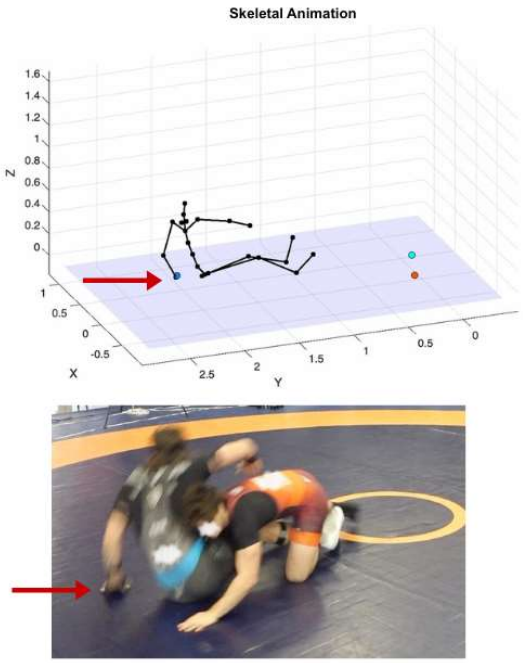
[1]Department of Kinesiology, Faculty of Applied Health Sciences, Brock University, St Catharines, Ontario, Canada. [2]Department of Engineering , Faculty of Mathematics and Science, Brock University, St Catharines, Ontario, Canada. [3]Department of Community Health Sciences, Cumming School of Medicine, University of Calgary, Calgary, Ontario, Canada

Introduction

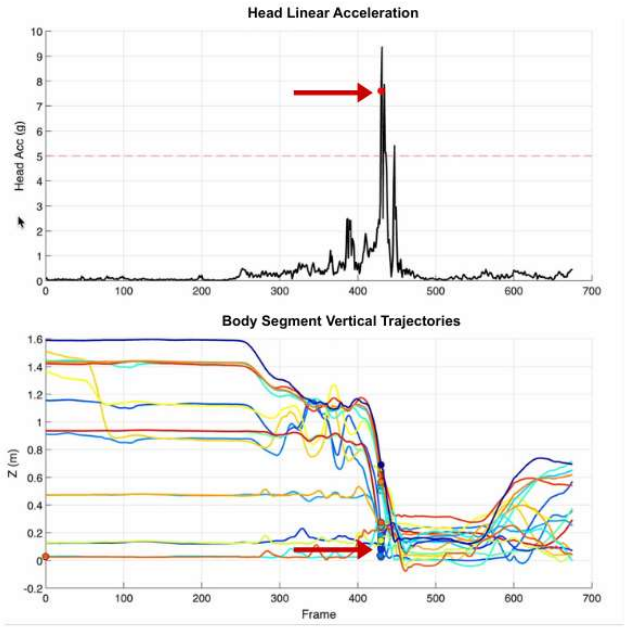
Wrestling has one of the highest concussion rates in collegiate sports [1]. Understanding head impact kinematics is critical to assessing concussion risk, yet few studies have quantified head accelerations in wrestling. The sequence of body segment contact with the mat may influence peak linear head acceleration (PLA). This study examined whether earlier body segment contact during takedowns reduces PLA.

Methods

Eight varsity wrestlers (4F, 18–23 years), paired by weight class, performed common takedowns in a controlled setting at submaximal intensity, completing 10 trials per maneuver (5 offensive, 5 defensive). Full-body kinematics were captured using 17 XSens Awinda IMUs (60 Hz) placed on 17 anatomical landmarks. The time between first limb contact to PLA was calculated (negative = contact after peak). A 5g threshold was applied to exclude accelerations associated with daily living. Linear mixed-effects models assessed whether contact timing predicted PLA, with takedown subtype and role as fixed effects and wrestler as a random effect.



Results



Head acceleration >5 g occurred in 42% of takedowns (157/374), distributed across subtypes (Double: 69, Throw: 66, Single: 12, Snapdown: 11). Body segment contact with the mat occurred before PLA in 18–45% of trials. For defense, preceding contact was most common at the lower leg (32%), shoulder (30%), and upper arm (30%). For offense, the lower leg (44%) and hand (29%) were most frequent. The time from first segment contact to PLA averaged 0.92 s (SD: 1.1; range: -4.93 to 3.22s). A role-specific relationship was observed: for offense, later segment contact was associated with higher PLA (β=2.83, p=0.014), whereas timing was not a predictor for defense.

Discussion

The timing of body segment mat contact relative to PLA during wrestling takedowns showed a role-specific association: for offensive athletes, later contact corresponded to higher PLA. This offensive-specific effect aligns with prior observations that offensive moves produce higher-magnitude head kinematics [3], highlighting a potential technical factor for concussion risk mitigation. This provides initial biomechanical evidence that skill execution - specifically, the sequence of ground contact - may modify injury risk in high-impact scenarios.

Biomechanical Determinants of Primary and Secondary ACL Injury Risk - A Comparison of Two Cases

Mr. Jeremy La Rosa, Mr. Walker Rost Kruger, Mr. Sergio Ibarra AT, MS, Dr. Santiago Ortega DPT, MS, Dr. Sara Gombatto PT, PhD

San Diego State University, San Diego, CA, United States

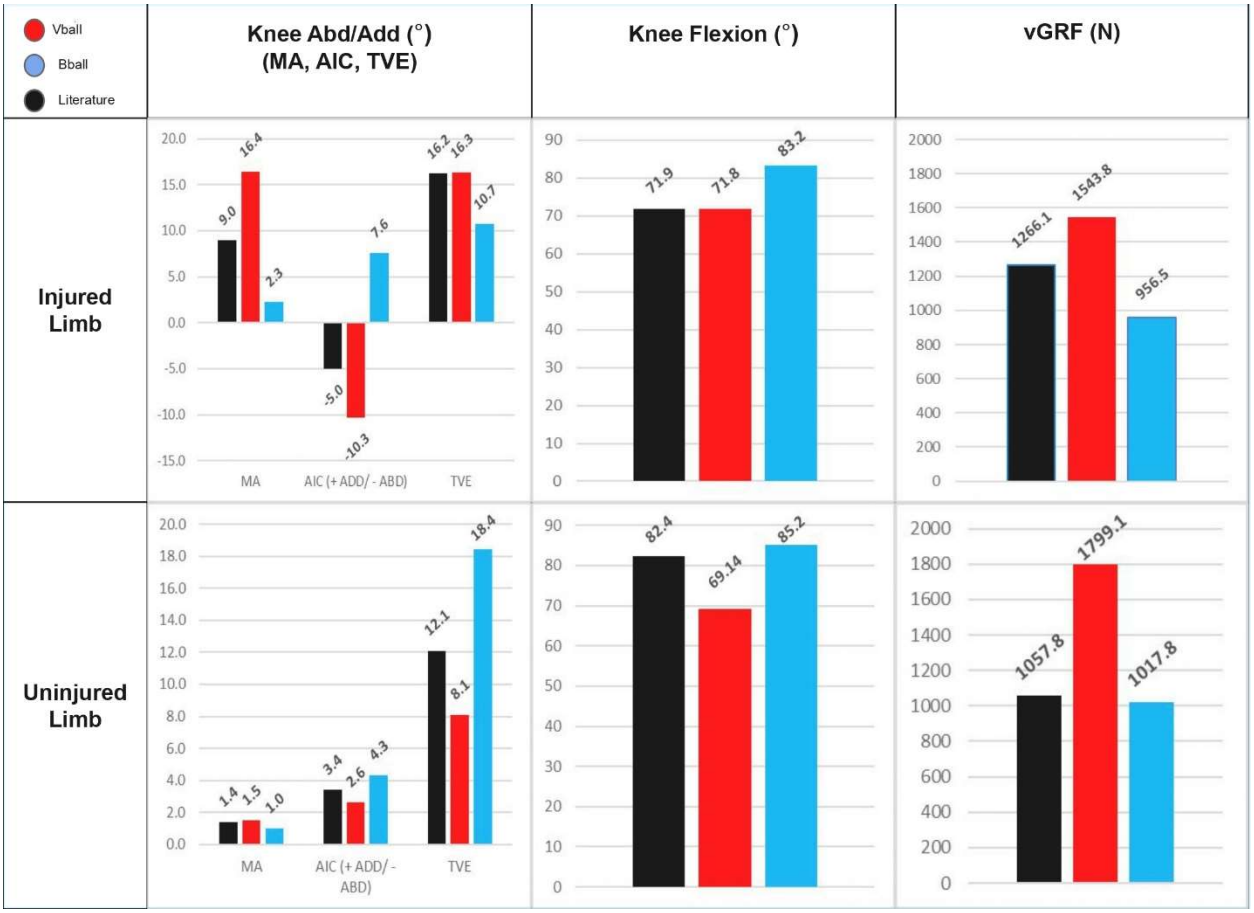
Introduction

Non-contact anterior cruciate ligament (ACL) injuries are common in female athletes. Nearly 1 in 29 female athletes experience an ACL injury and return-to-sport with a higher risk for reinjury [1]. Kinetic and kinematic measures have been identified as risk factors for primary or secondary ACL injury [2,3]. We retrospectively examined biomechanics screenings in two female collegiate athletes to determine presence of risk factors associated with ACL injury.

Methods

Two female collegiate athletes were examined (Vball,Bball). Vball was tested pre-season, several weeks prior to ACL injury; Bball was tested 6-months after ACL reconstruction. Drop vertical jumps (DVJ) were performed in a 3D motion capture lab with 16-cameras and two force plates. 3D lower extremity kinematics and kinetics were measured during DVJ landing. Risk factors from prior studies, including peak vGRF and the following knee joint angles were calculated: maximum abduction (MA), initial contact abduction (ICA), total abduction excursion (TAE), maximum flexion (MF). Measures were compared to average values for athletes who developed ACL injuries from prior prospective studies.

Results



Injured limbs: Peak vGRF was greater for Vball (1544N) but less for Bball (956N) than from prior studies (1266N). MA was greater for Vball (16.4°) and less for Bball (2.3°) than prior studies (9°). ICA was greater for VBall (-10.3°) than prior studies (-5°), but Bball exhibited adduction (7.6°). TAE for Vball (16.3°) was similar to prior studies (16.2°), but Bball was less (10.7°). MF for Vball (71.8°) was similar to prior studies (71.9°), but MF was greater for Bball (83.2°). *Uninjured limbs*: Peak vGRF was greater for Vball (1799N) and TAE was greater (18.4°) for Bball in their uninjured limbs when compared to injured limbs from prior studies.

Discussion

Vball displayed movement patterns associated with increased risk of ACL injury, then suffered an ACL injury during the season. Bball did not display increased risk factors on the

affected limb. Both athletes displayed isolated risk factors on their unaffected limbs, which may increase risk of subsequent ACL injury. Integrating 3D motion analysis into screenings may help identify injury risk factors that can be targeted in ACL injury prevention programs.

The Effects of Kinesio Taping on Countermovement Jump Performance Before and After Fatigue in Collegiate Basketball Athletes

Dr. Po-Teng Huang[1,2], Lecturer Che-Yi Yang[3], Professor Jia-Hao Chang[1]

[1]Department of Physical Education and Sports Sciences, National Taiwan Normal University, Taipei, Taiwan, Taiwan. [2]Office of Physical Education, Fu Jen Catholic University, New Taipei, Taiwan, Taiwan. [3]Department of Physical Education, Fu Jen Catholic University, New Taipei, Taiwan, Taiwan

Introduction

Kinesio Taping (KT) is widely used in sports, but its acute biomechanical effects remain unclear in trained athletes. This study investigated the immediate effects of KT on countermovement jump (CMJ) performance before and after fatigue in collegiate basketball players.

Methods

Six male athletes completed CMJ testing under three taping conditions: non-taping, placebo taping, and KT applied with 50% tension to the both quadriceps muscles. The CMJ trials before and after fatigue procedures were recorded by a force plate in each condition. Jump height was calculated using flight time, and take-off impulse was obtained by integrating vertical ground reaction force from the lowest center of mass (COM) position to take-off. A two-way ANOVA with repeated measurement was used to evaluate the effects of taping condition, fatigue, and their interaction.

Results

The values of jump height in non-taping, placebo, and KT groups before fatigue procedure were 39.05 ± 5.04, 37.32 ± 5.27, and 36.80 ± 5.39 cm, respectively. And the values were decreased to 28.46 ± 5.21, 28.99 ± 7.19, and 27.66 ± 4.44 cm after fatigue procedure. No significant effects were noted in take-off impulse.

Discussion

These findings indicate that KT does not acutely enhance jump height or take-off impulse and does not mitigate fatigue-related performance decline. The effects observed may reflect the high neuromuscular efficiency of trained athletes, limiting the potential influence of external sensory input. Although KT may provide benefits in joint support, proprioception, or injury conditions, its acute biomechanical influence on explosive tasks appears minimal in healthy trained populations. Further research with larger samples and

additional biomechanical variables is recommended to clarify the conditions under which KT may provide functional benefits.

Does a Directional Compression Garment Alter Lower-Body Kinematics and Jump Performance?

Mr. John Grace, Dr. Bahman Adlou, Dr. Christopher Wilburn, Dr. Wendi Weimar

Auburn University, Auburn, AL, United States

Introduction

Athletes choose to wear compression garments when competing to provide support and improve performance. Previous literature has indicated that compression wear alters movement patterns [1]. Some companies are designing directional compression wear to mitigate poor mechanics and improve performance, yet their efficacy is still in question. Therefore, this study analyzed the ability of directional compression garments to alter joint angle and jump performance.

Methods

Ten healthy men (180.27 ± 7.99 cm, 85.75 ± 12.16 kg) between the ages of 18 and 40 provided informed consent and participated in this project. They completed 5 trials of two different movements: counter-movement jump (CMJ) and 30 cm drop jump (DDJ) in two conditions: wearing normal compression shorts and wearing shorts with directional compression. The directional compression shorts have a band fixed on the outside of the shorts in the sacrum area that travels around the lateral side of the thigh to the medial portion of the thigh, just above the knee. The proposed intervention is to encourage external rotation of the hip. The last 3 jumps of each set were used for analysis. Jump height and hip rotation angles for each leg were collected at their peak and at the bottom of the countermovement for each leg. Linear mixed models were used on each outcome variable, with condition and movement as fixed effects and participant as a random effect.

Results

None of the outcome variables showed significant differences between the shorts conditions. There was a significant difference in jump height between the CMJ and DDJ trials ($p<.001$), so this data was separated and reanalyzed. After further analysis, there was no significant difference in jump height between the shorts conditions in either jump trial type.

Discussion

This project indicates that directional compression garments may not be able to control specific movement pattern alterations during dynamic motions. While traditional

compression attire such as shorts and tights has been shown to alter movement patterns, including reducing hip abduction, this style of directional compression shorts was not able to provide any significant improvement over existing compression attire during functional sport-specific movements.

Impact of Upper-Extremity Training on Shoulder Abduction Acceleration During Rapid Reactive Movements

Dr. Jonathan Lee-Confer Ph.D., Ms. Sierra Bogner B.S., Dr. James Tracy Ph.D.

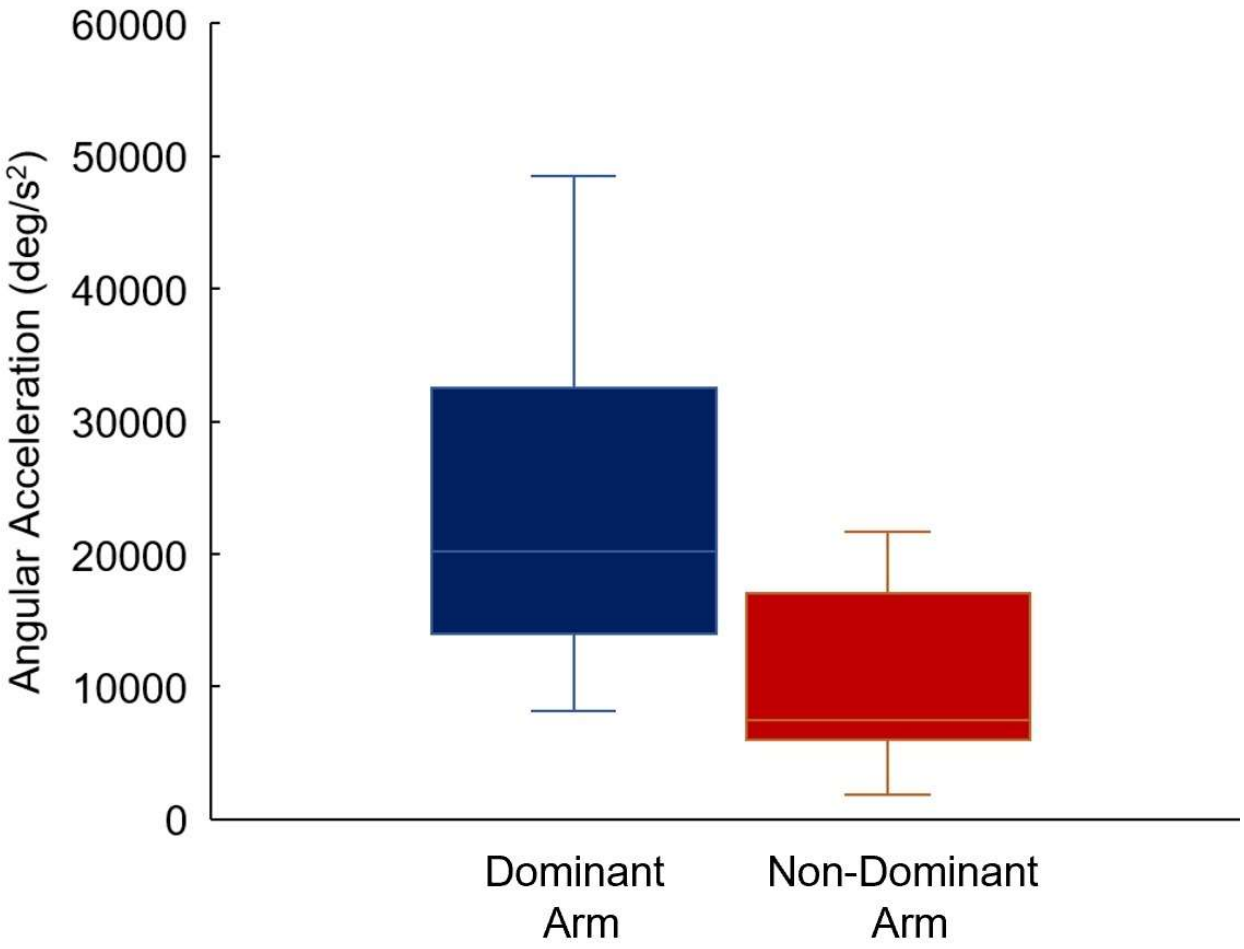
University of Arizona, Tucson, Arizona, United States

Introduction

Falls impose substantial healthcare costs and remain a major public health concern. Current fall-prevention programs emphasize lower-extremity training. Recent biomechanical evidence also highlights a rapid arm movement's ability, particularly shoulder abduction, to restore stability during slips or trips. Whether individuals with targeted upper-extremity training exhibit faster abduction responses is unknown. Racket-sports athletes utilize their dominant arm for high-velocity overhead movements like serves and forehands, resulting in a disproportionate exposure and training compared with the non-dominant arm. Determining whether training influences shoulder abduction acceleration may guide development of arm-focused interventions to reduce fall risk.

Methods

To date, this study enrolled 3 male trained athletes in racket sports (mean(SD) 28 (11) y/o, 183 (5) cm, 84 (8.6) kg). An inertial measurement unit (MetaMotionRL, MBientLab, USA, 800 Hz) was secured to the middle upper arm (dominant and non-dominant). Participants stood with arms at their side and were instructed to perform shoulder abduction "as fast as possible without moving the trunk". Five maximal-effort repetitions for each arm with one minute of rest between trials were conducted. IMU-derived peak shoulder abduction acceleration served as the primary outcome. Each participant's five trials were averaged to yield a single peak acceleration value for the dominant and non-dominant arms. A paired samples t-test with Cohen's *d* effect size was conducted to compare the peak abduction acceleration between the dominant and non-dominant arms.



Results

Peak shoulder abduction acceleration was greater in the dominant arm compared with the non-dominant arm with a large effect size (dominant: 24667 (13295) deg/s^2, non-dominant: 13051 ± 11054 deg/s^2, $p = 0.01$, $d = 0.95$).

Discussion

These findings demonstrate that trained upper-extremity function is associated with faster shoulder abduction acceleration. This between-arm difference suggests that upper-extremity training and repeated sport-specific use may enhance the reactive capacity of the shoulder abductors. Given that rapid arm movements contribute to stabilizing the body during slips and trips, these results support the premise that arm-focused training may be a modifiable factor for improving protective arm reactions during balance disturbances. The observed acceleration asymmetry provides preliminary evidence for targeting upper-extremity strengthening or power-based training into fall-prevention programs.

Subjective and Objective Assessment of Cleated Footwear Preference

Dr. Brett Pexa[1], Dr. Jeffrey Taylor[1], Mr. Garrett Hess[1], Mr. Joseph Helseth[2], Mr. Noah Rauch[1], Ms. Isabelle Lee[1], Dr. Kevin Ford[1]

[1]High Point University, High Point, NC, United States. [2]Nike Sport Research Lab, Beaverton, OR, United States

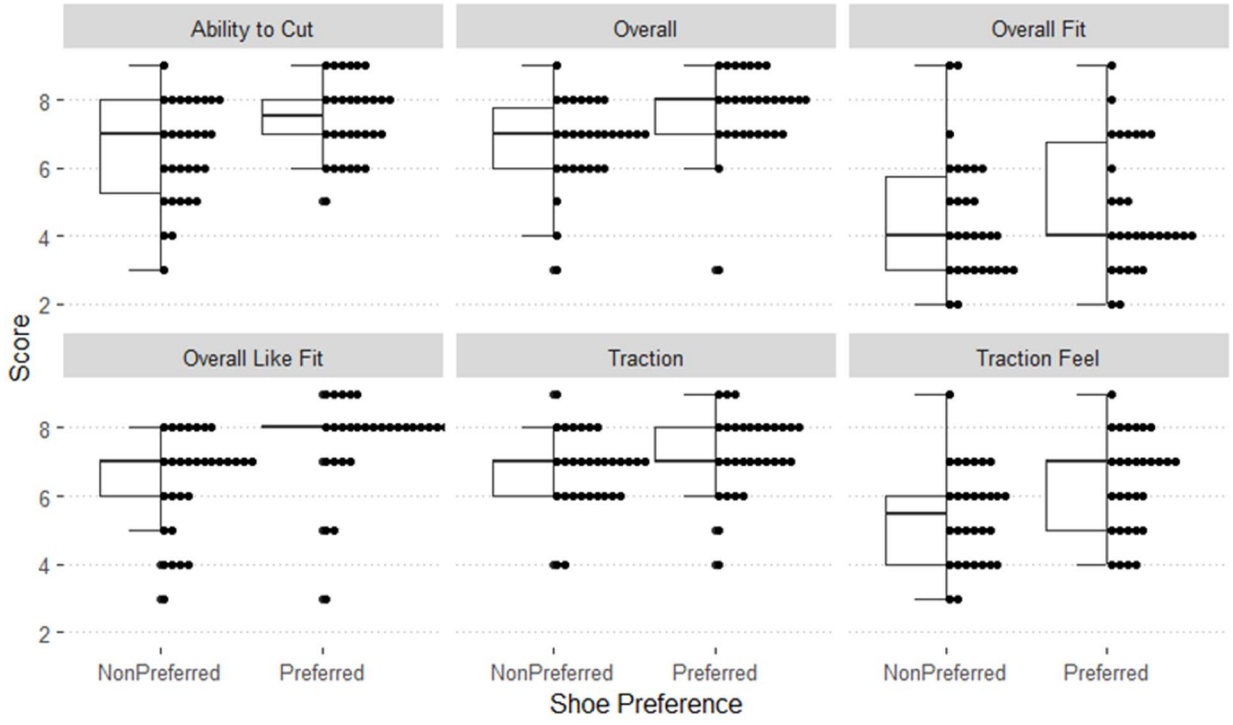
Introduction

There is limited subjective and objective data on the preference for specific cleated footwear. The purpose of this study was to determine the differences in subjective and objective outcomes between preferred and nonpreferred cleated footwear in a collegiate soccer population.

Methods

Thirty collegiate soccer athletes (15M, 15F, age: 21.0 ± 1.2 yrs; mass: 78.5 ± 7.1 kg; height: 177.9 ± 5.5 cm) completed 180-degree cutting trials in two randomized cleated conditions (Nike Phantom GX II Elite Artificial Grass (AG) & Nike Phantom GX II Elite Firm Ground (FG)) over an infill turf surface. The footwear had the same upper and midsole, with different soleplate configurations. During the cutting tasks, kinematics were captured with 14 motion capture cameras (200Hz) and two in-ground force plates (1200Hz). After each cleated condition, participants provided self-reported data on fit, traction, and cutting ability. Participants were asked, following the completion of all trials, to indicate the shoe they preferred. Self-reported data was compared with Wilcoxon signed rank tests (W) and associated effect size (r). A paired t-test was used to compare lower extremity biomechanics between preferred and nonpreferred shoes.

Results



Fifteen participants preferred AG (7F, 8M) and fifteen preferred FG (8F, 7M). There was a significant difference between preferred and non-preferred shoes regarding how participants perceived the fit, the overall shoe, the ability to cut, and the feel of the traction ($p<0.05$). The preferred shoe had more favorable scores in the overall rating of the shoe ($W = 236.5$, $p = 0.001$, $r = 0.42$), ability to cut ($W = 286.5$, $p = 0.013$, $r = 0.32$), the traction feel ($W = 186.5$, $p = 0.013$, $r = 0.32$), and the overall enjoyment of the fit ($W = 192.5$, $p<0.001$, $r = 0.51$) than the nonpreferred shoe. There were no significant differences in cut performance,

ground reaction forces, or utilized traction measures between preferred and nonpreferred shoe.

Discussion

There are subjective differences between preferred footwear, however no significant differences were found in biomechanics. Future research should continue to measure subjective outcomes related to shoe preference to determine if shoe preference influences lower extremity biomechanics.

Rowers With Low Back Pain Demonstrate Altered Kinematic Patterns That May Reflect a Strategy of Trunk Restriction and Invariant Timing in Static vs. Dynamic Ergometry

Ms. Julia Tamai, Dr. Stephanie Jones

Smith College, Northampton, Massachusetts, United States

Introduction

Low back pain (LBP) accounts for up to 53% of injuries among competitive rowers, which is associated with ergometer training volume, total training hours, and fatigue. Stationary ergometers are associated with higher loads during training as the rower must contend with motions not dampened by inertia of dynamic ergometer motion. Standard rowing ergometry is also confined to sagittal movements, however, sweep rowers use one oar when on water employing asymmetric patterns of trunk rotation and side bending. This mismatch may provide a misalignment between the demands of on-water rowing and trained movements. The purpose of this study was to investigate joint kinematic patterns of rowers with and without LBP when performing static vs. dynamic ergometry at two stroke rates.

Methods

Five female collegiate rowers with LBP (rLBP) and five without (CON) rowed on an ergometer for two randomized blocks, static vs. dynamic (ergometer on sliders to allow translation); in each block, participants rowed at Low and High (20 vs. 30 strokes/min) cadence each for 5 minutes. Reflective markers were placed on 13 body segments and recorded using high speed digital cameras. 3D kinematics of trunk and lower limbs bilaterally were computed; cycle parameters, joint ranges of motion (ROMs) and peak angular velocities were computed and analyzed using mixed model repeated measures ANOVAs (ergometer modeXstrokeXgroup) with significance set at $P<0.05$.

Results

rLBP had invariant cycle times between static vs. dynamic, with trends to longer drive and shorter recovery phases; CON demonstrated reduced cycle time in dynamic vs. static. Ankle and knee ROMs were similar between groups, but rLBP demonstrated increased hip ROM and decreased trunk ROM compared to CON. Similarly, rLBP demonstrated increased hip and tended to decrease trunk peak velocities compared to CON.

Discussion

rLBP demonstrated increased hip motion and restricted trunk motion regardless of stroke rate or ergometer condition. Movement patterns were invariant among rLBP between conditions, particularly in cycle timing and trunk velocity, which may be an attempt to restrict trunk movement. Prolonged drive and shortened recovery phases among rLBP could contribute to fatigue, which may increase susceptibility to pain. Additional analyses will assess asymmetries and multi-joint coordination.

Biomechanics of Slide Board Training in Sprint Speed Skaters

Jung-Min Yoon M.S.[1,2], Prof. Sukhoon Yoon Ph.D.[1,2], Prof. Sihyun Ryu Ph.D.[1,2], Prof. Sang-Kyoon Park Ph.D.[1,2]

[1]Korea National Sport Univercity, Seoul, Seoul, Korea, Republic of. [2]Motion Innovation Center, Seoul, Seoul, Korea, Republic of

Introduction

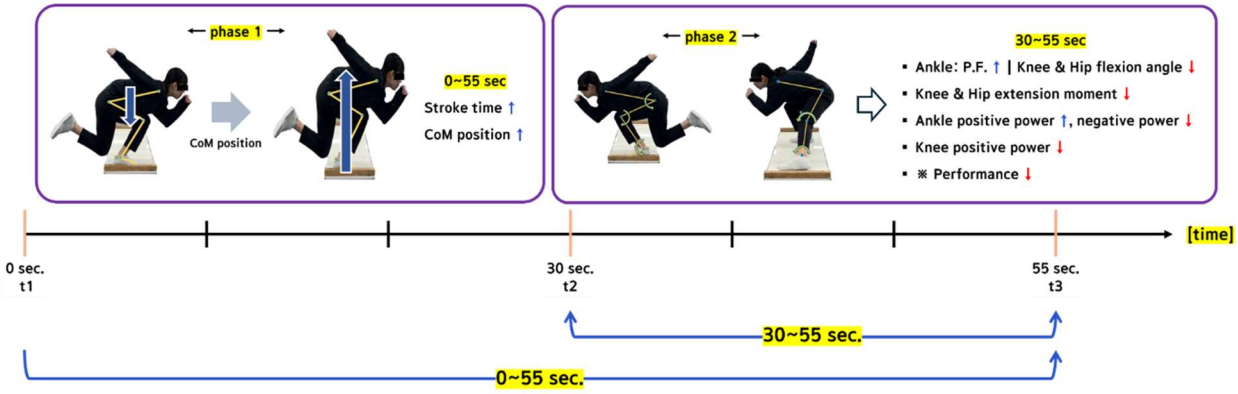
The purpose of this study was to analyze temporal changes in biomechanical variables during slide-board movements in 500m speed skating athletes and to provide various insights for improving performance and technique.

Methods

Ten elite male short-distance speed skaters in their 20s and 30s (n = 10; age: 23.5 ± 3.4 yrs, height: 174.7 ± 3.1 cm, weight: 74.9 ± 5.9 kg) participated in the study. Eight infrared cameras (sampling rate: 100 Hz), one force platform (sampling rate: 1,000 Hz), and a custom-made slide board were used for data collection. The variables analyzed included trunk segment angles, lower-limb joint angles, and lower-limb joint moments. In this study, five strokes were extracted and analyzed at 0 s, 30 s, and 55 s, and one-way repeated-measures ANOVA were conducted for statistical analysis. The level of statistical significance was set at $\alpha = .05$.

Results

The results showed that, over time, ankle plantarflexion angle and knee extension, and hip extension angles increased during the push-off phase ($p<.05$), while knee and hip extension moments decreased ($p<.05$).



Discussion

Increased in ankle plantarflexion angle can cause the blade tip to scrape the ice during the stroke, resulting in deceleration (Ingen Schenau, De Groot, Scheurs, Meester & De Koning, 1996). Conversely, maintaining greater lower-limb flexion during the push-off phase enhances pushing force and consequently increases propulsive power. De Boer et al. (1987) reported that larger pushing forces lead to greater knee and hip extension moments during the stroke. However, if knee and hip extension angles increase while extension

moments decrease, the skating posture becomes more upright, which reduces the magnitude of pushing force and step width, ultimately impairing performance.

Therefore, athletes should aim to maintain a flexed lower-limb position throughout the push-off phase during slide-board training. This strategy is expected to positively influence key biomechanical factors and enhance on-once skating performance.

The Implications of the Menstrual Cycle on Upper Extremity Performance Metrics

Ms. Emma Cochran[1], Dr. Kaitlyn Armstrong[2], Dr. Thomas Andre[2], Dr. Corbit Franks[2], Dr. Chip Wade[2]

[1]University of Mississippi Medical Center, Jackson, MS, United States. [2]University of Mississippi, University, MS, United States

Introduction

There has been a significant rise in the number of female athletes participating sports. While there are a variety of studies looking at physiology in sports on performance, training methods, and injuries; this research is often generalized. When it comes to female-specific physiology concerning training and performance, there are very few high quality studies. One area of interest is the menstrual cycle in the female population. The literature suggests biological plausibility for changes in joint laxity and muscle repair throughout the various phases of the menstrual cycle, which can affect how female athletes perform and respond to training. To optimize performance, potentially reduce injury risk, and ensure better care for female athletes, a deeper understanding of the implications of these hormonal fluctuations is crucial.

Methods

16 physically active females completed the study. Saliva samples were completed at each visit to confirm menstrual cycle phase and urinary testing was completed prior to visits 2 and 5 to confirm ovulation, while the Proteus Motion was used for physical assessments. The Proteus evaluates the full range, velocity, and power of upper and lower extremity movement profiles. The participants completed a testing protocol consisting of 7 different tests. These tests include (1) chest press and pull, (2) straight arm trunk rotation, (3) PNF D2 flexion and extension. Visits were timed to occur within 96 hours of the onset of menses, within 24 hours of a positive urinary LH test, and 7 to 9 days post-ovulation.

Results

There were quantitative and statistical differences across Proteus measures. Most notably, there were significant quantitative differences within cycle 1 for visits 1 and 2 (ΔP= 12.982W), visits 2 and 3 (ΔP= 9.471W), and visits 1 and 3 (ΔP= 22.453W). While there were quantitative differences across matched phases across cycles, these differences were insignificant.

Discussion

The results of this study suggest that the luteal phase of the menstrual cycle was associated with enhanced performance in certain upper extremity tasks involving power, velocity, acceleration, and deceleration. however, there was no clear phase-specific effect. Future research should further investigate the relationship between the typical hormonal fluctuations across the cycle.

The Effect of Sex-Specific Footwear on Cutting Kinematics in Youth Female Soccer Players

Ms. Karen Chen PhD(c), PT[1,2], Mr. Ethan W.C. Wilkie PhD(c), MSc[1], Mr. Nicolas Herrera MSc[3], Dr. Shawn Robbins PhD, PT[1,2]

[1]McGill University, Montreal, Qc, Canada. [2]Center for Interdisciplinary Research in Rehabilitation, Montreal, Qc, Canada. [3]Shriners Hospitals for Children, Montreal, Qc, Canada

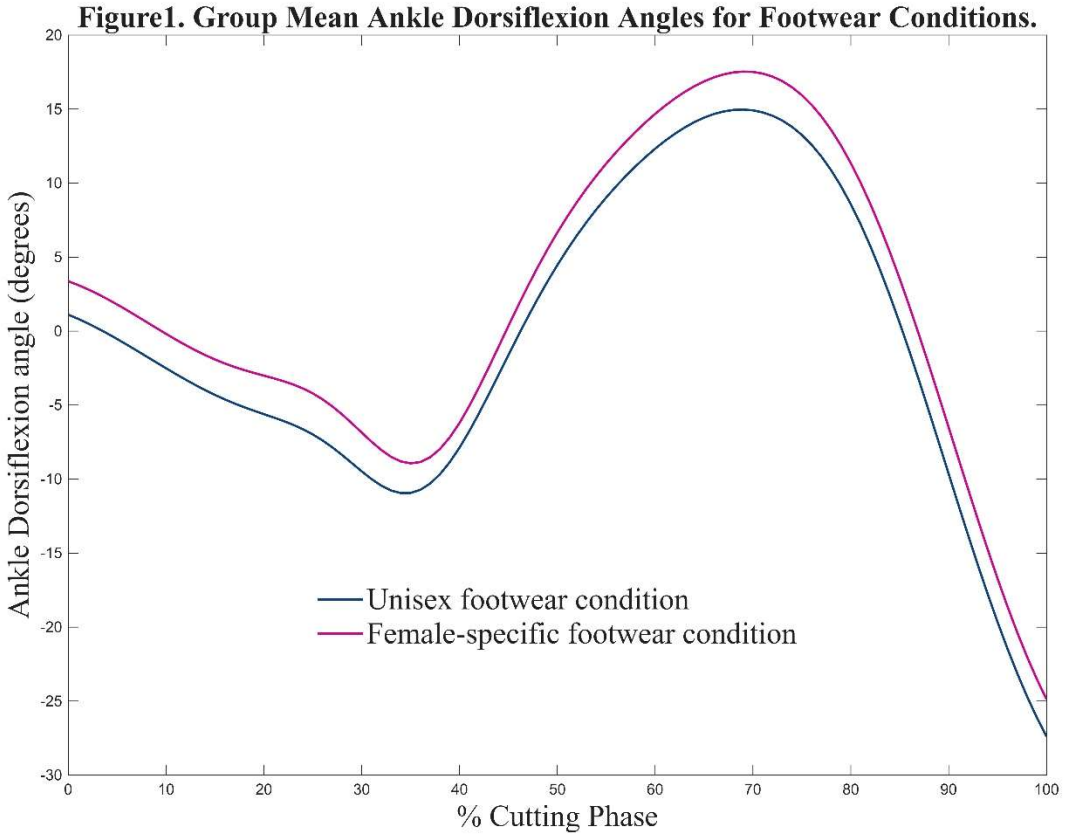
Introduction

Injury rates in female athletes are disproportionately higher than males. Sex differences have been identified in foot morphology and movement patterns during sport-specific movements. Yet, soccer footwear for females are commonly manufactured using a male foot template (i.e., last), overlooking distinct biomechanical sex differences. Therefore, this study examined whether sex-specific soccer cleats affect joint kinematics during unanticipated sidestep cutting, compared to unisex soccer cleats among female youth soccer players.

Methods

This cross-over study recruited 32 female soccer players, aged 13-17 years old and enrolled in the sport etude program at Soccer Montreal. Participants tested both the female-specific (IDA centra FG/AG) and unisex (Nike Tiempo Legend 10 Academy, multi-ground) cleats. Kinematic data were captured using markerless motion capture system (Miqus Video, Qualysis, 120Hz, 720p resolution) during unanticipated sidestep cuttings at $45^0 \pm 10^0$ on indoor artificial turf and processed with Theia3D. Principal component analysis extracted important features from trunk and lower extremity joint angles. Hierarchical linear model examined the impact of shoe condition on angle principal component scores (*PC-scores*).

Results



Specifically, female-specific shoe condition showed greater differences in knee flexion angles (*PC2-scores*, p=0.03) between early/mid-stance (0-50%) and late stance (60-100%) of cutting, and greater ankle dorsiflexion angles throughout cutting (*PC1*, p=0.002) and during mid/late stance (40-80%, *PC2*, p=0.04) than the unisex footwear (Figure1). Female-specific footwear showed greater ankle inversion angles throughout cutting (*PC1*, p<0.001) and greater differences in inversion angles between mid/late (50-80%), pre/early (0-30%) and late stance/foot-off (90-100%, *PC3*, p=0.002) than the unisex footwear. Additionally,

unisex footwear showed greater differences in ankle inversion angles (PC2, $p<0.001$) between early/mid (25-50%) and late stance (80-100%) than the female-specific footwear. No differences between shoe conditions were found for other joint angles.

Discussion

Female-specific footwear may allow greater mobility at the ankle. As most findings pertain to the ankle, there may be potential effects regarding stabilization of the ankle during midstance and pre-positioning the foot towards the cutting direction (ankle inversion). Although these findings may have less impact on injury. These insights may further the understanding of female adaptations during cutting and aid in the development of more targeted female-specific footwear.

The Effect of Sex and a Shortened FIFA11+ Warm-Up Program on Cutting Kinematics in Youth Soccer Players

Ms. Karen Chen PhD(c), PT[1,2], Mr. Ethan W.C. Wilkie PhD(c), MSc[1], Mr. Nicolas Herrera MSc[3], Mr. Adrien Moufflet MSc[4], Dr. Moreno Morelli MD, MSc, FRCSC[5], Dr. Shawn Robbins PhD, PT[1,2]

[1]McGill University, Montreal, Qc, Canada. [2]Center for Interdisciplinary Research in Rehabilitation, Montreal, Qc, Canada. [3]Shriners Hospitals for Children, Montreal, Qc, Canada. [4]Roses de Montreal, Montreal, Qc, Canada. [5]St. Marys Hospital, Montreal, Qc, Canada

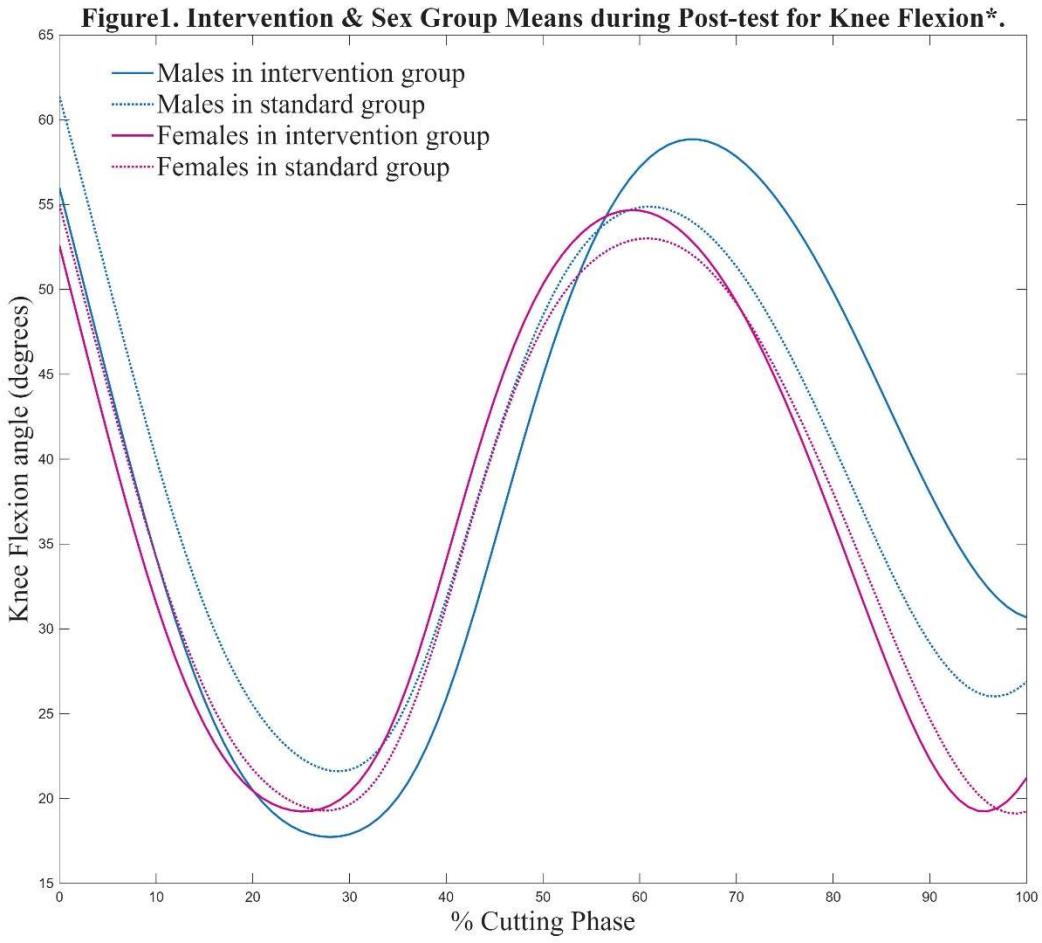
Introduction

Injury prevention programs, such as the FIFA11+ have been proposed to decrease soccer-related injury rates. However, exercise adherence remains challenging and its ability to modify at-risk movement patterns remains unclear. This study examined the effect of sex and a shortened FIFA11+ program lasting 3 months, compared to a standard warm-up program, on joint kinematics during unanticipated sidestep cuttings in youth soccer players.

Methods

Sixty-four healthy soccer players (32 males, 32 females), aged 13-17 years old and enrolled in the sport etude program at Soccer Montreal, were recruited for this two-group parallel randomized controlled trial. The standard group (SG, n=32) followed a Brazilian warm-up, while the intervention group (sFIFAG, n=32) followed a shortened FIFA11+ warm-up consisting of five exercises from the original FIFA11+, focusing on lower-extremity alignment and cutting-specific tasks. Programs were conducted at least twice a week for 3 months. Data were captured at baseline and 3-months using a markerless motion capture system (Miqus Video, Qualysis, 120Hz, 720p resolution) during unanticipated sidestep cuttings at $45^0 \pm 10^0$ and processed with Theia3D. Principal component analysis extracted important features from lower extremity and trunk angles. An analysis of covariance examined sex and intervention effects on angle principal component scores (*PC-scores*), while accounting for baseline angle using a per protocol approach.

Results



One intervention effect was found for ankle dorsiflexion (*PC3-scores*) showing greater differences in angles between pre/early stance (0-30%) and late stance (60-90%) of cutting for sFIFAG than SG (p=0.02). Intervention and sex interaction effects showed lower knee

flexion during late stance (60-100%, *PC2*, post-hoc p=0.01) (Figure 1) and greater differences in ankle dorsiflexion between mid-stance (40-75%) and late stance/foot-off (90-100%, *PC2*, post-hoc p=0.01) in males for SG than sFIFAG. Within sFIFAG, females showed greater differences in ankle dorsiflexion *PC2-scores* (post-hoc p=0.04) than males. Differences between sexes were found for hip flexion, knee adduction, and trunk rotation and side-flexion.

Discussion

A shortened FIFA program showed potential influences in cutting patterns, although at-risk patterns (e.g., excessive knee abduction) were not improved. Sex differences remained prominent, indicating potential needs of sex-specific prevention programs. Nonetheless, these insights may help in the development of more effective training programs.

Training Characteristics and Individual Variability Among Recreational Runners: Implications for Running Load Monitoring

Mr Jasper Wong MSpEx[1], Dr Hannah Wyatt PhD[1,2,3], Associate Professor Chris Whatman PhD[1], Dr Matt Cross PhD[1], Associate Professor Kelly Sheerin PhD[1]

[1]Sports Performance Research Institute NZ, Auckland University of Technology, Auckland, Auckland, New Zealand. [2]Sports, Health and Rehabilitation Research Cluster, University of Canterbury, Christchurch, Canterbury, New Zealand. [3]Biomolecular Interaction Centre, University of Canterbury, Christchurch, Canterbury, New Zealand

Mr Jasper Wong

Dr Hannah Wyatt

Associate Professor Chris Whatman

Dr Matt Cross

Introduction

Much of the running-related injury research has been lab-based, targeting specific biomechanical variables. This does not account for load accumulation or individual training preferences, both important considerations for individuals who run for long periods of time, with substantial contributions from injury risk factors, which may contribute to more injuries. Wearable technology developments allow for the monitoring of biomechanical variables and workload accumulation during normal training. The purpose of this study was to describe the training characteristics of recreational runners to better understand differences in training profiles and the implications for ongoing load monitoring.

Methods

One-hundred injury-free recreational runners were recruited. Participants' self-selected (normal) training pace was determined on a treadmill, followed by two velocity bands below and above their normal training pace, in 0.3 m/s increments. Habitual running was captured via a GPS smartwatch for 26 weeks. Data were processed to align with the five predetermined velocity bands. Weekly velocity-band totals were expressed as proportions of each athlete's total weekly distances and summarised at two levels: 1) between-individual differences, using each runner's typical weekly proportion per band (as mean and standard deviation [SD] of individual means, and coefficient of variation [CV]); 2) within-individual variability, reflecting week-to-week fluctuations (mean of each runner's SD).

Results

93,478 km of data were collected from 9776 sessions. Variability between individuals in the proportion of distance covered was greatest at the 'slowest' and 'fastest' velocity bands (CV=75-133%), while the 'slow' and 'normal' velocity bands were more consistent between athletes (CV=43-49%). Within-runner absolute variability was greatest in the 'slow' and 'normal' velocity bands (mean SD=0.155-0.156), and lowest in the 'fastest' velocity bands (mean SD=0.049-0.061).

Discussion

Training profiles differed markedly between runners, especially in the extreme velocity bands (slowest and fastest), suggesting runners accumulate volume differently. However, the greatest absolute week-to-week variation for individual runners was in moderate velocity bands, where the two fastest bands showed less (likely explained by intermittent and lower proportional volumes). These findings highlight runners differ in how they structure their training, which may not be evident from session-averaged data. Therefore, velocity-banded data provides a more informative representation for load monitoring.

Audio Versus Visual Unanticipated Stimuli on Kinetics and Kinematics in a Run-to-Cut Maneuver

Miss Kendra Graham, Dr. Joshua Weinhandl

University of Tennessee, Knoxville, TN, United States

Introduction

Anterior cruciate ligament (ACL) injuries are among the most common sport-related knee injuries, with almost 250,000 instances annually in the United States. Approximately 70% occur via non-contact mechanisms, often during rapid loading and directional changes such as sidestep-cut. These tasks elicit knee joint kinematics associated with increased ACL strain, such as an increase in knee adduction moment. During sport, athletes frequently respond to auditory and visual cues, yet the influence of stimulus modality on knee kinematics and kinetics is still unclear. Understanding these effects will inform injury prevention and rehabilitation strategies. The purpose is to determine if knee kinematic and kinetic differences exist in a sidestep-cut in response to an unanticipated audio versus visual stimulus.

Methods

16 individuals performed unanticipated sidestep-cut maneuvers in response to visual (arrow) and auditory ("right"/"left") stimuli at approach speeds of 3.0m/s–3.5m/s. Three-dimensional marker coordinate and ground reaction force data were collected for each trial. Peak knee angles and moments were extracted for analysis. Separate 2×2 repeated measures ANOVAs (limb×condition) were performed (α=.05).

Results

Significant stimulus × direction interactions were observed for peak knee adduction moment (pKAM, p=.044), peak knee abduction angle (pKAA, p=.006), and peak knee rotation angle (pKRA, p=.007). Audio cues elicited greater pKAM during left direction cuts compared with visual cues (p=.02) and with audio right direction cuts (p=.01). In contrast, visual cues produced greater pKAA (p<.001) and pKRA (p=.007) during right direction cuts compared with audio cues.

Discussion

Sensory modality differentially influences frontal and transverse plane knee mechanics in a limb specific manner during unanticipated cutting. When planting on the dominant limb and cutting to the left, auditory cues specifically resulted in increased pKAM, a variable

notably associated with ACL injury risk. Conversely, visual cues resulted in larger pKAA and pKRA when planting on the nondominant limb and cutting to the right. Results suggest auditory stimulus may have greater influence on the dominant limb while visual stimulus may have greater influence on the non-dominant limb during an unanticipated cut maneuver. Incorporating multimodal reaction stimuli into training and rehabilitation may improve adaptability and neuromuscular control during unpredictable situations that result in risky biomechanics.

The Influence of Calibration Poses on Scapular Kinematics during the Windmill Softball Pitch

Dr. Kenzie B. Friesen, Dr. Angelica Lang

University of Saskatchewan, Saskatoon, Saskatchewan, Canada

Introduction

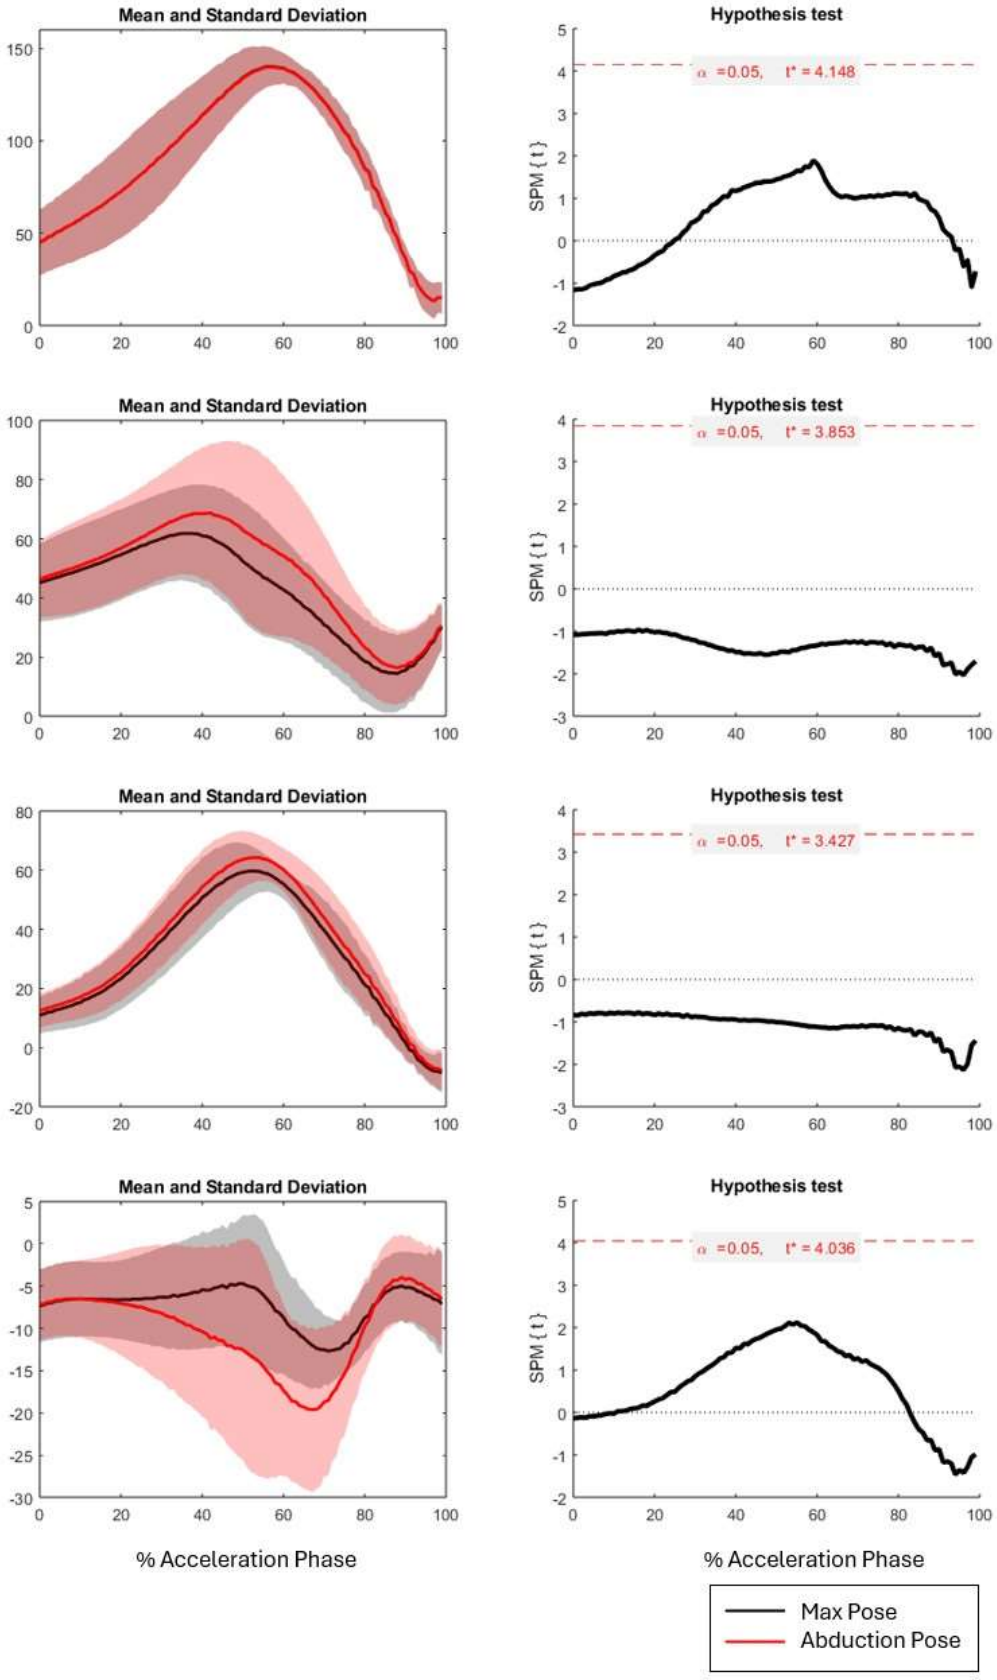
Unique properties of the scapula make it difficult to measure, particularly during fast motions like the windmill pitch. Targeted procedures may improve the accuracy of scapular motion tracking [1], allowing for characterization of scapular motion during softball pitching. This study compared scapular and humeral kinematics during the windmill pitch using two scapular calibration procedures.

Methods

Seven youth softball pitchers (15±2 years, 167±31cm, 70±14kg) completed 5 fastball pitches (averaged for analysis) while their upper body motion was tracked. Landmarks of the scapulae were first digitized during three poses: rest, maximal humeral elevation, and 90º shoulder abduction. Scapular angles were estimated based on humeral elevation using a double calibration procedure [1] with two sets of poses: 1) rest and maximum humeral elevation, and 2) rest and 90º humeral abduction. Paired t-tests compared kinematics between the two calibrations at pitch events including “top of pitch” (peak humeral elevation), “stride foot contact,” and “ball release.” Statistical parametric mapping t-tests were conducted to compare kinematics during the pitch acceleration phase (peak push off the ground to ball release).

Results

Humeral elevation, scapular internal, and upward rotation did not differ at pitch events or during the acceleration phase of the pitch between calibration poses ($p>0.05$) (Figure 1).



Discussion

Results indicate that double calibration methods produce similar scapular angles at discrete pitch events and during the pitch acceleration phase. Mean scapular angles from this current study report greater scapular motion than previous literature [2]. Given the double calibration procedure estimates scapular angles based on humeral elevation, and the humerus achieves near 140º humeral elevation throughout the windmill pitch, it is hypothesized that the double calibration procedure may more accurately assess scapular

angles predominantly during high range of motion tasks and should be incorporated for dynamic overhead tasks.

Limitations include the small sample size. More participants across a broader skill range are necessary to explore the influence of multiple poses on scapular kinematic calculations. Future research might seek to explore the effects of implementing multiple poses to reflect certain pitch positions.

Traction and Perception Differences During Cutting Between Female Collegiate Soccer and Lacrosse Players

Dr. Kevin Ford, Mr. Garrett Hess, Dr. Jeffrey Taylor, Mr. John Kilzi, Mr. Quinn Hopkins, Ms. Ashley Glass, Dr. Brett Pexa

High Point University, High Point, NC, United States

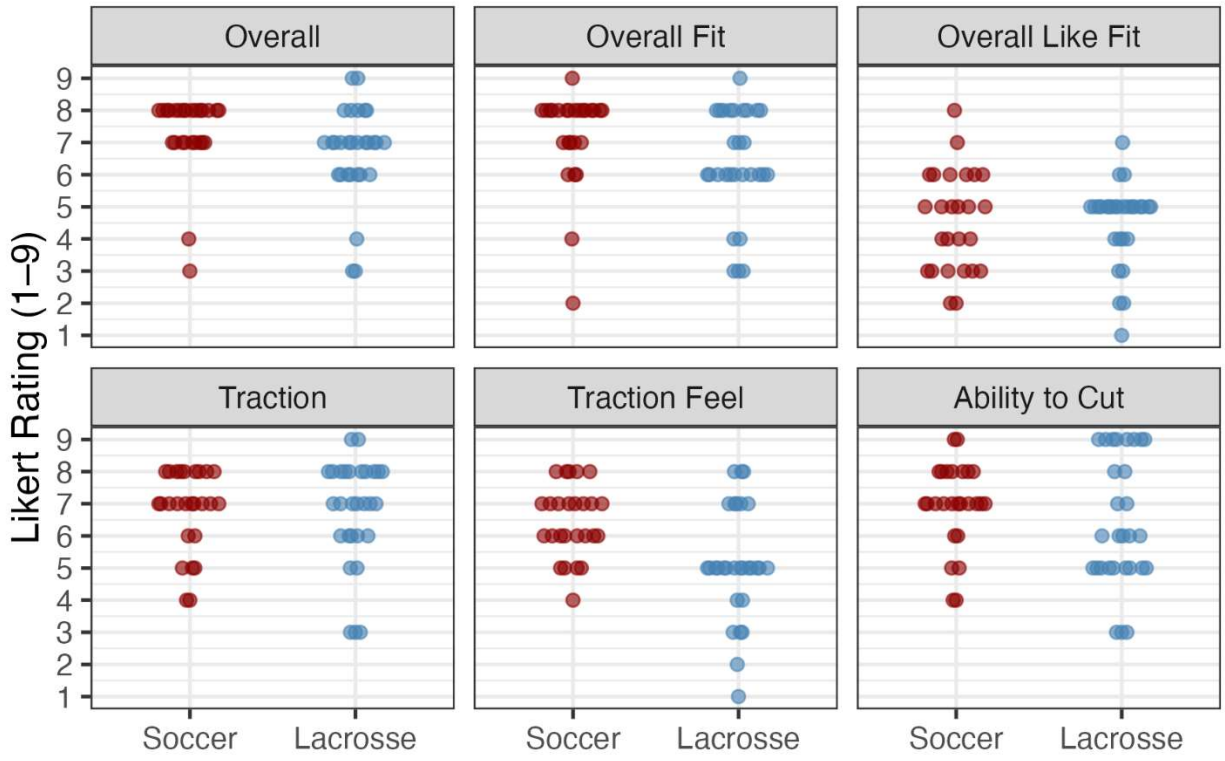
Introduction

Subjective ratings of cleated footwear during cutting tasks may provide distinct insights when combined with utilized traction and biomechanical analyses. Both female soccer and lacrosse athletes increasingly participate on synthetic turf surfaces. The purpose of this study was to compare the traction and perception of currently worn footwear during a cutting task between collegiate soccer and lacrosse players.

Methods

55 female collegiate soccer (n=26) and lacrosse (n=29) players (age: 20.0 ± 1.3 yrs; mass: 63.7 ± 6.8 kg; height: 165.6 ± 5.6 cm) performed left foot and right foot 180-degree cutting on an infill turf surface. Participants were asked to wear the cleats they currently use when playing on synthetic turf fields. Vertical and horizontal ground reaction forces were collected with two in-ground force plates (1200Hz). Following the completion of trials, a survey was administered. Three items assessed overall liking, fit, and traction preference using a 9-point Likert scale ranging from *Dislike Extremely (1)* to *Like Extremely (9)*. Three additional items used construct-specific anchors: overall fit feel (*Very Tight (1)* to *Very Loose (9)*), traction feel (*Very Slippery (1)* to *Very Sticky (9)*), and ability to cut (*Very Unconfident (1)* to *Very Confident (9)*). Differences between soccer and lacrosse players were evaluated for survey Likert scores (1-9) (Mann-Whitney U) and ground reaction force (independent t-test) variables.

Results



Traction feel was greater (closer to “sticky”) in soccer players compared to lacrosse players ($p=0.002$). However, there were no group differences in how much they liked or disliked the traction of the footwear ($p=0.9$). Soccer players also rated footwear higher in overall liking ($p=0.014$) and overall fit feel ($p=0.024$, closer to “loose”). Utilized translational traction was not different ($p=0.6$) between lacrosse players (0.77 ± 0.06) compared to soccer players (0.77 ± 0.04). Statistically significant differences were not found between sports for peak

vertical (Soccer 2.1 ± 0.3xBW, Lacrosse 2.0 ± 0.3 xBW, p=0.7) or braking force (Soccer 1.39 ± 0.2 xBW, Lacrosse 1.39 ± 0.2 xBW, p=0.98).

Discussion

Soccer players subjectively perceived their footwear traction to "feel" more "sticky" than lacrosse players which appears to contrast the utilized translational traction results. Additional studies should investigate the effects of varying footwear and surface conditions.

Estimating Baseball Pitch Velocity from Popular Field-Based Performance Tests

Dr. Kiara Barrett[1], Ms. Neha Kapoor[2], Dr. Lauren A Luginsland[3]

[1]Bertec Corporaation, Columbus, Ohio, United States. [2]Bertec Corporation, Columbus, Ohio, United States. [3]University of South Florida, Tampa, Florida, United States

Introduction

Baseball pitching is a multifaceted full-body movement with complex movement patterns. The countermovement jump, squat jump, isometric mid-thigh pull, hop test and plyometric push-up are often performed during pitching training sessions and utilized as quantitative measures of muscular improvement, despite differing movement profiles. While previous research demonstrated associations between pitch velocity (PV) and metrics from performance assessments [1], no studies integrated these metrics into a comprehensive predictive model. The purpose of this study was to use kinematic and kinetic metrics from standard upper- and lower-body performance assessments to predict PV in collegiate baseball players using multivariate regression analyses.

Methods

Performance and pitching data from 167 male collegiate athletes (89.28±10.09kg, 21.29±2.25yrs, 1.85±0.07m) were collected on ForceDecks and Bertec force plates, stored in Driveline's OpenBiomechanics dataset [2], and retrospectively analyzed. An elastic net generalized regression model ($\alpha = 0.99$) with BIC stopping rule-based selection was used to predict peak PV (mph) from 35 performance metrics. Model fit was evaluated using R^2 and root averaged square error (RASE), and predictor effects were assessed using Wald chi-square tests ($\alpha = 0.05$). Analyses were performed in *JMP Pro 18* (SAS Institute, Cary, NC).

Results

The elastic net regression model explained 33.6% of pitch speed variance ($R^2 = 0.336$; RASE = 4.39 mph), retaining 6 predictors shown in Table 1.

Discussion

Selected force plate-derived metrics from standard performance assessments explained 33.6% of variance in PV. Pitchers with higher peak power, peak force, jump height, and reactive strength pitched faster. Practitioners can utilize this information to develop targeted training exercises to improve relevant neuromuscular qualities.

Previous research has reported models predicting around 30% of variance in pitch velocity [3]; this low value is most likely due to the complexity of pitching movement patterns. While our multivariate approach provides marginally more insight compared to isolated testing, 67% of variance remains unexplained. The inclusion of more upper-body strength and rotational assessments may provide further insight into pitching performance.

Influence of Available Reaction Time on Knee Joint Biomechanics and the Implications for Anterior Cruciate Ligament Injury

Miss Lauren Crawford

University of Tennessee, Knoxville, Knoxville, TN, United States

Introduction

Anterior cruciate ligament injuries frequently occur through non-contact mechanisms during rapid, unanticipated movements which are often influenced by cognitive and reaction time demands. This study examines how varying time available to respond to unanticipated stimuli influences knee biomechanics during a run-to-cut maneuver. Findings aim to better connect laboratory research with real-world athletic maneuvers and inform targeted prevention strategies.

Methods

This study analyzed cutting mechanics of 15, right leg dominant, recreationally active college students (aged 21.6 ± 3.57 years) with no lower extremity injury history. Participants performed 20 run-to-cut maneuvers in response to visual cues displayed 1.5m (short RT) or 2.5m (long RT) from the plates front edge. 3D kinematics and GRF's were recorded using a 12-camera Vicon motion capture system and embedded force plates. Peak hip and knee angles and moments during the stance phase were extracted.

Results

Significant effects for both leg and time were observed. Significant leg effects indicate that the right leg exhibits greater peak hip extension moments, peak knee external rotation moments, and peak knee abduction angles compared to the left. Significant time effects indicate that long reaction time trials were performed with increased peak hip internal rotation moments and peak hip flexion angles, whereas short reaction time trials resulted in greater knee flexion and abduction angles at initial contact.

Discussion

Preliminary results suggest that the right limb may experience greater knee joint loading, potentially reflecting dominant-side movement strategies or uneven neuromuscular control patterns. These differences may have implications for injury risk, particularly during rapid deceleration and fast cutting movements. The time dependent effects may indicate

that movement patterns change when reaction time is limited. This altered strategy could heighten joint loading, thereby increasing injury risk. Further work should aim to quantify muscle activation patterns to verify the suggested neuromuscular control strategy.

Motorcycle Finger Braking Techniques Affect Forearm Muscle Fatigue During a Simulated Race

Mr. Leon Lauret[1,2], Mr. Philip Maschlanka[1], Dr. Daniel Hahn[1,3]

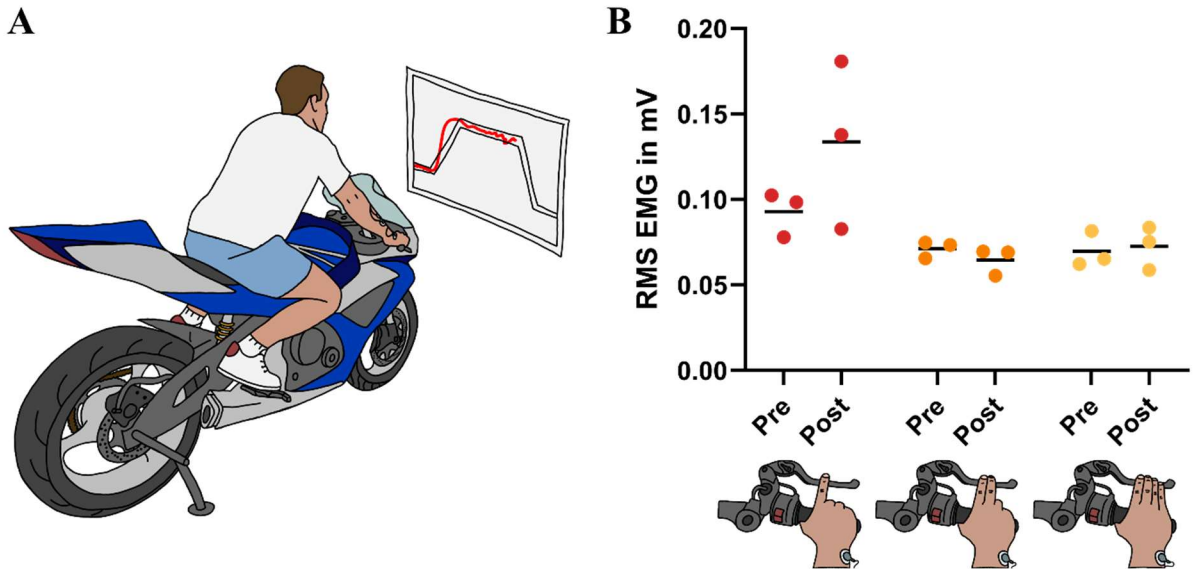
[1]Human Movement Science, Faculty of Sport Science, Ruhr University Bochum, Bochum, NRW, Germany. [2]Biomedical Engineering Lab, Department of Mechanical Engineering, Ruhr University Bochum, Bochum, NRW, Germany. [3]School of Human Movement and Nutrition Sciences, The University of Queensland, Brisbane, Queensland, Australia

Introduction

In professional motorcycle racing, speeds nowadays exceed 360 km/h. The physical demands during races cause many drivers to suffer from chronic exertional compartment syndrome (CECS), mainly affecting the forearms [1,2]. With CECS, fascia surrounding the muscles does not expand during muscle contraction, resulting in higher compartment pressure and muscle compression. Symptoms range from the sensation of tightness to loss of forearm muscle control and strength, posing a concerning safety risk. One factor contributing to CECS in racing is the constant use of the hand-controlled front brake, which is applied hundreds of times during a race [2]. Interestingly, riders use different braking techniques (1-finger, 2-finger or 4-finger, Fig. 1B) based on personal preference. We aimed to investigate whether the specific braking techniques lead to distinct forearm muscle fatigue and could thus reduce the prevalence of CECS.

Methods

We simulated braking by a repeated braking protocol, which matched a typical sprint-race in braking numbers (81), magnitude (15 bar), and duration (3.6 sec, Fig. 1A). For this, a pressure sensor recorded and displayed the braking pressure of a motorcycle brake. Participants had to complete the protocol for each braking technique in a random order, and differences in forearm muscle fatigue between braking techniques were evaluated using electromyography (m. flexor digitorum superficialis), grip strength, and tissue stiffness measurements.



Results

Preliminary results (n=3, mean±SD: 30.5±1.9yr, 1.76±0.04m, 73.7±2.5kg) are shown in Figure 1B. Braking with one finger led to increased muscle activity and increased tissue stiffness after the braking protocol. Additionally, post grip strength was reduced by -6%, -5% and -5% (1-, 2- and 4-finger braking, respectively).

Discussion

Our preliminary data shows that the 1-finger braking technique induces fatigue during repeated braking compared with 2- and 4-finger braking. Contrary to our expectations, 4-finger braking has no additional benefit compared with 2-finger braking. These findings may help to develop preventive and rehabilitative measures for riders suffering from CECS, as reducing fatigue could help to decrease compartment pressure. Additionally, race performance of habitual 1-finger brakers could be improved.

Biomechanical Validity of the Swing Test

Dr Lindsay Carroll PT, DPT, PhD,OCS, Dr AJ Lievre PT, DPT, EdD, Dr. Dominic Nestor PT, DPT, Dr. Saige Silva PT, DPT

Shenandoah University, Winchester, VA, United States

Introduction

The swing test (ST) is a dynamic test that is used to clinically assess a runner's hip motion when a full running evaluation is not possible due to injury, time, or resources. While the ST is believed to reflect hip motion occurring during running, its relationship to running kinematics is unknown. The purpose of this study was to determine if the sagittal plane hip motion during running was related to the motion occurring during the ST. The secondary aim was to determine if static clinical tests of hip range of motion (ROM) were related to the hip motion occurring during running.

Methods

Thirty-six healthy, recreationally active participants between 18 and 45 years of age (mean age = 23.6 ± 1.5 years; 78.38% female; mean BMI = 25.78 ± 3.37 kg/m^2) participated in this cross-sectional study. Inertial measurement units measured sagittal plane hip motion during the ST and treadmill running. Static hip ROM was measured with a blinded goniometer and the modified Thomas test (mTT) and the straight leg raise (SLR). Pearson correlation coefficients evaluated the relationships between maximum hip flexion/extension and total excursion during the ST and running and between the mTT and SLR and running.

Results

Moderately strong, statistically significant correlations were found when maximum hip extension ($r = 0.688$, $p < 0.001$), maximum hip flexion ($r = 0.415$, $p = 0.012$), and total sagittal plane hip motion ($r = 0.679$, $p = 0.001$) occurring during the ST and running were compared. In contrast, the relationships between mTT and maximum hip extension during running ($r = -0.132$, $p = 0.444$) and between SLR and maximum hip flexion during running ($r = 0.121$, $p = 0.480$) were not statistically or clinically meaningful.

Discussion

The ST may be more useful for assessing running-related sagittal plane hip mobility than static clinical tests such as the mTT and SLR. Clinicians may consider using the ST to estimate sagittal plane hip kinematics when a full running evaluation is not feasible.

Further research is needed to determine if this relationship can be reliably assessed clinically and if the test is valid in individuals with injuries.

P1-327

Phase-Specific Whole-Body Coordination Associated With Countermovement Jump With Arm Swing Height Performance in Soccer Female Athletes

MSc, PhD Candidate Lucie Courtois, Ryan Graham

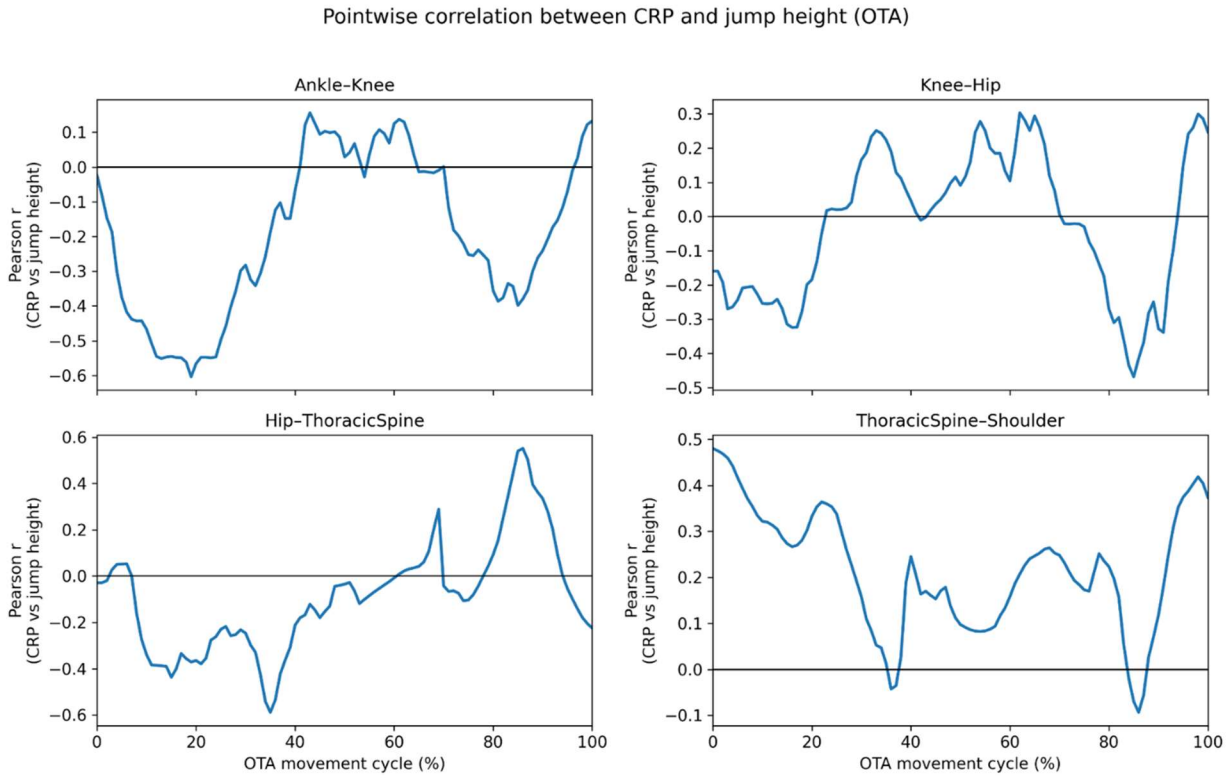
University of Ottawa, Ottawa, Ontario, Canada

Introduction

Countermovement jump (CMJ) is typically studied through lower-limb mechanics, meanwhile jumping is a whole-body task requiring coordinated motion. While lower-limb coordination has been quantified using Continuous Relative Phase (CRP), trunk and upper-body contributions remain unexplored. Understanding how whole-body coordination relates to jump performance could refine training strategies. This study investigated whether phase-specific inter-joint coordination during CMJ correlates with jump height performance.

Methods

Seventeen female soccer players performed three CMJs with arm swing. Markerless kinematics were collected using Vicon Vue and processed using Theia3D. Sagittal plane Mean Absolute Relative Phase (MARP) was computed for four joint pairs: ankle-knee (AK), knee-hip (KH), hip-thoracic spine (HT), and thoracic spine-shoulder (TS). From movement onset to jump apex, signals were time-normalized to 100%, and jump height was computed using pelvis center-of-mass displacement. Functional Data Analysis (FDA) was applied to compute pointwise Pearson correlations between MARP and jump height across the movement.



Results

Jump height ranged from 0.33-0.52 m (mean: 0.41 ± 0.05 m). FDA revealed distinct phase-specific coordination-performance correlations for each joint pair. AK showed significant negative correlations in early countermovement ($r \approx -0.55$, $p < 0.001$) and late propulsion ($r \approx -0.35$, $p < 0.01$). KH showed significant negative correlation in late propulsion phase ($r \approx -0.45$, $p < 0.01$). HT demonstrated significant negative correlations during the countermovement ($r \approx -0.50$, $p < 0.05$) and positive correlations during the propulsion ($r \approx -0.55$, $p < 0.05$). TS showed small to medium positive correlations throughout the movement, with peaks in early countermovement ($r \approx -0.45$, $p < 0.001$) and early flight ($r \approx -0.40$, $p < 0.01$).

Discussion

This study provides novel evidence that whole-body coordination is correlated to CMJ performance, with distinct joint-pair contributions varying across movement phases. Negative correlations indicate synchronized coordination, whereas positive correlations reflect out-of-phase coordination. Higher performers modulate inter-joint coupling across the kinetic chain, synchronizing lower-limb joints during countermovement and propulsion while using more out-of-phase trunk and shoulder patterns. These results suggest that training should target coordinated lower-limb triple extension, HT sequencing, and dynamic arm swing, which may lead to more effective jump-performance training interventions.

Experimental Characterisation of Wrist Biomechanics During Upper Limb Loading in Gymnastics

Miss Lucy Buchanan[1,2], Prof. Liang He[1,2], Prof. Amy Zavatsky[2]

[1]Podium Institute for Sports Medicine & Technology, University of Oxford, Oxford, Oxfordshire, United Kingdom. [2]Department of Engineering Science, University of Oxford, Oxford, Oxfordshire, United Kingdom

Introduction

Gymnastics places large physical demands on the body, and unlike in most sports, the wrist functions as a weight-bearing joint. Repetitive upper limb loading predisposes gymnasts to high risks of wrist injury. Gymnast's wrist is a stress injury to the distal radial physis common in adolescents who sustain high training volumes during periods of musculoskeletal immaturity. The injury mechanism involves repetitive wrist loading in an extended position. Understanding wrist biomechanics during loading conditions is essential for developing monitoring techniques and injury prevention strategies. This study characterises wrist motion and loading in terms of the key variables associated with gymnast's wrist: extension and force.

Methods

Ten adult participants (5M, 5F; height 1.72 m (SD 0.095); mass 65.3 kg (SD 9.2)) performed three trials of handstand, cartwheel, handstand-walk, handstand-hop. Full-body motion and ground-reaction forces (GRFs) were recorded by a sixteen-camera Vicon motion capture setup (Valkyrie 16), and force plates (AMTI). The calculated wrist extension angle was projected into the sagittal plane in the initial analysis of the data.

Results

Mean maximum wrist extension angles were Handstand: 58.7° (SD: 4.5°, max: 69.4°); Cartwheel: 61.8° (SD: 7.7°, max: 75.8°); Handstand Walk: 67.4° (SD: 4.5°, max: 77.4°); Handstand Hop: 57.3° (SD: 4.5°, max: 68.7°). Forces experienced were largest in the handstand-hop movement, with peak GRFs reaching more than three times bodyweight in some cases. Technique differences between participants were identified, most notably in the handstand hop, where wrist extension angle and the magnitude of GRF during the first-hand contact were affected by approach angle and timing of hop initiation (Figure 1).

Discussion

Results are consistent with the knowledge that gymnasts sustain forces multiple times their bodyweight at the wrist joint whilst it is in extreme extension [1]. The largest extension angles were observed in the handstand walk, with most variation between participants in the cartwheel. Differences in wrist extension and GRF patterns between movement strategies indicate that technique choice alters wrist loading; therefore, technique selection may be a key modifiable factor influencing wrist injury risk.

Images (Optional)

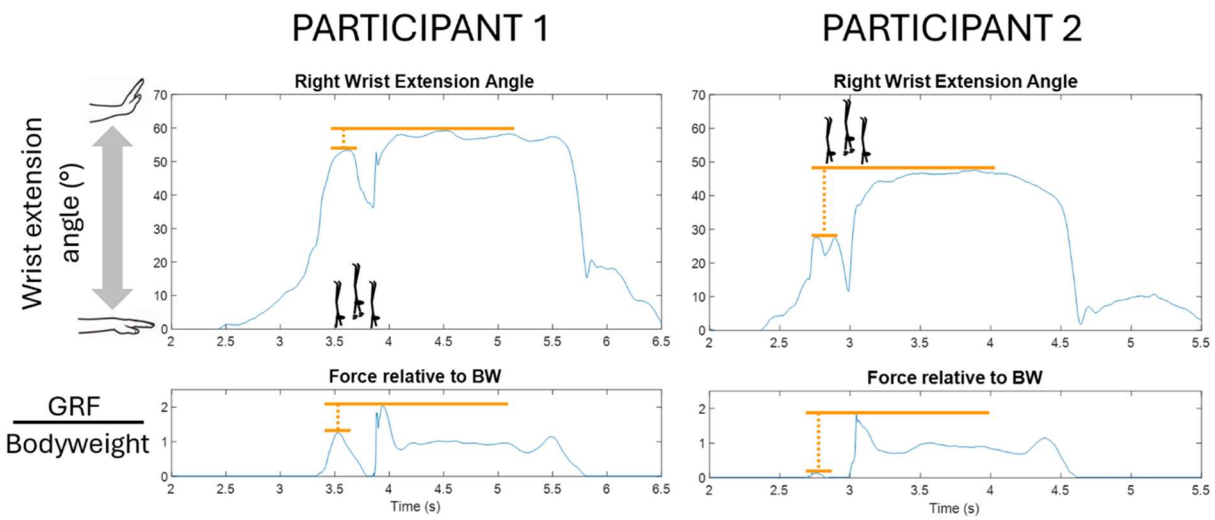

Figure 1: Wrist extension angle and magnitude of ground reaction force (GRF) relative to bodyweight for a handstand hop trial, for two different participants. Orange lines highlight the difference between maximum wrist extension angle, and peak GRF at each hand contact.

Effects of Lighting Conditions on Trail Running Performance Measures

Mr. Malicki Diallo BS[1], Dr. Key Nahan PhD[1], Mr. Adam Grimmitt MS[1], Mr. Aidan Watts[2], Dr. Meghan Huber PhD[1], Dr. Wouter Hoogkamer PhD[1]

[1]University of Massachusetts Amherst, Amherst, MA, United States. [2]State University of New York College of Environmental Science and Forestry, Syracuse, NY, United States

Introduction

Ultramarathon running provides a unique paradigm where runners navigate complex terrains with often varying lighting (e.g. day, night). Runners depend on wearable lighting devices during night sessions; however, it is still unclear whether this illumination allows nighttime running to match daytime performance. Previous research has found walking gait slows in older adults while navigating simple terrain in near darkness [1]. However, the effects of lighting conditions have not yet been explored for trail running. We hypothesize runners will run slower during nighttime with wearable lighting devices as compared to running in the daylight.

Methods

Five recreational runners (3M, 2F) ran four trials on a ~500m uneven trail during the day and six trials at night at their easy pace. At night, participants ran twice with a headlamp, twice with a waist lamp, and twice with both. We measured split times with a stopwatch and ground reaction forces with force insoles (LoadSol, Novel) at 200 Hz. Gait events were identified using a 20N threshold, and stride and contact time were calculated in MATLAB. Temporal measures were averaged across legs and trials, and speed was averaged across trials. A paired t-test was completed to observe mean differences across measures.

Results

Participants ran slower at night (2.04±0.36 m/s) compared to during the day (2.38±0.29; $p=0.0103$). Stride time ($p=0.0705$) and contact time ($p=0.0533$) did not differ significantly between night and day trials.

Discussion

Nighttime running with wearable lighting devices provides a greater challenge than daytime running resulting in slower running speeds. For this initial small sample differences in stride time and contact time were not significantly different. Further research will reassess

this with appropriate statistical power and also evaluate the effects of different wearable lighting devices (headlamp or waist lamp) on trail running speed.

Images (Optional)

Fatigue-Related Changes in Knee Kinematics During Incremental Treadmill Running in Well-Trained Runners

M.Sc. Marco Rahner[1], B.Eng. Leah Reiter[2], Dr. Jörg Lohscheller[3], Dr. Juliane Mueller[1], Dr. Steffen Mueller[1]

[1]Trier University of Applied Sciences, Department of Computer Science – Therapeutic Sciences, Trier, Rhineland-Palatinate, Germany. [2]Trier University of Applied Sciences, Department of Engineering, Trier, Rhineland-Palatinate, Germany. [3]Trier University of Applied Sciences, Department of Computer Science, Trier, Rhineland-Palatinate, Germany

Introduction

During running, acute fatigue has been shown to increase maximal knee flexion (MKF) during swing phase and at initial contact, while stance phase MKF appears unaffected. However, few studies have examined stance phase maximal knee adduction (MKAD) and abduction (MKAB) or the effects of higher running velocities [1].

The present study aims to expand understanding of fatigue-induced acute changes in knee kinematics during incremental treadmill running in well-trained runners.

Methods

Eight male, healthy well-trained runners (31±7years; 178±2cm height; 71.8±4.3kg weight; 65±24.5km in 6.5±1.8h training per week) performed a maximal incremental test on a treadmill (incline: 0%; initial running velocity: 8km/h; increment duration: 3min; increment step: +2km/h). Blood-lactate concentration was measured between increments. Full-body kinematics were measured for each increment after 30s (A) and 150s (B) for 20s using a markerless motion-capturing system (Theia3D; Axiom v2025) with eight cameras (100Hz).

After gait events detection, knee kinematics (MKF [°], MKAD [°], and MKAB [°]) during stance phase were calculated and averaged across legs.

A two-way repeated-measures ANOVA (Measurement × Increment) was conducted to assess between-increment changes. Furthermore, within-increment changes were evaluated using a one-way repeated-measures ANOVA on absolute measurement-point differences (B-A) for each increment. Both analyses were carried out across the following increments: Start (8km/h), Aerobic Threshold (LT1; 2mmol/L), Anaerobic Threshold (LT2; 4mmol/L), and the last completed increment (Final). Holm-corrected post-hoc tests were applied where appropriate.

Results

Velocity at Start were 8.0±0km/h, at LT1 14.8±1.4km/h, at LT2 17.0±1.4km/h, and at Final 20.3±1.6km/h. Fig.1 shows distribution and individual changes between-increments (A) and within-increments differences for all outcomes.

There was a significant main effect for between-increment MKAD (p=.039; Greenhouse–Geisser corrected). However, post-hoc comparisons revealed no significant pairwise differences. No other outcomes showed significant changes within or between increments.

Discussion

The absence of significant (pairwise) within- and between-increment changes across all outcomes, suggests that maximal knee kinematics during the stance phase are not sensitive indicators of acute fatigue. Nonetheless, increasing within-increment heterogeneity appears, especially for Final. These findings align with [1] and extend prior work by adding knee ad-/abduction measures and higher running velocities.

Images (Optional)

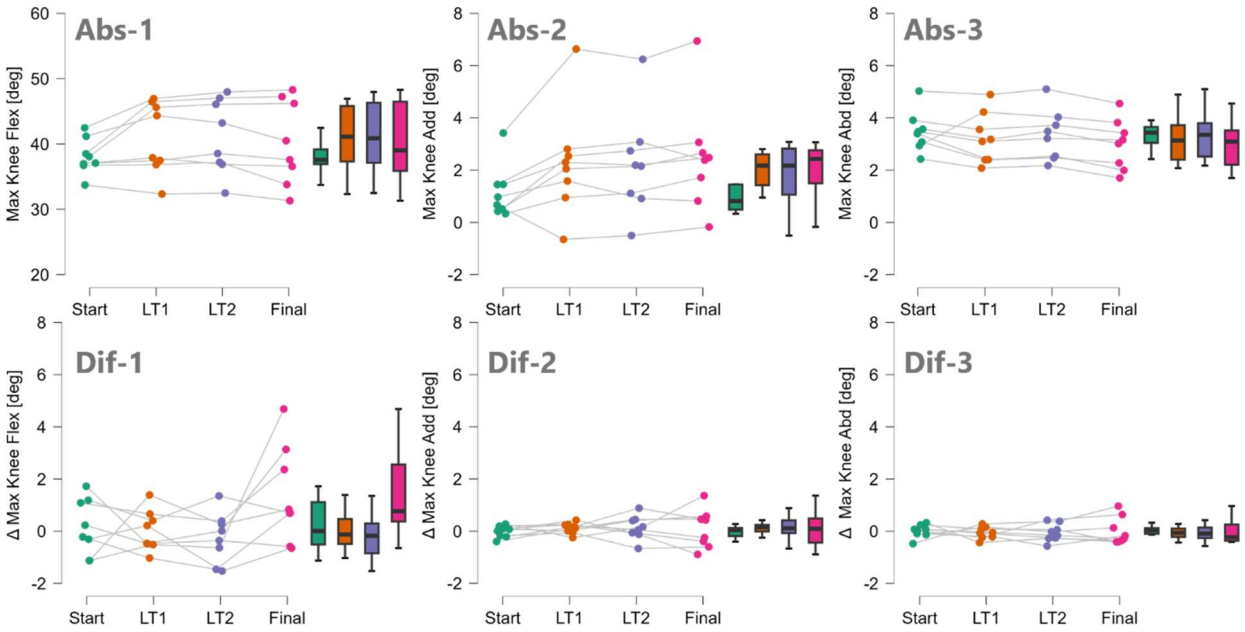

Fig. 1: Absolute between-increment changes in maximal knee flexion (Abs-1), adduction (Abs-2), and abduction (Abs-3) for the measurement A, and relative within-increment changes (Dif-1, Dif-2, Dif-3) during stance phase of an incremental treadmill test (Start, LT1, LT2, Final) in well-trained runners.

P1-331

Field-Based Evaluation of an ACL Injury Prevention Training Intervention on Change-of-Direction Movements

MSc Mareike Kühne, BA Semjon Schmidt, Dr. Maurice Mohr

University of Innsbruck, Innsbruck, Tyrol, Austria

Introduction

ACL injuries often occur during unplanned change-of-direction (COD) movements [1]. Injury prevention training programs have shown promising effects in improving injury-prone movement patterns while maintaining performance [2]. Previous studies have tested the effects of training programs on preplanned COD kinematics in lab-settings. We used a field-based approach to investigate whether such training effects can be observed in a more sports-specific setting with unplanned scenarios. We hypothesized to find an adaptation in COD kinematics after the intervention training and no change in COD performance.

Methods

Seventeen male soccer players (mean age = 19 years) of the third highest league in Austria participated in a six-week training intervention and completed a field-based pre- and post-assessment. The intervention focused on practicing COD techniques associated with lower knee joint loading under increasing cognitive demands. The pre- and post-test consisted of twenty COD maneuvers of different anticipatory conditions (preplanned, unplanned with equal (50:50) and unequal (80:20) probability of direction). Performance (completion time) and IMU-based kinematics at the initial contact of the sidestepping leg were assessed and statistically analyzed using linear mixed models (alpha = 0.05, fixed effect ‘time x anticipatory condition’).

Results

The kinematics of the sagittal plane (higher knee (p = 0.08) and hip flexion (p < .001), lower trunk flexion (p = 0.003)). A significant interaction effect revealed that hip abduction angles were specifically reduced in unplanned (p < 0.04) but not preplanned COD movements (p = 0.799). COD completion times significantly increased by 0.04s after the intervention (p = 0.009).

Discussion

Our field-based approach revealed adaptations in on-field COD kinematics following a six-week COD training intervention, even in unplanned scenarios. Lower-body COD kinematics

of the sagittal and frontal plane changed in a way consistent with a reduced risk of non-contact ACL injury [3], however, at the cost of a small performance decrease. Additionally, some adaptations can only be observed under cognitively demanding conditions.

Images (Optional)

Application of a Single-Camera Markerless Motion Capture System to Assess Sprint Biomechanics Following Hamstring Injury: A Case Study

Dr. Margherita Mendicino[1], Dr. Stefano Di Paolo[2], Dr. Francesco Della Villa[2], Prof. Stefano Zaffagnini[1,3]

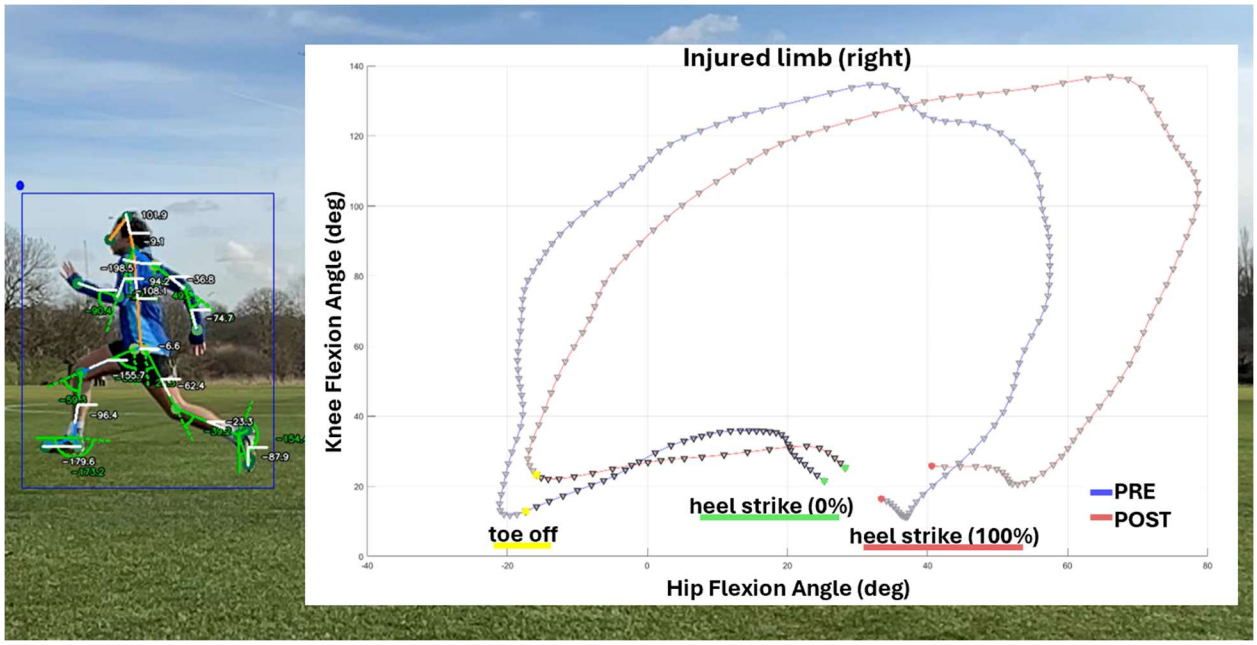
[1]2nd Orthopaedic and Traumatologic Clinic, IRCCS Rizzoli Orthopaedic Institute, Bologna, Emilia Romagna, Italy. [2]Education and Research Department, Isokinetic Medical Group, FIFA Medical Centre of Excellence, Bologna, Emilia Romagna, Italy. [3]Department of Biomedical and Neuromotor Sciences, University of Bologna, Bologna, Emilia Romagna, Italy

Introduction

Markerless motion capture systems based on artificial intelligence (AI) are emerging as practical alternatives to optoelectronic marker-based (OMB) systems for biomechanical assessment [1]. This study validates the accuracy of an AI-based single-camera markerless system, Sports2D, against a gold-standard OMB system in quantifying sagittal-plane kinematics during typical rehabilitation and return-to-sport (RTS) movements. A case study of an athlete recovering from a hamstring injury further illustrates the system's ecological applicability.

Methods

For the concurrent validation, 166 valid trials from 6 healthy athletes were evaluated using a 10-camera OMB system (Vicon Vero, 120Hz) and videos recorded with three synchronized high-speed RGB cameras and processed with Sports2D (Pagnon, 2024). Athletes performed six tasks: single-leg squat, single-leg hop, drop jump, 90° change-of-direction, forward sprint with single-leg deceleration, and sliding. Sagittal-plane lower limb and trunk kinematics were compared using peak differences, RMSE and correlation coefficients. For the case study, an athlete with a history of hamstring injury performed maximal sprint trials before and after targeted rehabilitation, recorded with a single-camera (iPhone13, Apple). Sagittal-plane kinematics was extracted from Sports2D to evaluate hamstring lengthening and lengthening velocity, hip–knee cyclograms, and joint flexion angles at key running cycle events, allowing pre-/post-training performance comparison.



Results

Overall agreement between systems ranged from poor to excellent depending on joint and task. Trunk showed the highest consistency (r=0.76–0.80, ΔOFF<4.2°), ankle exhibited small peak differences in most tasks (ΔOFF 0.3°–4.3°). Hip and knee agreement was excellent in drop jumps (r=0.83–0.88) and for the hip joint also in single-leg squats (r=0.75). Change-of-direction tasks produced the largest discrepancies. Sports2D detected meaningful changes in pre-/post-rehabilitation sprint biomechanics (Figure 1), including improved hip flexion ROM (Δ=17°), higher hip (Δ=3-7°) and knee (Δ=4-9°) flexion at heel strike, higher peak hamstring lengthening velocity (Δ=14deg/s) and increased cyclogram area (Δ=821deg^2).

Discussion

An AI-based single-camera markerless system showed good agreement with OMB in controlled tasks, with larger discrepancies in complex multidirectional movements. The case study further highlights Sports2D as an ecological, rapid, non-invasive on-field data collection tool, that could be used to support rehabilitation and RTS decisions with near real-time data processing.

Can Footwear Affect Rope Climbing Performance?

Lead Biomechanics Researcher Marlon Rainville, Director of Footwear Biomechanics Jay Worobets

Nike Sport Research Lab, Beaverton, Oregon, United States

Introduction

Rope climbing is a common task in functional fitness competitions and training among first responders and military personnel [1, 2]. To maximize climbing speed, athletes use various foot wrap techniques to create traction between the feet and rope, allowing substantial leg forces to contribute to vertical acceleration (**Figure 1a**) [3]. Increasing available traction between the shoe and rope may also improve performance.

The purpose of this study was to quantify the effects of rope climb-specific footwear design features on rope climbing performance and perception.

Methods

Sixteen athletes completed six rounds of three repetitions (ascent and descent) of 4.5 m rope climbs as fast as possible in two footwear conditions. The NIKE Metcon 9 ("Extra Grip") shoe incorporates a textured midfoot rubber intended for enhanced grip on a climbing rope. The NIKE Free Metcon 6 ("Control") shoe has no rope climb-specific design features.

Kinematic data were collected with Theia markerless MOCAP. Metrics of interest were statistically compared between footwear using paired-sample t-tests ($\alpha < 0.05$).

After each trial, athletes were asked to rate on a 9-point intensity scale, ranging from "1 - strongly disagree" to "9 - strongly agree", their response to a statement reading "This shoe allowed me to complete rope climbs with ease."

Results

Rope climbing ascent performance was significantly faster in the Extra Grip shoe by 6.2% on average (6.60 ± 3.09 sec vs. 7.09 ± 3.65 sec; $p = 0.04$), with 13 out of 16 athletes achieving faster ascents in the Extra Grip shoe (**Figure 1b**).

Athletes perceived that the Extra Grip shoe made rope climbing easier (8.56 ± 0.79 vs 4.88 ± 2.12; $p < 0.01$) (**Figure 1c**).

Discussion

Rope climb-specific footwear design features enhanced rope climbing performance and perception. We speculate that the mechanism responsible is an increased available traction between the shoe and rope, enabling the athlete to transfer more leg force to the rope.

A limitation of this study was a lack of mechanical test methods to directly measure available traction between shoes and a climbing rope.

Plantar Intrinsic Muscle Excitations During Running Before and After a Locomotor Fatiguing Task

Ms Megan Spencer BS[1], Ms Sydney Menendez[1], Dr Ross Smith PhD[2], Dr Jason Franz PhD[1]

[1]University of North Carolina and North Carolina State University, Chapel Hill, NC, United States. [2]University of Memphis, Memphis, TN, United States

Introduction

The plantar intrinsic muscles (PIMs) play a critical role in supporting the medial longitudinal arch and actively regulating foot mechanics during dynamic activities such as walking [1-2] and running [3-4]. However, their contribution during high-intensity tasks such as running, to include changes therein following a locomotor fatiguing task, remains poorly understood. Beyond improving our foundational understanding of PIM and foot function, addressing this knowledge gap has the potential to inform the development of interventions designed to prevent injury. Here, we used indwelling electromyography (EMG) to test the hypothesis that, compared to baseline, PIM excitations during running would exhibit a shift toward slower-frequency intensities following a locomotor fatiguing task.

Methods

16 young adults (9M/7, age: 23.6±3.1 years) completed a one-minute run at 9:40 mile pace before and after a 30-min walk performed at 20% faster than preferred overground speed. This task was selected given its relevance to locomotion, known PIM engagement, and propensity to elicit leg muscle fatigability. We recorded indwelling EMG from the abductor hallucis (AH, a greater toe flexor) and flexor digitorum brevis (FDB, a lesser toe flexor) from which we compared EMG mean frequencies and amplitudes before and after the locomotor fatiguing task.

Results

FDB showed a significant 13.8% average decrease in EMG mean frequency following locomotor fatigue (pre-post, $p = 0.042$) whereas AH exhibited no significant difference ($p=0.258$). Conversely, EMG amplitudes were unaffected by locomotor fatigue.

Discussion

We discovered muscle-specific differences in the vulnerability to locomotor fatigue among the plantar intrinsic muscles during running. FDB, which regulates flexion of the lesser toes, showed disproportionate vulnerability to fatiguability than AH. One key implication of this discovery is in potentially helping to explain why 2nd and 3rd metatarsal stress fractures

are among the most common overuse injuries in runners. With this understanding, we may be better positioned to develop anatomically-informed interventions, such as footwear modifications or strength training, designed to promote fatigue resistance and thereby mitigate running-related overuse injuries.

Images (Optional)

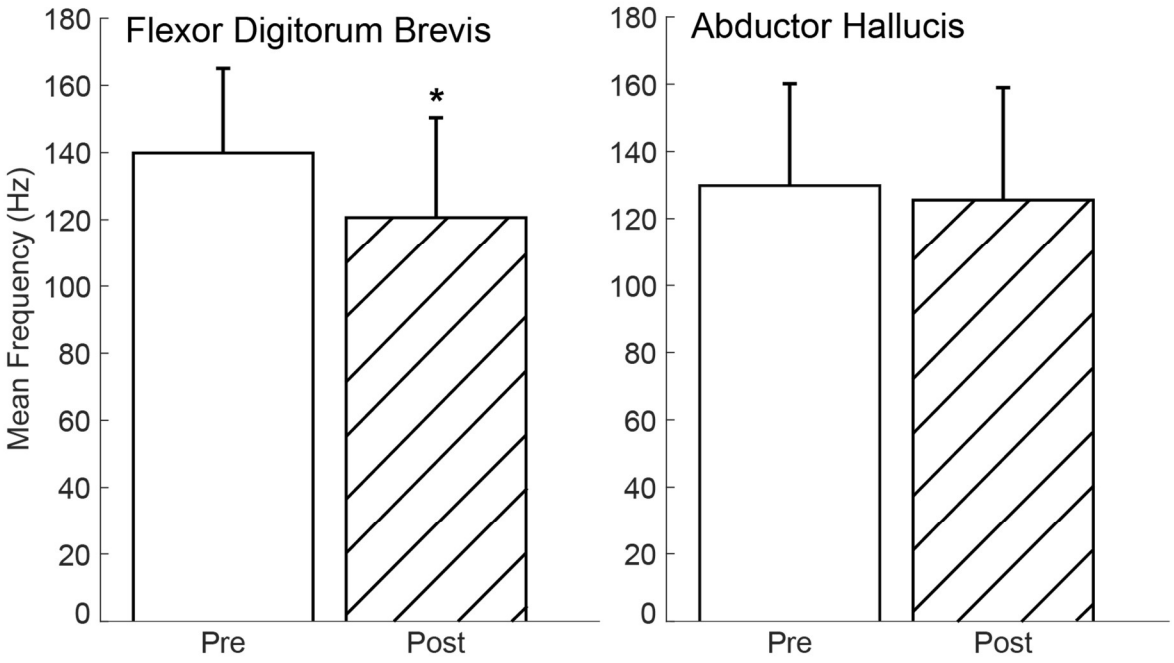

Figure 1. EMG mean frequency before (Pre) and after (Post) the locomotor fatiguing task for FDB and AH. Based on pairwise comparisons, only FDB exhibited a significant decrease in EMG mean frequency, reflecting disproportionate vulnerability to fatigue.

Comparing Landing Ground Reaction Forces in Cushioned and Traditional Flat Ballet Shoes

Dr Michael Pohl PhD, Mr Andy Jenkins, Mr Jacob Mizrahi, Ms Katherine Podoll, Dr Karin Steere PhD

University of Puget Sound, Tacoma, WA, United States

Introduction

Overuse injuries are highly prevalent in ballet, with 66–91% affecting the lower extremities, reflecting the substantial mechanical demands of leaps such as the grand jeté, where landing forces are high. Previous research in running has shown that differences in footwear can alter ground reaction forces and loading rates. However, studies examining the biomechanical effects of non-pointe shoe footwear in ballet remain limited. A cushioned ballet shoe (ORZA, USA) has recently been developed, but its biomechanical impact has not yet been evaluated. This study aimed to compare ground reaction forces during grand jeté landings between this novel cushioned shoe and a traditional flat ballet shoe.

Methods

Four elite ballet dancers, free from pain or current injury rehabilitation, performed grand jeté leaps in both traditional (Trad) and cushioned (ORZA) shoes. Three successful trials were recorded per condition, with order randomized. Kinetic data were collected at 1000 Hz using a floor-embedded force plate (AMTI BP600600, USA) and filtered with a 50-Hz low-pass Butterworth filter. Ground reaction forces were normalized to body weight. Dependent variables included peak vertical GRF, time to peak vGRF, and vertical loading rate (peak vGRF divided by time to peak). Given the small sample size at this point, effect sizes (Cohen's d) were calculated.

Results

There were no meaningful differences between the ORZA and traditional shoes for peak vGRF, time to peak vGRF, or loading rates as indicated by the small to trivial effect sizes. Statistical data including mean (standard deviation) and effect sizes (d) are presented in the table.

Discussion

This ongoing study is the first to compare landing ground reaction forces between a novel cushioned ballet shoe and a traditional flat shoe. While cushioned footwear has been

shown to alter impact ground reaction force variables in running, these changes are often linked to significant shifts in foot-strike patterns, which are unlikely to occur during ballet landings due to aesthetic requirements. Although preliminary results from the current study showed no differences between shoe types, continued investigation as the sample size increases is warranted. Additionally, accompanying kinematic analyses may provide deeper insight into landing mechanics across footwear conditions.

Wrap Fit Enables Better Trail Performance

Miss Milena Singletary, Dr. Eric C. Honert PhD., Mrs. Bethany Kilpatrick, Mr. Adam Luftglass, Dr. Daniel Feeney PhD., Dr. Kathryn Harrison PhD.

BOA Technology Inc., Denver, Colorado, United States

Introduction

Improvements in shoe fit and running performance have been found in trail running with a wrap fit system compared to traditional laces [1]. Another common fit system in trail shoes is speed lace. It is unknown if there is also a performance and fit difference between speed lace and wrap fit systems.

Methods

Ten experienced trail runners ran a 1700m loop twice in two shoes in a counter balanced order: An on-market zonal speed lace shoe, and the same base shoe prototyped with a wrap fit system. The shoes were equipped with plantar pressure insoles and an inertial measurement unit (IMU) attached to the heel counter. From the IMU, peak foot eversion velocity (PFEV) and speed were computed for each stride. Peak toe pressure was computed for each step from the plantar insoles. Heart rate was also collected. Bayesian models were used to assess the effect of fit system on shoe fit and running performance. Percent of posterior above/below zero and 95% credible interval and differences between Wrap and Lace are presented.

Results

On average, Wrap decreased peak toe pressures by 1.4 kpa (98% < 0, CI: -2.7 to -0.6%) and decreased PFEV by 25.0 deg/s (80% < 0, CI: -5.2 to 1.2%). Participants ran faster, after controlling for heart rate, in Wrap by 0.03 m/s (83% > 0, CI: -0.3 to 2.1%).

Discussion

Despite having targeted closure at the midfoot and forefoot, the speed lace provided a worse fit than the Wrap. Better fit reduces the need to grip the shoe with the toes, resulting in lower peak toe pressures [1]. This has been associated with improved mechanical energy efficiency, which may help explain the improvement in running speed [2]. Further, Wrap reduced the PFEV suggesting a better fit allowing better control of the foot – this is critical in sports requiring navigation of technical terrain.

Marathon Training and Fatigue Resistance: Effects on Running Mechanics

Mr. Nate Goldcamp, Ms. Shannon Hugard, Dr. Michael Hahn PhD

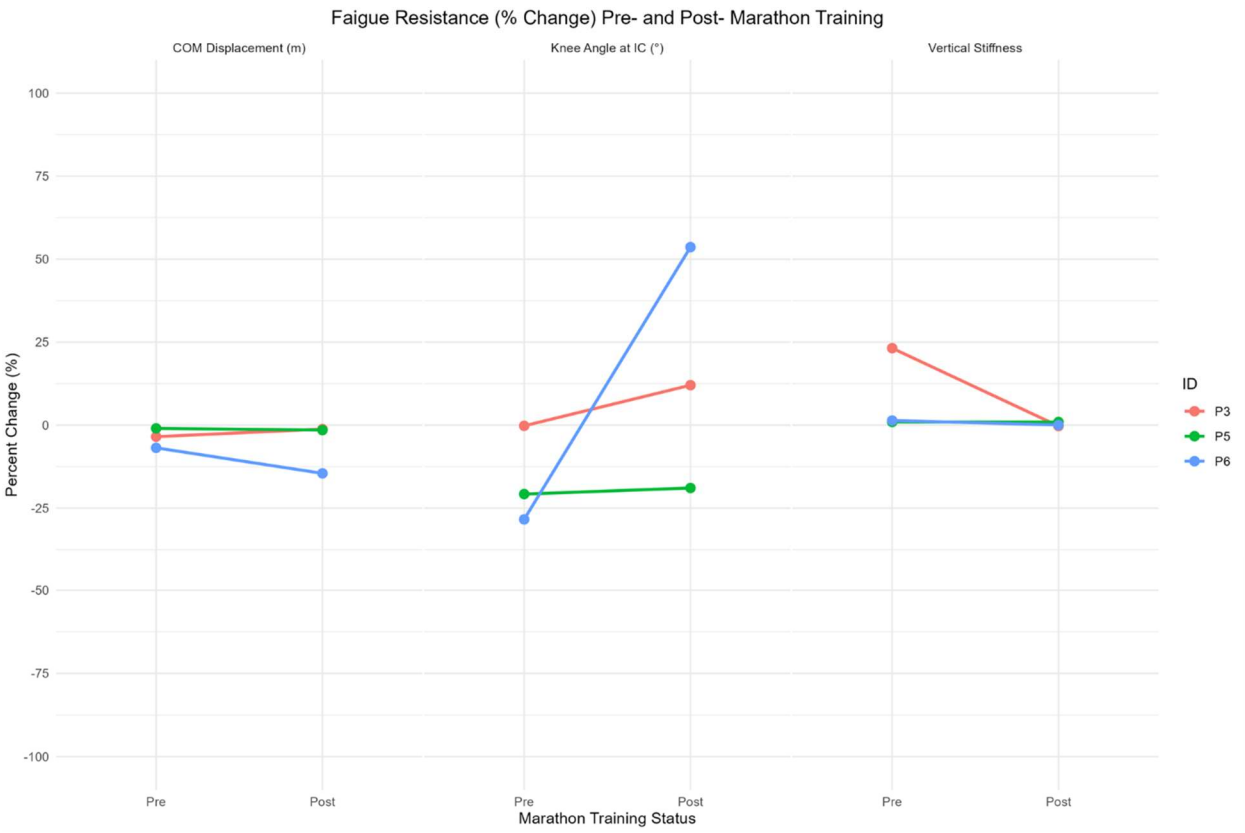
University of Oregon, Eugene, Oregon, United States

Introduction

Novice runners experience running-related injuries at a disproportionate rate compared to their trained counterparts. One factor thought to contribute to the increased injury risk is altered running mechanics after fatigue. The ability to resist biomechanical changes from fatigue (joint angles, center of mass displacement, and vertical stiffness) can be described as fatigue resistance, which has been shown to be greater in trained runners compared to novice runners.[1] However, no work has investigated how a training program influences fatigue resistance. This study aims to examine the effect marathon training has on fatigued running mechanics. It is hypothesized that marathon training will improve fatigue resistance, shown by a smaller percent change in biomechanical metrics following fatigue when comparing pre- and post-training.

Methods

Three novice marathon runners (1F, 2M; height: 177.1±15.3 cm; weight: 74.1±15.2 kg) completed a 16-week marathon training plan. Prior to beginning the training plan (week 0), participants completed a biomechanical analysis consisting of three running trials. The first and third trials consisted of a 10-minute submaximal run at 80% of their speed at lactate turn point. The second trial served as the fatiguing element, consisting of a run at 105% of the participants' speed at lactate turn point until volitional exhaustion. Lower-extremity biomechanics data were collected using a force-instrumented treadmill (Bertec,1000 Hz) and an 8-camera motion capture system recorded marker trajectories (Motion Analysis Corp., 200 Hz). Running trials were repeated in week 14 of marathon training. Fatigue resistance metrics were quantified as the percent change before and after the fatiguing trials. A within-subject comparison of percent change values between weeks 0 and 14 was conducted using paired t-tests.



Results

No significant changes in fatigue resistance metrics were observed following marathon training ($p>0.05$). Metrics assessed included joint angles (at initial contact and maximum), center of mass displacement, and vertical stiffness during stance.

Discussion

Preliminary analysis includes data from three participants. Currently, no mechanical factors of fatigue resistance show significant change, however, no conclusions can be made at this point in the research process. The study aims to reach a sample size of 28.

A Model for Predicting Bat Speed from Popular Field-Based Performance Tests

Ms. Neha Kapoor[1], Dr. Kiara Barrett[1], Dr. Lauren A Luginsland[2]

[1]Bertec Corporaation, Columbus, Ohio, United States. [2]University of South Florida, Tampa, Florida, United States

Introduction

Bat speed (BS) is a critical metric for evaluating hitting performance in baseball that reflects an athlete's capacity to generate and transfer force through the kinetic chain. To better understand the physical factors that contribute to BS and assess athletic ability, performance professionals evaluate strength-based force plate assessments such the countermovement jump (CMJ), squat jump (SJ), isometric mid-thigh pull (IMTP) and hop test (HT) [1]. The purpose of this study was to determine the collective variance in BS explained by force plate-derived metrics from CMJ, SJ, IMTP, and HT assessments using multivariate regression analysis in collegiate baseball players.

Methods

Data from Driveline's OpenBiomechanics dataset was retrospectively analyzed [2]. 231 male collegiate athletes (87.84±9.95kg, 20.12±2.16yrs, 1.80±0.07m) visited a Driveline performance center and completed CMJ, SJ, IMTP, and HT protocols; kinetic data during hitting was collected with Bertec force plates (Bertec Corporation, Columbus, OH). An elastic net regression model ($\alpha = 0.99$) with BIC stopping rule-based selection was used to predict peak BS (mph) with 31 variables averaged across trials. Analyses were performed in *JMP Pro 18* (SAS Institute, Cary, NC); significance was evaluated using Wald chi-square tests ($\alpha = 0.05$).

Results

The elastic net regression model explained 49.6% of bat speed variance ($R^2 = 0.496$; RASE = 3.58 mph) and retained 5 predictors from CMJ, SJ, and IMTP as shown in Table 1.

Discussion

Force plate-derived metrics from CMJ, SJ, and IMTP explained 49.6% of the variance in BS, indicating that lower-body force and power qualities substantially contribute to swing performance. No predictors from HT were retained. Coaches can use the derived prediction equation to estimate an athlete's expected BS based on their neuromuscular profile; if an athlete's BS falls below the predicted value, this may indicate inefficiencies in energy transfer through the kinetic chain. This model therefore offers a practical tool for

identifying performance gaps and guiding individualized training. Future work should validate these relationships in broader athlete samples and examine the contribution of additional performance assessments.

The Biomechanical Effects of Weighted Perturbed Jumps

Mr. Nicholas Tom[1], Mr. Malicki Diallo[2], Mr. Daniel Richie MS[1], Dr. Ajit Chaudhari PhD, FACSM[1]

[1]The Ohio State University, Columbus, OH, United States. [2]University of Massachusetts Amherst, Amherst, MA, United States

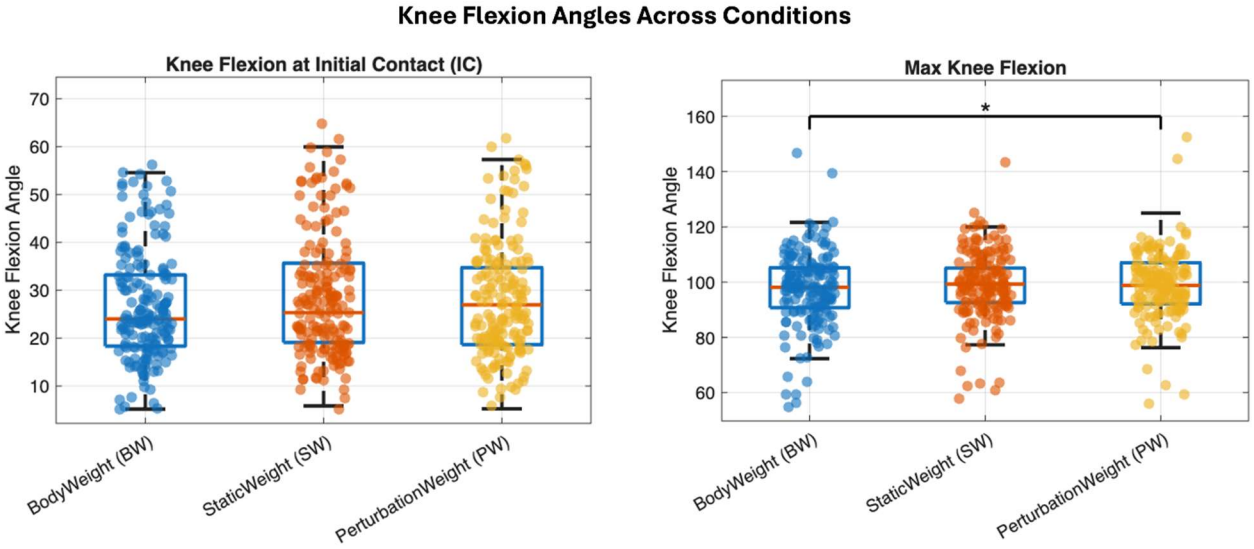
Introduction

The drop vertical jump (DVJ) has been demonstrated to be a useful tool in identifying injury risk factors, and past research suggests that stiffer landings increase injury risk [1]. Current DVJ protocols occur in controlled environments; however, this may not represent sporting contexts where athletes experience external perturbations. Research has begun exploring the effects of dual tasking (i.e. cognitive perturbations) on DVJs, but research is limited on the effect of physical perturbations [2,3]. The purpose of this study was to identify if weighted perturbations affect movement patterns in ways that could increase injury risk. Therefore, we hypothesized that knee flexion (KF) at initial contact (IC) and max would decrease in response to perturbations.

Methods

30 healthy adults (26.3±6.2 years, 15F) completed 9 DVJs, 3 under each condition: baseline (BW), static weight (SW), and perturbation weight (PW). The PW comprised 4.54kg of water in a Tidal Tank Hydrovest, donned across the upper back. The SW comprised 4.54 kg of metal affixed in a foam roll similarly attached to the Hydrovest. Jumps were done off a 30 cm box onto two force plates, and 3-D motion capture (9 Vicon Vero cameras, 300 Hz) was used to estimate kinematics. Mixed effects models compared differences between conditions KF at IC and max using SPSS.

Results



Significant effects of jump condition were found for KF max ($p=0.043$) but not for KF IC ($p=0.113$). Pairwise comparisons revealed significant differences between the BW and PW for max ($\Delta 1.7°$, $p=0.013$). KF angles increased across conditions (BW, SW, PW) for IC (26.8°, 27.9°, 28.6°) and max (97.6°, 98.6°, 99.3°).

Discussion

Previous research has linked dual tasking DVJs with stiffer landings as exhibited by decreased KF [2,3]. However, in this study we see KF increase with PW. This is the opposite of our hypothesis and may indicate that participants were anticipatorily softening their

landing in preparation for perturbations. Perturbations have promise in making DVJ testing more realistic, and future research should continue focusing on their effects.

Effects of Slip Events on Lower Extremity Biomechanics During Cutting Maneuvers in Collegiate Soccer Players

Mr. Noah Rauch[1], Dr. Brett Pexa[1], Mr. Garrett Hess[1], Dr. Jeffrey Taylor[1], Mr. Joseph Helseth[2], Dr. Kevin Ford[1]

[1]High Point University, High Point, NC, United States. [2]Nike Sport Research Lab, Beaverton, OR, United States

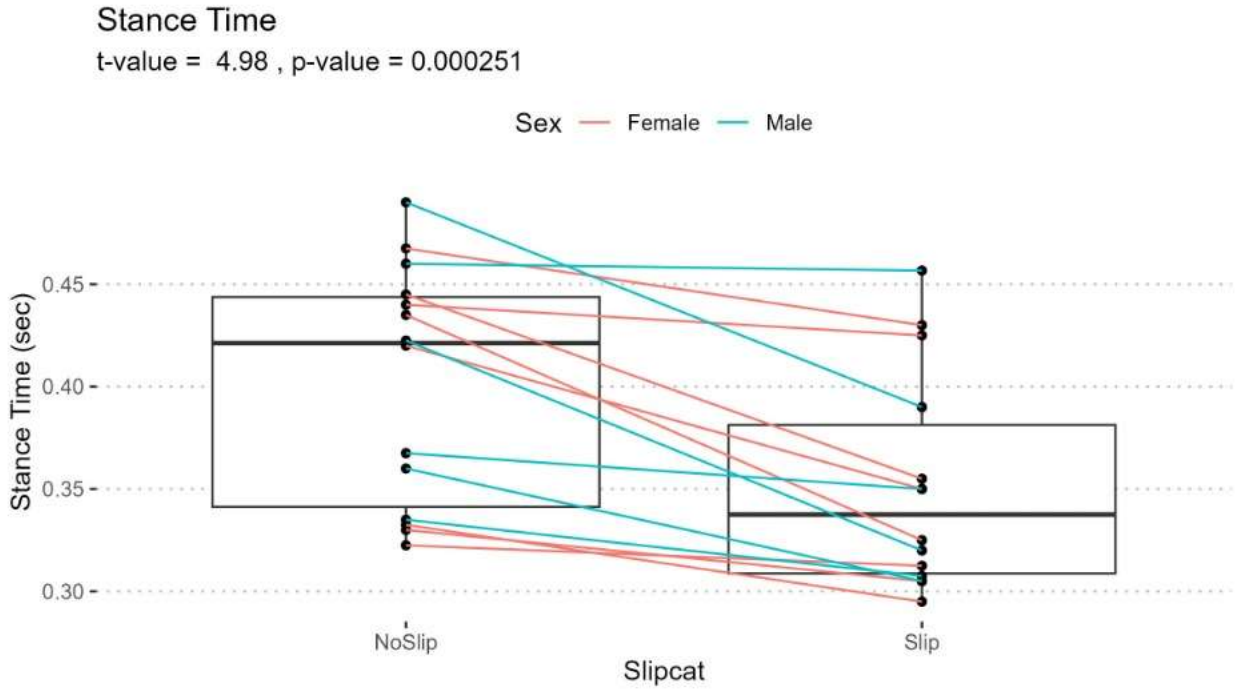
Introduction

There is limited information on lower extremity biomechanics during a slip when performing a sporting movement, such as a quick change-of-direction cut. A slip may lead to high-risk biomechanical movements, which may predispose athletes to injury. The purpose of this study was to determine the difference in lower extremity biomechanics between a slip versus a non-slip movement in collegiate soccer athletes.

Methods

Thirty competitive soccer players (15M, 15F; age: 20.8±1.2yrs), performed a 180-degree cutting task in a cleated condition (Nike Phantom GX II Elite Artificial Grass (AG)) on an infill turf surface. Kinematics were recorded with a 14-camera motion capture system (Qualisys AB, Göteborg, Sweden, 200 Hz), and kinetics were captured with two in-ground force plates (AMTI, Watertown, MA, USA, 1200 Hz). Slips were identified visually by anterior displacement of the center of gravity of the foot (relative to running approach direction in lab coordinate system) during the first 50% of ground contact time. Participants who had at least one slip and one non-slip trial were included for statistical analysis. Pairwise t-tests and Cohen's d effect sizes were used to compare the biomechanics between slip and non-slip trials.

Results



Fourteen participants had a slipping trial (8F, 6M). There was a significant difference in peak hip extension angle ($t=4.36$, $p<0.001$, $d=1.16$), peak knee extension angle ($t=-4.20$, $p=0.001$, $d=1.12$), and stance time ($t=4.98$, $p<0.001$, $d=1.33$) between slips and non-slips. Slip trials had increased hip and knee extension with a decreased stance time. When comparing kinetics, knee flexion moment at initial contact ($t=2.93$, $p=0.016$, $d=0.78$), peak hip abduction moment ($t=2.83$, $p=0.014$, $d=0.75$) and braking force ($t=2.73$, $p=0.016$, $d=0.73$) were significantly different between slips and non-slips. Slips

demonstrated decreased peak knee flexion moment at initial contact, decreased hip abduction moment, and increased peak braking force than non-slip trials.

Discussion

Slip trials significantly reduced stance time compared to non-slip trials, indicating that athletes likely adopt a rapid transition strategy to minimize potential deleterious effects. The altered biomechanics during the slip require further investigation on different surface and footwear conditions. Future footwear innovations targeting utilized traction may mitigate adverse effects during slip events.

P1-341

Evaluation of Jump Height Variance in Collegiate Men Team Sport Athletes

Ms Noelle D Saine MS, CSCS, Dr Erica King PhD, Dr. Angela Miller Phd, Dr Margaret Jones PhD, CSCS*D

George Mason University, Fairfax, VA, United States

Introduction

Countermovement jumps (CMJs) are becoming more widespread in sport science settings to evaluate athlete readiness, recovery, and maximal power. There is conflicting literature in determining the best metric to evaluate athlete performance in team sport athletes. Although jump height (JH) remains the most commonly interpreted measure, limited research has examined how athletes achieve maximal performance through different CMJ phase strategies. Therefore, this study aims to quantify variance in JH across team sports and determine how phase-specific variables contribute to performance differences within each sport.

Methods

NCAA Division I men' athletes (n=201) from baseball (BASE, n=64), basketball (MBB, n=31), swimming (MSD, n=22), soccer (MSOC, n=31), volleyball (MVB, n=25), and wrestling (WREST, n=28) participated. Athletes performed routine CMJ testing over two years, where after a standardized warmup, each athlete completed 3 maximal effort CMJs on bilateral force plates. The jump with the maximal jump height (JH) from that session was recorded for analysis. To evaluate CMJ phase utilization eccentric peak power standardized by body mass (ECC) and concentric mean power standardized by body mass (CON) were analyzed in this model. On average, athletes completed 16 jump sessions, and a total of 3313 jump sessions were analyzed. Hierarchical linear modeling with random intercepts assessed the variation within and between individuals. MSOC athletes were used as the reference group as they recorded the lowest average JH. Both CMJ phase variables were grand mean centered.

Results

With average ECC and CON, MSOC had an average jump height of 39.09cm. BASE and MBB athletes did not significantly differ from men's soccer when ECC and CON were centered. As CON increases, MBB JH decreases ($\beta = -0.75$, $p<0.001$), MVB JH increases ($\beta = 0.80$, $p<0.001$), and WREST JH increases ($\beta = 0.30$, $p<0.01$). As ECC increases, MBB JH increases ($\beta = 0.16$, $p<0.001$), MVB JH decreases ($\beta = -0.30$, $p<0.05$) and WREST JH decreases ($\beta = -0.44$, $p<0.001$).

Discussion

Although jump heights may be similar, utilization of eccentric and concentric components varies across team sport athletes. These findings underscore the importance of individualized CMJ phase monitoring for optimizing training and rehabilitation in team sport athletes.

Relationships Between Countermovement Jump Metrics and Fastball Pitching Metrics in Collegiate Baseball Athletes

Ms Noelle Saine MS, CSCS, Dr Erica King PhD, Dr Margaret Jones PhD, CSCS*D

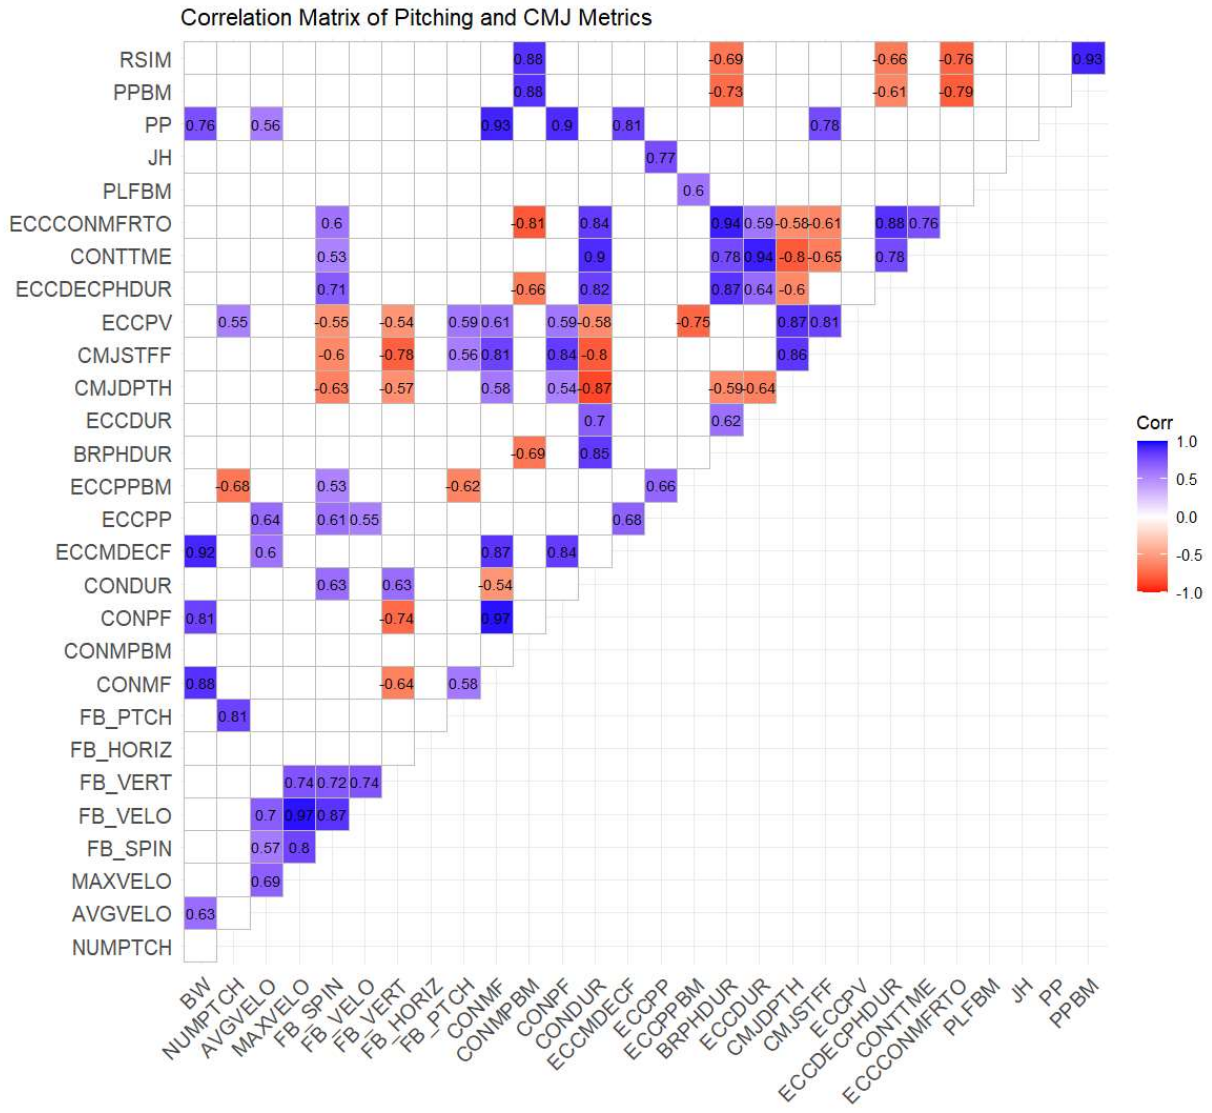
George Mason University, Fairfax, VA, United States

Introduction

Countermovement jumps (CMJs) are becoming increasingly more prevalent in sport science programs to monitor sport performance and neuromuscular readiness. Previous studies have identified significant associations between CMJ performance and pitch velocity, suggesting that lower body power production can influence throwing performance. However, limited research exists examining same-day CMJ performance and fastball pitch performance.

Methods

National Collegiate Athletic Association DI baseball players (n=10 mean + SD; age: 21.35 + 1.76 years; body mass: 90.46 + 10.12 kg; height: 186.84 + 7.62 cm; body fat: 17.56 + 1.99 %) participated. Over two fall-ball weekends, the athletes had outings where they threw a minimum of 50% fastballs, and were considered to be primarily fastball pitchers. On the morning before play, all athletes completed 3 CMJs after a standardized warmup, four hours prior to the first pitch. CMJ metrics include variables derived from the eccentric and concentric phase of the jump, as well as performance outcome variables. All pitching data was recorded via radar-based tracking software. From this software, the following fastball pitching metrics were derived: spin rate, velocity, induced vertical break, and horizontal break. A Pearson correlation coefficient was conducted to determine relationships between the CMJ and the fastball metrics. Significance was set at $p < 0.05$.



Results

Fastball velocity was significantly correlated with ECCPP (0.55, $p<0.05$). Fastball spin rate was significantly correlated with ECCDECPHDUR (0.71, $p<0.01$), CMJDPTH (-0.63, $p<0.05$), CONDUR (0.63, $p<0.5$), ECCPP (0.61, $p<0.05$), ECCCONMFRTO (0.60, $p<0.05$), CMJSTFF (-0.60, $p<0.05$), ECCPV (-0.55, $p< 0.05$), ECCPPBM (0.54, $p<0.05$), and CONTTME (0.53, $p<0.05$). Fastball induced vertical break was significantly correlated with CMJSTFF (-0.78, $p<0.01$), CONPF (-0.74, 0.01), CONMF (-0.64, $p<0.05$), CONDUR (0.63, $p<0.05$), CMJDPTH (-0.57, $p<0.05$), and ECCPV (-0.54, $p<0.05$). Horizontal break was not significantly correlated with any CMJ metrics.

Discussion

Same-day CMJ metrics are significantly correlated with fastball pitching metrics, highlighting the potential for utilization in decision-making for pitching staff outings. Future studies are needed to further explore the relationships between CMJ and fastball pitching metrics in larger samples and across competitive contexts.

In-Situ Horizontal Force Velocity Profiling in Wheelchair Rugby

Mr. Paul Lucas Spagnuolo M Sc.[1,2], Mr. Daniel Geneau M Sc.[1,2], Dr. Marc Klimstra PhD[1,2]

[1]University of Victoria, Victoria, British Columbia, Canada. [2]Canadian Sport Institute Pacific, Victoria, British Columbia, Canada

Introduction

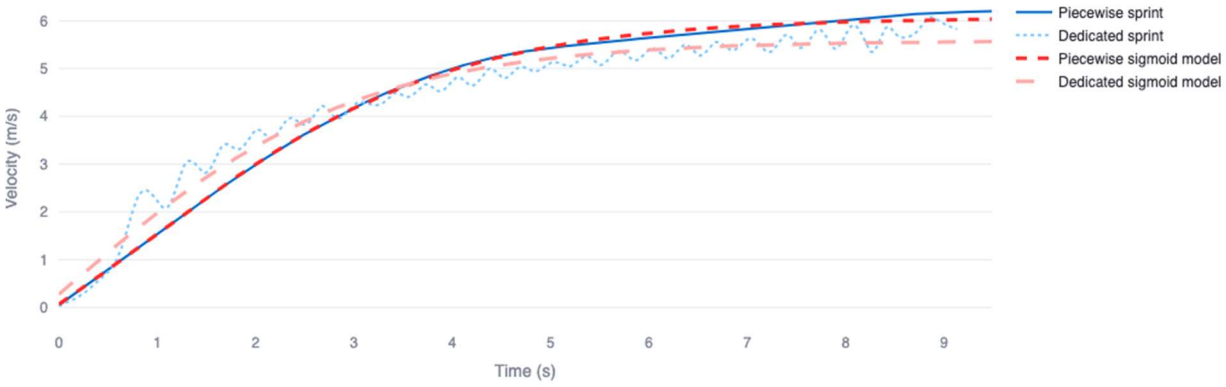
In sport it is standard practice to assess athlete physical capacity. However, isolated testing sessions can be disruptive to training. Therefore, “invisible” or “in-situ” monitoring has emerged in recent years utilizing microtechnology.

As sprinting is important in invasion sports like soccer and rugby, horizontal force-velocity-power (hFVP) profiles, have received attention. In wheelchair sport there is evidence that hFVP can be generated from wheel-mounted IMU sensors. However, there are no studies with In-Situ FV profile development. Further, new approaches support the development of a complete sprint record from piece wise sprints during training and competition.

The goal of this project was to determine whether valid FV profiles can be derived using a single wheel-mounted IMU data collected during match and practice play from piece-wise developed sprints.

Methods

Wheelchair velocity was calculated using a wheel-mounted IMU during standalone sprints (40m) and continuous in-game and training movement from 4 national wheelchair rugby athletes. The data was then filtered using a 5th order lowpass Butterworth filter with a cutoff frequency of 0.15 Hz. A piecewise sprint was constructed using maximal onset acceleration across the entire continuous dataset at every 0.01m/s. The minimum time it would take the athlete to reach the next velocity bin was then computed. This process was repeated across an athlete's dataset. A sigmoid model was fit to both the piecewise and dedicated sprint to produce a FVP profile (Figure 1.). Interclass Correlation (2,1) (ICC) was used to compare FV outcomes.
Figure 1. Dedicated Sprint and Piecewise Sprint overlayed with respective sigmoid fits



Results

Preliminary results suggest we can accurately predict theoretical maximum velocity (Vo) using these methods (R= 0.93). There was less correlation between the two methods in generating theoretical maximum force (Fo) (R = 0.65). We did not observe significant correlation between the FV Slope (R= -0.21).

Discussion

While Vo can be accurately predicted using current methods refinement of methods is required to predict Fo and FV slope. Through further development in-situ FV profiling in wheelchair sports may provide athletes and coaches accurate assessments without the need for isolated testing.

Biomechanical Characteristics During High-Demand Functional Tasks in Females After Anterior Cruciate Ligament Reconstruction: A Systematic Review

Dr Peta Johnston, Dr Brodwen McBain, Professor Jodie McClelland, Professor Kate Webster

La Trobe University, Melbourne, Victoria, Australia

Introduction

Female athletes returning to sport after anterior cruciate ligament (ACL) reconstruction have a higher risk of reinjury compared to their uninjured female counterparts. Although numerous factors have been explored, the role of altered movement mechanics during high-demand functional tasks in females has received less attention.

The aims of this systematic review were to (1) identify the high-demand functional tasks most commonly studied, (2) describe biomechanical assessment methods and (3) synthesise lower limb movement patterns in females following ACL reconstruction.

Methods

A systematic review of the literature was conducted using four databases searched until 19th of March 2025 (Embase, MEDLINE, SportDiscus and PubMed). Inclusion required that participants were assessed post-operatively for at least one biomechanical variable during high-demand functional tasks, and that biomechanical data for the ACL reconstructed limb was compared with either the unaffected limb or healthy female counterparts. Meta-analysis with standardised mean differences (SMD) were performed for peak knee angles during the bilateral drop vertical jump.

Results

A total of 71 studies met inclusion criteria. Studies evaluated biomechanics during high-demand functional tasks between five months post ACL reconstruction surgery up to 13.4 years. The most frequently investigated tasks were the bilateral drop vertical jump (21 studies), followed by running/cutting manoeuvres (13 studies), and single leg forward hops (9 studies). During the bilateral drop vertical jump, studies consistently reported increased peak knee valgus angle in the ACL reconstructed limb compared with a healthy control group (SMD 0.59; 95% confidence interval [CI] 0.04 to 1.15). In contrast, no significant differences in the peak knee flexion angle were identified during the bilateral drop vertical jump between the ACL reconstructed limb and a healthy control group (SMD 0.10; 95% CI -0.70 to 0.91).

Discussion

These findings highlight persistent alterations in knee loading patterns in females after ACL reconstruction, particularly increased knee valgus during bilateral drop vertical jumps compared with healthy controls, a movement pattern repeatedly implicated in primary and second ACL injury risk. Recognising these sex-specific biomechanical characteristics may inform more targeted rehabilitation strategies to mitigate reinjury risk in female athletes.

Biomechanical Modelling for Safety and Performance Enhancement of Running Footwear

Mr Pramod Yadav, Dr Arnab Chanda

Indian Institute of Technology Delhi, New Delhi, Delhi, India

Introduction

Running is one of the most widely practiced physical activities and a common entity in every sport. However, inadequate conditioning and improper technique frequently lead to injuries such as sprains and fractures. The design of footwear, particularly the insole and outsole, plays an important role in enhancing performance and preventing injuries by influencing lower limb biomechanics. While extensive research has been conducted on midsole behavior, limited studies have focused on how insole and outsole characteristics interact for traction, shock absorption, and overall injury risk. Key knowledge gaps include the biomechanics of progressive outsole wear and the combined influence of insole hardness, geometry, and thickness.

Methods

This study examines the traction performance of both worn and unworn running shoes, assesses the shock absorption during controlled jumping and gait tasks, and identifies design features that can improve running safety and performance. This study evaluated the traction performance of eighteen commonly used running shoes on two different track surfaces under controlled slipping conditions, including common surfaces such as ethylene propylene diene monomer (EPDM) and synthetic material-based track surfaces, in both wet and dry conditions. Further, to assess the impact of insoles on impact attenuation, vertical ground reaction forces (vGRF) were analyzed during jumping tasks.

Results

The results showed that footwear with modified hexagonal or block-based tread patterns and radial grooves produced the highest ACOF in both tracks and conditions. Additionally, a correlation analysis was conducted between ACOF and the apparent contact area, suggesting that these tread designs exhibit better resistance to synthetic surfaces due to their unique pattern. In Drop Jump, the maximum vertical reaction force was measured with and without cushioning (insole), and it was reduced by 12% with the insole. Similarly,

the vertical reaction force was significantly reduced by 35% in Counter Movement Jump with an insole compared to without an insole.

Discussion

Future work will incorporate real-time pressure mapping during Quattro Jump tasks to examine dynamic load distribution and cushioning performance. Overall, this work aims to support the development of novel footwear solutions that enhance traction, reduce injury risk, and improve performance, with direct applications for the athletic footwear industry.

Do Pitching Biomechanics Differ Between Windup and Stretch Pitching Deliveries from a Dirt Surface Mound In College Baseball Pitchers?

Dr Rafael Escamilla PhD, PT, CSCS, FACSM[1], Dr Jonathan Slowik PhD[2], Dr Rodney Imamura PhD[1], Dr Irwin Thompson EdD, PT[1], Dr Robert Asuncion DPT, PT[1], Dr Arnel Aguinaldo PhD, ATC, CSCS[3], Dr Glenn Fleisig PhD[2]

Dr Jonathan Slowik

Dr Rodney Imamura

Dr Irwin Thompson

Dr Robert Asuncion

Dr Arnel Aguinaldo

Introduction

It's unknown how pitching biomechanics in college baseball pitchers differ between windup and stretch pitching deliveries from a dirt-surface-mound. The purpose was to assess differences in shoulder and elbow kinetics and pitching kinematics in college pitchers between windup-and-stretch pitching deliveries from a dirt-surface-mound. It was hypothesized that between windup and stretch pitching deliveries, there would be a

limited number of significant kinetic differences and a greater number of significant kinematic differences.

Methods

Eighteen college pitchers pitched from a dirt-surface-mound using windup-and-stretch pitching deliveries. Inclusion criteria included healthy pitchers who all employed both windup and stretch deliveries in baseball games, employed overhead or three-quarter pitching deliveries, and pitched exclusively on dirt mounds. All pitchers were tested using a 240-Hz, 12-camera motion-analysis-system, and 28 kinematic and 7 kinetic parameters were calculated. Paired t-tests (Benjamini-Hochberg adjusted $p < 0.05$) assessed biomechanical differences between windup-and-stretch deliveries.

Results

From Table 1, maximum shoulder horizontal adduction torque, maximum shoulder anterior force, maximum lead knee height, ball velocity at ball release, forward trunk tilt at ball release, maximum upper trunk angular velocity, maximum elbow extension angular velocity, and maximum shoulder internal rotation angular velocity were all significantly greater using a windup delivery compared to a stretch delivery, while pelvic drift at maximum lead knee height was significantly greater in a stretch delivery compared to a windup delivery.

Discussion

As hypothesized, of the 35 pitching biomechanical comparisons, just over a quarter of these (9 out of 35) resulted in significant differences between windup and stretch deliveries, with most of these kinematic differences. It can be concluded that pitching kinetics in college pitchers are more similar than different between windup and stretch pitching deliveries. More research is needed to assess if the greater shoulder force and torque generated in the windup compared to the stretch increases shoulder injury risk in the windup compared to the stretch. The kinematic differences found suggest that shoulder, elbow trunk, and pelvis pitching kinematics do differ some between windup and stretch deliveries. The results of this study are important in assessing how pitching biomechanics differ between windup and stretch deliveries from a dirt surface mound for college pitchers.

Dr. Jennifer Sumner

Introduction

Prolonged running induces muscular metabolic stress, potentially impacting neuromuscular support and increasing deviations from habitual motion paths (HMP; runner's typical joint movement patterns[1]). However, the link between muscular metabolic stress and HMP deviations during running is unknown. This study examined the relationship between running kinematics and muscle oxygenation (%SmO_2), which indicates muscle oxygen supply-demand balance. We hypothesized that during a fatiguing run, a more negative rectus femoris (RF) %SmO_2 slope (i.e., deteriorating oxygen supply-demand balance) would be associated with greater ranges of motion (ROMs) and HMP deviations at the knee.

Methods

Ten recreational runners (8M/2F; 41±12yr; 73±12kg; est. 5K: 23.4±4.0min) performed a 45-minute run at 88% of maximal metabolic steady state speed. Heart rate (HR) and RF %SmO_2 were collected continuously. %SmO_2 slope was calculated between 30% and 100% of the run to exclude exercise onset muscle oxygenation dynamics. Rating of perceived exertion (RPE), three-dimensional lower limb kinematics, and ground reaction forces were collected at the start and end of the run. HMP deviations were quantified according to Sumner et al.[1]. Start- to end-of-run changes in frontal (AbAd) and transverse (TIR) plane knee deviations and tri-planar ROMs were determined.

Results

HR rose from 139±9 to 168±11 bpm (p<0.001) and RPE rose from 9.0±1.8 to 16.3±2.1 (p<0.001), indicating increased physiological stress. Linear mixed-effects modeling revealed a more negative RF %SmO_2 slope was significantly associated with greater decreases in flexion ROM (p<0.001), and greater increases in AbAd ROM (p<0.001), AbAd deviation (p≤0.002), and TIR ROM (p=0.034), but not TIR deviation (p≥0.307).

Discussion

Reduced ability of the RF to maintain oxygen supply-demand balance (negative %SmO_2 slope) during prolonged running was related to decreased sagittal ROM, increased frontal and transverse ROMs, and frontal deviation from HMP at the knee. The observed response may indicate that muscular fatigue of the RF leads to reduced neuromuscular support of the knee joint and altered movement patterns. Though further work is needed to confirm causal relationships, these findings may provide a physiological basis for targeted interventions aimed at reducing injury risk in fatigued runners.

[6]Tampere Research Center of Sports Medicine, UKK Institute, Tampere, Pirkanmaa, Finland

Introduction

Female athletes have a 4-6x greater risk of non-contact anterior cruciate ligament (ACL) injury than males [1], potentially due to biomechanical patterns including increased knee joint loading, greater knee valgus, and reduced flexion during cutting and landing [2,3]. How limb dominance and sport influence these biomechanics during these tasks remains understudied. Therefore, we investigated the effects of limb dominance and sport on ACL injury relevant biomechanics during sport-specific maneuvers in female university soccer and basketball athletes.

Methods

Female university soccer (n=23, age=20.07years, height=1.67m, weight=63.47kg) and basketball (n=12, age=20.23years, height=1.77m, weight=74.29kg) athletes completed four tasks: 180° pivot-turn, 90° cut, single-leg drop jump, and a sport-specific heading/rebound task with a 45° cut on landing. 3-D motion capture and force plates measured three trials per leg and task. Inverse dynamics calculated peak external knee abduction (pKAM), internal rotation (pKIRM) and flexion moments (pKFM), knee valgus and flexion angles (peak and initial contact), and peak resultant ground reaction force within 100 ms of ground contact. A 2×2 mixed ANOVA statistically analyzed the effects of limb (within-subject) and sport (between-subject) effects on all variables (a = 0.05).

Results

A main effect of sport revealed greater pKAM in soccer athletes during cutting tasks, and basketball athletes during the heading/rebound task. Limb main effects indicated greater non-dominant limb pKIRM for all tasks, and greater knee flexion at initial contact for the single-leg drop jump. Significant interaction effects in the heading/rebound task showed basketball athletes exhibited greater non-dominant pKFM and knee valgus at initial contact. Meanwhile, soccer athletes demonstrated greater non-dominant limb pKIRM and lesser knee flexion at initial contact.

Discussion

Limb dominance and sport significantly influenced ACL injury relevant biomechanics in female university athletes. Main and interaction effects highlighted riskier non-dominant limb cutting and landing mechanics associated with ACL injury. As sport also influenced biomechanics, perhaps sport-specific demands, training history, and anthropometric characteristics partially drive these differences. Future studies may consider these variables when aiming to modify ACL injury relevant biomechanics.

Supporting Ankle Angle Differences During Roundhouse Kicks at Two Heights

Miss Renee Alexander, Dr Timothy Derrick

Iowa State University, Ames, Iowa, United States

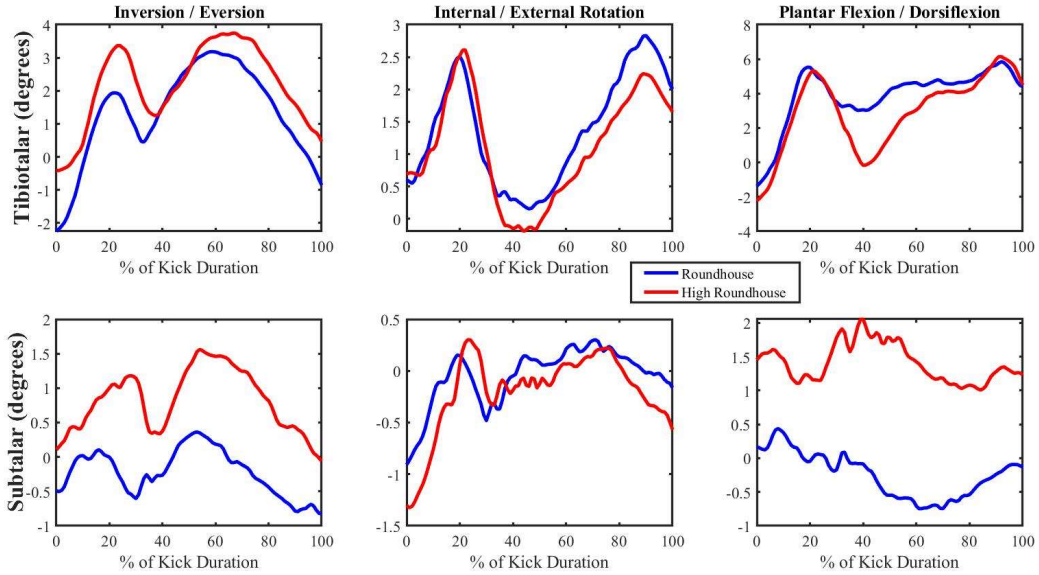
Introduction

Olypmic taekwondo sparring awards additional points for kicks to the head compared to kicks to the chest. Higher roundhouse kicks have been found to increase pelvic tilt, hip internal rotation, and maximum distal knee joint flexion [1, 2]. However, there is limited research on the supporting leg during martial arts kicks to varying heights and even less on the supporting ankle during martial arts kicking. It was hypothesized that kicking higher would change tibiotalar and subtalar ankle angles at the supporting foot.

Methods

Twenty-six black belts in kicking martial arts were recruited for the study. Marker clusters were placed on both legs and on the left ankle and foot. Ground reaction forces (AMTI, 1125 Hz) and 3D kinematics (12 camera Qualisys system, 225 Hz) were collected during five trials of roundhouse kicks to a paddle held at hip height and then at neck height. Trials were trimmed based on when the kicking foot left and then returned to the ground. Subtalar and tibiotalar angles were derived based on the relative motion of their segment markers using helical angles. SPM with an alpha of 0.05 was used to statistically compare between heights.

Results



Tibiotalar inversion angles generally increased with kick height (Figure 1). Tibiotalar internal rotation increased between about 19% to 32% of the kick duration. From 32% of the kick to the end of the kick, internal rotation at the tibiotalar joint was decreased with increased height. A higher kicking target increased tibiotalar plantar flexion, but decreased dorsiflexion. Dorsiflexion and inversion angles were increased at the subtalar joint when kicking higher. Internal and external rotations at teh subtalar joint remained similar between both conditions. No statistically significant differences were found between conditions using SPM.

Discussion

Inversion/eversion and dorsiflexion/plantar flexion angles were observed to have changed at the tibiotalar and subtalar joints of the supporting ankle when the kick height was

increased, while any changes were less prevalent for internal/external rotation. Further testing and analysis is needed to evaluate differences at the supporting ankle joints.

P1-350

Muscle Coordination Effects On Pedal-Force Direction and Mechanical Effectiveness During Incremental Stationary Cycling

Mr Reza Ahmadi, Dr Shahram Rasoulian, Dr Walter Herzog, Dr Amin Komeili

University of Calgary, Calgary, AB, Canada

Introduction

Cycling performance and joint loading depend not only on how much force is produced, but also on where and in what direction forces are applied across the crank cycle. The correlation between the ratio of the tangential component to the resultant force, or index of effectiveness (IE) [1], and muscle coordination has not been studied across different power levels.

Methods

Twenty healthy adult amateur cyclists (male/female=8/12, age 22.6±4.5 years), performed an incremental step test on a stationary bike at three intensities: the lowest power level (LPL), the middle power level (MPL), and the highest power level (HPL) at 70 RPM. EMG from 6 lower-limb muscles was synchronized with crank angle and 3D pedal reaction forces. EMG was processed to linear envelopes and normalized to a dynamic maximum. Tangential (F_t) force component was computed using standard pedal-force decomposition approaches [2], and IE = F_t / |$F_R$esultant| was calculated within crank-angle bins. Muscle coordination of the ankle joint was quantified by using the coactivation index (CI) as a ratio of agonist to antagonist pairs relevant to ankle control [3].

Results

IE increased with intensity for both limbs ($p < 0.05$). Dominant- non-dominant IE (mean±SD) was 0.32±0.14 - 0.26±0.14 (LPL), 0.59±0.07 - 0.63±0.08 (MPL), and 0.76±0.05 - 0.76±0.07 (HPL). Ankle CI also increased with exercise intensity ($p < 0.05$): 0.19±0.09 - 0.16±0.06 (LPL), 0.23±0.07 - 0.19±0.07 (MPL), and 0.33±0.11 - 0.27±0.09 (HPL). Post-hoc tests indicated significant increases from HPL compared with LPL and MPL ($p < 0.05$). Phase-specific patterns suggested that higher ankle CI coincided with relatively greater tangential force contribution and higher IE.

Discussion

These preliminary results suggest that mechanical effectiveness increased with power level. Since the ankle joint is an extensor joint in cycling, increasing CI reflects its adaptation to higher exercise intensities. Conducting the CI analysis on knee and hip

joints may provide an interpretable target for real-time biofeedback to improve effective force application while maintaining stability.

Images (Optional)

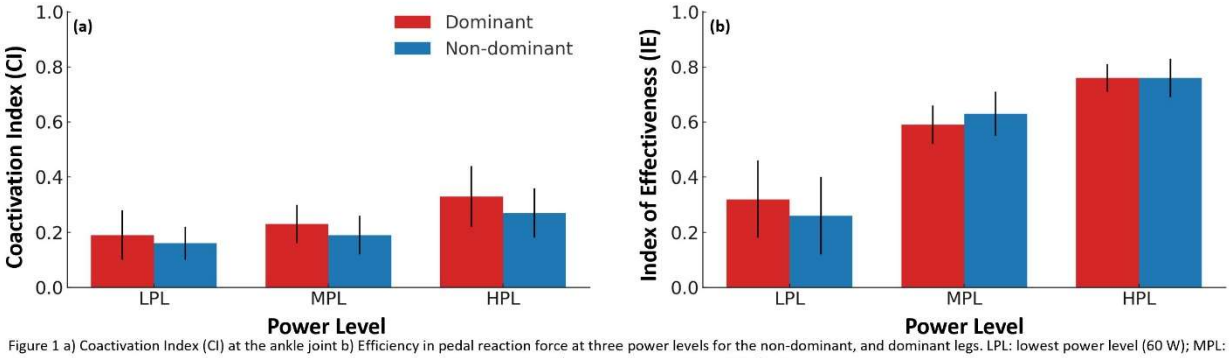

Figure 1 a) Coactivation Index (CI) at the ankle joint b) Efficiency in pedal reaction force at three power levels for the non-dominant, and dominant legs. LPL: lowest power level (60 W); MPL: middle power level (midway between LPL and HPL); HPL.

Influence of Attentional Cues on Inter-Limb Biomechanics During the Rear Foot Elevated Split Squat

Mr. Ryan Burke[1], Mr. Morgan Murray[1], Dr. Stain Larsen[2], Dr. Erik Hummer[1]

[1]Rutgers, The State University of New Jersey, New Brunswick, NJ, United States. [2]AFPT, Fredrikstad, Ostfold, Norway

Introduction

INTRODUCTION: This study aimed to investigate how different attentional focus cues influence acute responses in vertical ground reaction forces (vGRF) and lower-extremity muscle action potentials measured via surface electromyography (sEMG) of resistance-trained individuals during the rear foot elevated split squat (RFESS).

Methods

METHODS: 20 individuals (10F; 23.2 ± 4.2 yrs; 169.8 ± 8.8 cm; 74.6 ± 13.7 kg) completed 2 sets of the RFESS at 10 RM load emphasizing either their front or rear limb to complete the task. Synchronous collection of vGRF data sEMG amplitudes of the rectus femoris (RF), vastus medialis (VM), vastus lateralis (VL), biceps femoris (BF), semitendinosus (ST), and medial gastrocnemius (MG) were collected. A 2 × 2 (limb × attentional focus cue) repeated-measures multivariate analysis of variance was conducted on key outcomes ($\alpha = 0.05$).

Results

RESULTS: A significant main effect of limb was observed ($F = 68.405$, $p<0.001$, $\eta_P^2=0.855$). Further statistical assessment found significant differences between limbs (Front – Rear) for average vGRF (mean difference [MD] = 779.01 N, $p<0.001$, d=4.9) and for the average normalized sEMG amplitude for the following: BF (MD = 0.392, $p<0.001$, d=1.8), MG (MD = 0.050, $p<0.001$, d=1.0), ST (MD = 0.333, $p<0.001$, d=1.4), VL (MD = 0.098, $p<0.001$, d=1.2), and VM (MD = 0.116, $p<0.001$, d=0.9) but not for RF (MD = 0.031, $p=0.116$, d=0.1).

Discussion

DISCUSSION: Directing individuals to emphasize the use of a specific limb did not elicit any statistically relevant responses in primary outcomes. More structured or objective feedback to enhance the verbal cue may be necessary for individuals to adopt significantly altered movement pattern during the RFESS. We did find a significant effect of limb on all key outcomes despite the average normalized sEMG amplitude for the RF. The average normalized sEMG for the BF, ST, MG, VM, and VL displayed decreased activation in the rear limb, supporting the notion of the rear limbs' role aiding in stabilization. The non-

significance found in the RF may be indicative of a similar degree of action potential activity in this bi-articular muscle in the rear limb compared to front limb.

Does Box Height During the Rear Foot Elevated Split Squat Impact Lower Extremity Biomechanics?

Mr. Ryan Burke[1], Mr. Morgan Murray[1], Dr. Stian Larsen[2], Dr. Erik Hummer[1]

[1]Rutgers, The State University of New Jersey, New Bunswick, NJ, United States. [2]AFPT, Fredrikstad, Østfold, Norway

Introduction

This study aimed to investigate how different rear foot heights (40 and 28 cm) impact vertical ground reaction forces (vGRF) and average normalized surface electromyography (sEMG) amplitudes in the lower extremities of resistance-trained individuals the rear foot elevated split squat (RFESS).

Methods

19 individuals (9F;23.2 ± 4.2 yrs;169.8 ± 9.0 cm;75.0 ± 13.4 kg) completed two sets of the dumbbell RFESS (40 cm and 28 cm heights, 10-RM load). Synchronous collection of 3D kinetics (1200 Hz, AMTI) and bilateral lower extremity muscle action potentials (1200 Hz, Delsys Inc.) for the biceps femoris (BF), semitendinosus (ST), medial gastrocnemius (MG), vastus lateralis (VL), vastus medialis (VM) and rectus femoris (RF) were conducted. sEMG data was processed using a linear envelope and normalized to the peak sEMG amplitude during a countermovement jump. A 2×2 (limb×height) repeated-measures multivariate analysis of variance was conducted with a *priori* alpha set to 0.05.

Results

No significant interaction ($F = 0.333$, $p=0.936$, $\eta_P^2=0.034$) or main effect of height ($F = 0.092$, $p=0.999$, $\eta_P^2=0.010$) were found but, a main effect of limb was demonstrated ($F = 84.693$, $p<0.001$, $\eta_P^2=0.900$). Further assessment found significant differences for vGRF (mean difference [MD] = 791.38 N, $p<0.001$, d=5.1) and for the average normalized sEMG amplitude for the following: BF (MD = 0.294, p 0.001, d=1.9), MG (MD = 0.052, $p<0.001$, d=1.3), ST (MD = 0.285, $p<0.001$, d=1.7), VL (MD = 0.105, $p<0.001$, d=1.0), and VM (MD = 0.099, $p<0.001$, d=1.1) but no statistical significance for the RF (MD = 0.004, $p=0.835$, d=0.4).

Discussion

The differences in height may not have been relevant enough to elicit notable changes in key variables. Additionally, rear foot heights exceeding 40cm were not assessed and merit further investigation with implications for lower extremity bi-articular musculature. The front limb displayed significantly greater average vGRF and average normalized sEMG amplitude of all lower extremity muscles apart from the RF. This may indicate that the RF plays a larger role in the stabilization of the rear limb during the RFESS. However, further

analysis is needed to draw more concrete conclusions. Future studies exploring muscle forces derived from muscle activation dynamics may provide additional insight.

Effects of Running Shoe Midsole Compliance on Running Performance

Mr. Ryan Knowles, Dr. Rachel Robinson, Dr. Alex Denton, Dr. Mike Hahn

University of Oregon, Eugene, OR, United States

Introduction

Modern running shoe parameters can enhance an athlete's biomechanical and physiological performance [1]; however, the independent and collective effects of midsole stiffness and bending stiffness remain unclear. Midsole stiffness alone [2] or the combined effect of midsole stiffness and longitudinal bending stiffness [3] can enhance running performance by improving running economy through the storage and return of elastic strain energy during ground contact. Thus, the purpose of this study was to examine the impact of running shoe midsole stiffness on running mechanics and metabolic cost of transport (MCOT) using musculoskeletal modeling and computer simulation. It was hypothesized that a more compliant midsole would lower MCOT.

Methods

Preliminary work generated predictive simulations of a stride of running (3.16 m/s) in OpenSim Moco [4] with a sagittal plane model [5]. The goal of the optimal control problem was to minimize the sum of cubed muscle excitations. Ground contact elements were calibrated to match the industry-tested stiffness of a neutral baseline running shoe and varied -75-100% of baseline. Each solution was used to estimate whole-body and muscle-specific MCOT [6].

Results

The data displayed a U-shaped relationship between midsole stiffness and MCOT (R^2 = 0.88) (Figure 1). Midsole stiffness 50% lower than baseline minimized MCOT and lowered whole-body MCOT by 1%. Lower whole-body MCOT was driven by lower hip (2.7% decrease) and knee (1.6%) extensor muscle-specific costs.

Discussion

A relatively compliant midsole was beneficial for lowering whole-body metabolic energy cost by lowering the demand on metabolically expensive muscle groups, but had no impact on more economical muscle groups, such as the plantar flexors. Running shoes with compliant midsoles should be considered for endurance efforts to enhance performance. Further investigation is required to characterize individual responses to

midsole stiffness. This work is being expanded using a 3-D musculoskeletal model paired with experimental data from a cohort of distance runners.

Competitive Level Influences Performance of Double Figure Skating Jumps

Ms. Sarah Trager Ridge PhD[1], Ms. Mia Caminita PhD[2], Ms. Elizabeth Klemm MS[3], Mr. Dustin Bruening PhD[4], Mr. Michael Jones PhD[4]

[1]University of Hartford, West Hartford, CT, United States. [2]Children's National Hospital, Silver Spring, MD, United States. [3]East Carolina University, Greenville, NC, United States. [4]Brigham Young University, Provo, UT, United States

Introduction

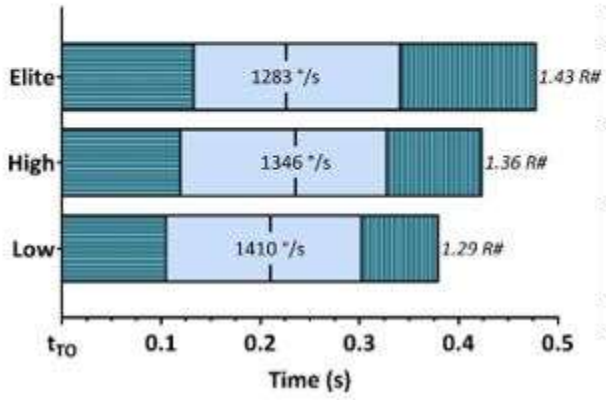
Success in competitive singles figure skating requires the performance of high-quality jumps. Historically, coaches and skaters have honed technique based on a combination of experience, trial and error, and the application of fundamental biomechanical principles. The current availability and quality of wearable devices now allow researchers to quantify jump performance and optimize technique for performance and injury prevention. The purpose of this study was to compare how skaters of different competitive levels perform multiple rotation jumps.

Methods

Fifty-six figure skaters wore a waist-mounted IMU as they performed 222 double rotation jumps. Synchronized high speed video was collected to identify take-off and landing events, jump type, and whether the jump was fully rotated. Key performance metrics (KPM) were calculated from the gyroscope. Groups were created based on skaters' US Figure Skating competition levels - Elite = Junior or Senior international (12 skaters/32 jumps); High = Novice, Junior, or Senior domestic (25 skaters/118 jumps); Low = Preliminary, Juvenile, or Intermediate, (19 skaters/71 jumps). KPM were compared between groups using ANOVAs followed by Tukey pairwise post-hoc tests ($\alpha<0.05$).

Results

Air time (t-air) and rotations completed (R#) increased with skater level, while peak angular velocity (ω-p) decreased (Figure 1). For these three variables, all pairwise comparisons were significant, except for R# between elite and high levels. Timing variables were not different among levels.



Discussion

Higher-level skaters who are able to successfully complete triple jumps performed their double jumps differently than lower-level skaters, primarily driven by their greater t-air. Theoretically, they could perform doubles either through a more open body position or by

altering timing, for instance completing the required rotations earlier to prepare for landing. Our results suggest that they typically choose the former, in line with a prior study showing similar timing control despite using a tool to increase rotation speed [1]. In contrast, lower-level skaters with lower t-air must rotate faster. This suggests that increasing t-air is a critical developmental step prior to attempting additional rotations (e.g. progressing from double to triple jumps). Using this type of objective data could increase training efficiency and, by extension, decrease injury risks.

Images (Optional)

Figure 1: Group average KPM during all double jumps (excluding Axels). The horizontal bars represent air time (t-air) and are split into intervals based on the timing of angular velocity events. The middle light shaded area includes peak angular velocity (ω-p, broken vertical line) and represents the time the skater is above 90% w-p. The darker horizontal and vertical striped areas represent periods leading up to (t+90) and dropping below (t-90) this threshold (both events expressed as % t-air). The number to the right of each bar represents the average number of rotations completed (R#) during the double jumps.

	t-air	ω-p	R#	t+90	t-90
Elite	0.48 ± 0.08	1283 ± 100	1.43 ± 0.19	27.6 ± 17.9	72.4 ± 20.2
High	0.42 ± 0.06	1346 ± 110	1.36 ± 0.18	28.9 ± 19.7	78.4 ± 21.8
Low	0.38 ± 0.06	1410 ± 127	1.29 ± 0.19	28.4 ± 18.0	80.5 ± 21.2
p	<0.001	<0.001	<0.001	0.936	0.203

[5]Research Institue, BC Children's Hospital, Vancouver, British Columbia, Canada. [6]Department of Orthopedics, Faculty of Medicine, UBC, Vancouver, British Columbia, Canada

Introduction

The Motion Lab (TML), BC Children's Hospital conducts clinical motion analysis following anterior cruciate ligament reconstruction (ACLr) to evaluate readiness to return to sport, using parameters including spatiotemporal characteristics [1]. Comparisons of marker-based versus markerless motion capture (MoCap) quantifying gait parameters have been studied showing reliable agreement [2]. These comparisons are underexplored for sport assessments, particularly in paediatrics. This study compares marker-based and markerless MoCap for measuring spatiotemporal characteristics in paediatric sport assessments following ACLr.

Methods

For this non-randomized cross-sectional study, participants were divided into two groups: >9 months post–ACLr, referred for sport assessment; and control population with no injury history. Retro-reflective markers were placed on anatomical landmarks and participants followed the PRiSM Sports Protocol [3]. Marker-based and markerless data was collected simultaneously using Qualisys MoCap system (12 Oqus, 12 Miqus cameras). Marker-based data was processed in QTM and markerless data using Theia for the same activity trials. Data was analyzed with Visual3D to calculate spatiotemporal characteristics, including single leg hop distance normalized to height (SLHDH) and limb symmetry index (LSI). Metrics were compared between MoCap techniques and groups.

Results

Participants in post-ACLr (n=4, 3 female, 3 left ACLr) were mean 15.7y (sd=1.6) and the control (n=2, 2 female) were mean 15.9y (sd=0.7). For post-ACLr, mean LSI for marker-based and markerless, was 95.83% (sd=2.76) and 96.08% (sd=2.71) (Figure 1). For the control, mean LSI for marker-based and markerless, was 99.76% (sd=5.09) and 100.05% (sd=3.27) (Figure 1). Mean SLHDH of post-ACLr for marker-based and markerless, was 88.37% (sd=15.78) and 88.37% (sd=15.48). For the control, mean SLHDH for marker-based and markerless, was 80.49% (sd=5.25) and 80.57%(sd=4.63). Average difference between marker-based and markerless LSI post-ACLr was 0.40% (sd=0.29) and control 1.82% (sd=0.29). For SLHDH post-ACLr was 0.52% (sd=0.25) and control 0.55% (sd=0.51).

Discussion

Preliminary results show minimal differences in the LSI and SLHDH between MoCap techniques. There is a greater difference in LSI between techniques for the control compared to post-ACLr. Additional participants are required to further explore the relationship between MoCap techniques and groups.

Are Failed Decisions Associated With Increased Knee Loading Under Complex Cognitive Demands?

Dr. Fatemeh Aflatounian[1,2], Dr. Keith Hutchison[1], Dr. James Becker[1], Dr. Corey Pew[1], Dr. Scott Monfort[1]

[1]Montana State University, Bozeman, Montana, United States. [2]Virginia Commonwealth University, Richmond, Virginia, United States

Introduction

Anterior cruciate ligament (ACL) injuries often occur during unplanned cutting/landing movements. Cognitively challenging jumping protocols aim to evaluate biomechanics during these scenarios by requiring participants to react to directional cues, which often produce failed or unbalanced landings. These imperfect trials are typically discarded, yet they may reveal meaningful deficits in muscle activation, joint stability, and dynamic postural control. This study examines whether knee biomechanics of unbalanced and successful jump landings vary with failure rate in response to challenging decision-making demands.

Methods

Forty-one active recreational athletes (17F/24M; 23.7±3.7yrs) completed drop-landing tasks recorded with markerless motion capture (100Hz) and force plates (1000Hz). Three conditions were tested: Baseline (anticipated direction), Simple (reactive single-leg landing toward a basketball image on one side of the screen), and Complex (reactive landing toward a basketball image or away from a simulated opponent). Trials were classified as successful, unbalanced, or failed. Unbalanced trials involved correct cue responses but inability to maintain balance for two seconds. Failed trials involved incorrect cue responses but landing on the wrong limb(s). Failed trial percentage (Failed%) was calculated for each cognitive condition. Kinematic/kinetic data were processed in Theia3D/Visual3D. Primary outcomes included changes between successful and unbalanced trials for peak knee flexion angle (ΔpKFA), peak knee abduction angle (ΔpKAbA), and peak knee abduction moment (ΔpKAbM), and their Pearson/Spearman correlations with Failed% (α=0.05).

Results

For ΔpKFA and ΔpKAbA, no significant correlations were observed. ΔpKAbM showed no association in the Simple condition; however, in the Complex condition, higher failure rates were associated with greater ΔpKAbM (ρ=-0.4,p=0.01; Figure-1).

Discussion

Differences in kinematic outcomes between successful and unbalanced landings were not associated with failure rate. However, under higher cognitive load, athletes with higher failure rates demonstrated riskier responses during unbalanced landings, which may indicate gross deficits in coordinating neuromuscular responses to directional stimuli. This result highlights the potential bias that may be introduced if isolating pKAbM estimates to only typically considered 'successful' trials (i.e., those with higher failure rates show greater deterioration in biomechanics for unbalanced trials that are often omitted). These findings support incorporating cognitively demanding tasks and unbalanced trials to reveal ACL-relevant neuromechanical vulnerabilities.

Images (Optional)

Individualized Biomechanical Responses to Rest Duration during an Ultra-Endurance Running Event

Mr. Sean K.T. Gaiesky MSc.[1,2], Ms. Minju Kim MSc.[1,2], Ms. Jessica Yeoman[1,3], Dr. Aïda Valevicius PhD[3], Mr. Tyler Chuang MSc.[3], Dr. Christopher Napier PhD[1,2]

[1]Simon Fraser University, Burnaby, B.C., Canada. [2]University of British Columbia Okanagan, Kelowna, B.C., Canada. [3]lululemon Athletica, Vancouver, B.C., Canada

Introduction

Ultra-endurance running (UER) performance is contingent on how an athlete balances the demands of the task with adequate rest. Although athletes appear to lower their peak vertical force from pre- to post-UER [1], individualized rest strategies during multi-day races could potentially lead to altered responses throughout the event. Our objective was to determine how individual rest strategies affect biomechanics during a multi-day UER event.

Methods

Ten athletes completed a 6-day time-limited UER event. Participants wore sacral-mounted inertial measurement units (IMUs; 500Hz; Plantiga Technologies, Vancouver, Canada) and re-oriented acceleration signals were used to calculate kinetic and spring-mass biomechanical outcomes [2,3]. Mean vertical stiffness (kNm^{-1}) and peak vertical force (BW) were calculated for non-overlapping 60-second windows. Rest strategy was self-regulated and preceding rest-type defined as short (≥10 and <60 min) or long (≥60 min). Athlete-specific linear models were used to determine the effects of rest-type and running-bout (periods of running separated by >10 minutes) on the biomechanical outcomes, while controlling for speed.

Results

The top two finishers who covered the most distance were analyzed (Athlete A: 42 y, 901.7 km; Athlete B: 32 y, 643.5 km). Both athletes demonstrated significant main effects of running-bout (β: 0.27 – 0.65; η^2: 0.26 – 0.65), and rest-type (β: -0.52 – 0.34; η^2: 0.01 – 0.10) on vertical stiffness and peak vertical force ($p < 0.05$). Both athletes also demonstrated significant interaction effects on vertical stiffness (β: -0.02 – 0.01; η^2: 0.01 – 0.04); however, only Athlete A showed an interaction on peak vertical force (β: -0.001; η^2: 0.02).

Discussion

Athlete B consistently exhibited higher vertical stiffness and similar peak vertical forces following a long rest, whereas Athlete A's rest-type response was dependent on rest-type and running-bout (Figure 1). Athlete B's rest strategy, centered around longer long rests, potentially enabled them to resist the decreases in vertical peak force often adopted following UER events [1]. Although limited to the specific individuals, our results provide further insight into how in-race rest strategies could play an important role in the maintenance of running technique.

Images (Optional)

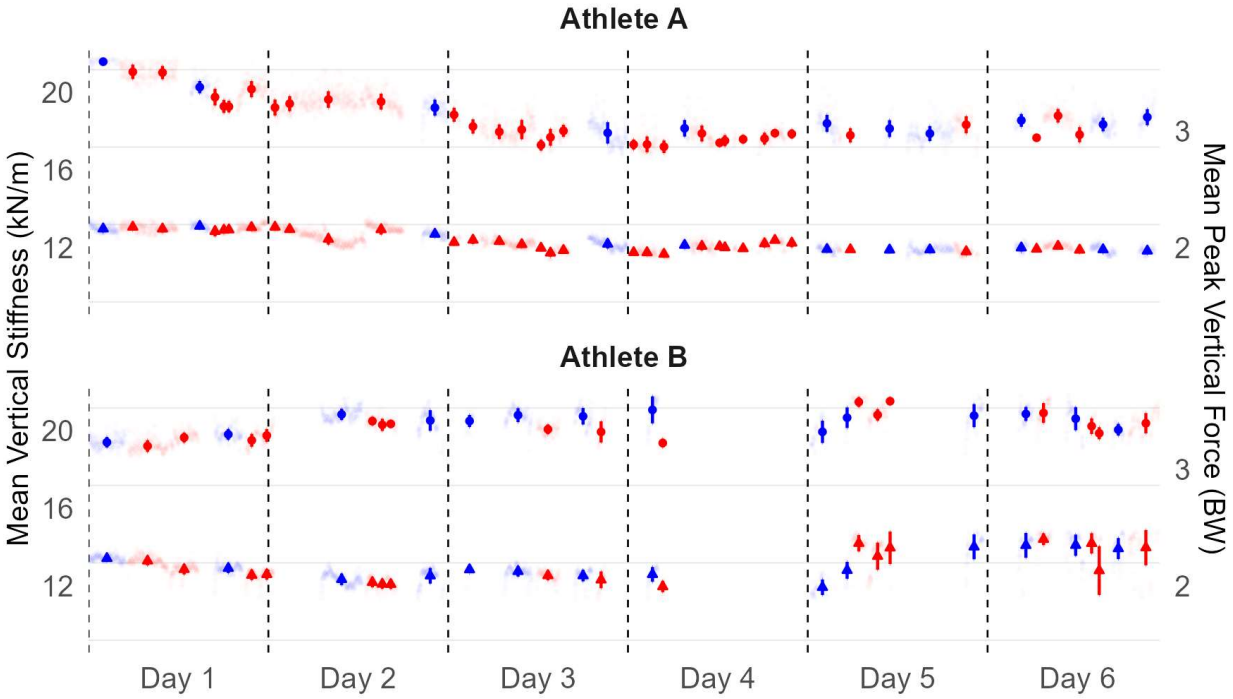

Figure 1. Running-bout and minute averaged vertical stiffness (kN/m) (●) and peak vertical force (BW) (▲) +/- 1SD following long (●) and short (●) rest-types over the 6-day UER event for Athlete A and Athlete B. Small translucent points represent individual observations.

Stopping Shots: Understanding the Relationship Between Goaltender Leg Pad Construction and Over Rotation During Common Goaltending Movements

Mr Seth Daley MSc, Ms Jasmine Kwan BSc, Dr Ryan Frayne PhD

Dalhousie, Halifax, NS, Canada

Introduction

Ice hockey goaltenders adopt complex, often extreme body postures, as they attempt to stop 110–141 km/hr shots; therefore, their equipment must provide adequate protection without impeding performance or interfering with their movements. Goaltender leg pad construction typically falls into one of two designs: a stiff leg pad, and a flexible leg pad. Common player feedback is that the stiff pads may interfere with movements and apply unwanted forces to the goaltender, and flexible pads may twist (along the long axis) or over-rotate causing holes beneath the leg pad and ice surface. The purpose of this study is to understand the effect that pad construction has on their respond to forces applied during common movements.

Methods

This study recruited 13 participants ranging in skill from junior hockey to professional. Each goaltender conducted four common goaltender movements (Ready stance, T-push, Butterfly and RVH) in 5 different pad conditions varying in knee and thigh region flexibility (i.e. control, Pre-curved-Flexible, Pre-curved-stiff with thigh extension, straight-flexible and straight- stiff with thigh extension). A 14 camera (Optitrack Inc.) passive motion capture system collected rigid bodies that tracked pad rotations during the movements. Tekscan pressure sensors, located at the goaltender/equipment interface recorded goaltender applied forces.

Results

Minimal interface forces were identified for all movements except the RVH, where increased forces were located lateral and below the knee of the pad. Preliminary analyses suggest that the pre-curved pads have greater longitudinal torsion (15°) during the RVH compared to straight pads (10°). Leg pad roll, relative the ice surface, was greatest (30°) in a straight stiff pad condition compared to straight flex pads (15°) or pre-curved pads of either design (17°).

Discussion

Leg pad over torsion and over-rotation is a concern for goaltenders during blocking positions, like the RVH, as it decreases pad surface area shown to the shooter. Over rotation, additionally, causes gaps in the seal between the pad and the ice surface where a puck could get through. Therefore, from a performance perspective, the pre-curved pads "bending" but not "breaking" the seal with the ice surface during the RVH may make them the preferable pad for goaltenders.

Effects of Non-Elastic Ankle Taping on Time-Series Muscle Activation and Joint Mechanics During Landing in Individuals With Chronic Ankle Instability

Dr. Seung-Min Baik[1], Prof. Heon-Seock Cynn[1], Prof. Chung-Hwi Yi[1], Prof. Woochol Choi[1], Prof. Jae-Hun Shim[2], Prof. Ji-Hyun Lee[2], Ms. Kyung-Eun Lee[1], Mr. Seok-Hyun Kim[1]

[1]Department of Physical Therapy, College of Software and Digital Healthcare Convergence, Yonsei University, Wonju-si, Kangwon-do, Korea, Republic of. [2]Departement of Physical Therapy, Baekseok University, Cheonan-si, Chungcheongnam-do, Korea, Republic of

Introduction

Individuals with chronic ankle instability (CAI) commonly exhibit altered neuromuscular control during landing, potentially increasing mechanical demands on the ankle [1, 2]. Although non-elastic ankle taping is frequently applied to enhance functional stability, its time-series effects on muscle activation and ankle joint mechanics across different landing tasks remain unclear. This study examined whether non-elastic ankle taping reduces neuromuscular demands and ankle joint loading during multiple landing conditions in individuals with CAI.

Methods

Twenty-nine participants with CAI were recruited using the International Ankle Consortium criteria [2]. Exclusion criteria included lower-extremity surgery or fracture, recent injury, and musculoskeletal or neurologic disorders. Participants completed single-leg drop landings on flat, foam, and laterally inclined surfaces, with and without taping. Surface EMG was collected from the biceps femoris, peroneus longus, tibialis anterior, and medial/lateral gastrocnemius. External ankle joint moments in sagittal, frontal, and transverse planes were computed using motion-capture and force-plate data. Time-series muscle activity and joint moments during the preactivation and landing phases were analyzed using one-dimensional statistical parametric mapping (SPM1d; paired t-tests, $\alpha = 0.05$) [2, 3]. The institutional review board approved all procedures.

Results

Across tasks, taping significantly reduced EMG activity in multiple muscles during both preactivation and landing phases. Reductions were most consistent in the peroneus longus, tibialis anterior, and gastrocnemius muscles across the flat, foam, and wedge conditions. Sagittal-plane external ankle moments were also decreased with taping during flat and foam landings. No significant differences were observed in frontal or transverse-plane moments for any task.

Discussion

Non-elastic ankle taping reduced neuromuscular activation and sagittal-plane ankle joint loading during single-leg landing in individuals with CAI, suggesting decreased neuromuscular demand when taped. However, the magnitude and timing of these effects varied by task, indicating that taping does not uniformly influence landing biomechanics across instability-provoking conditions. These findings highlight the task-dependent nature of taping effects and underscore the need to consider landing context when implementing taping strategies for CAI management.

Images (Optional)

Impact of Sex and Skate Blade on Backwards Skating Kinematics and Plantar Pressure in Ice Hockey Players

Dr. Shawn Robbins BscPT, PhD[1,2], Ms. Natalie Schwarz MSc[1], Mr. Tayfun Ertekin BSc[1], Mr. Philippe Renaud MSc[1], Dr. Richard Preuss BSc, MSc, PhD[1], Dr. Dustin Bruening BSE, MSc, PhD[3], Dr. Philippe Dixon BSc, MSc, PhD[1]

[1]McGill University, Montreal, QC, Canada. [2]Centre for Interdisciplinary Research in Rehabilitation of Greater Montreal, Montreal, QC, Canada. [3]Brigham Young University, Provo, UT, United States

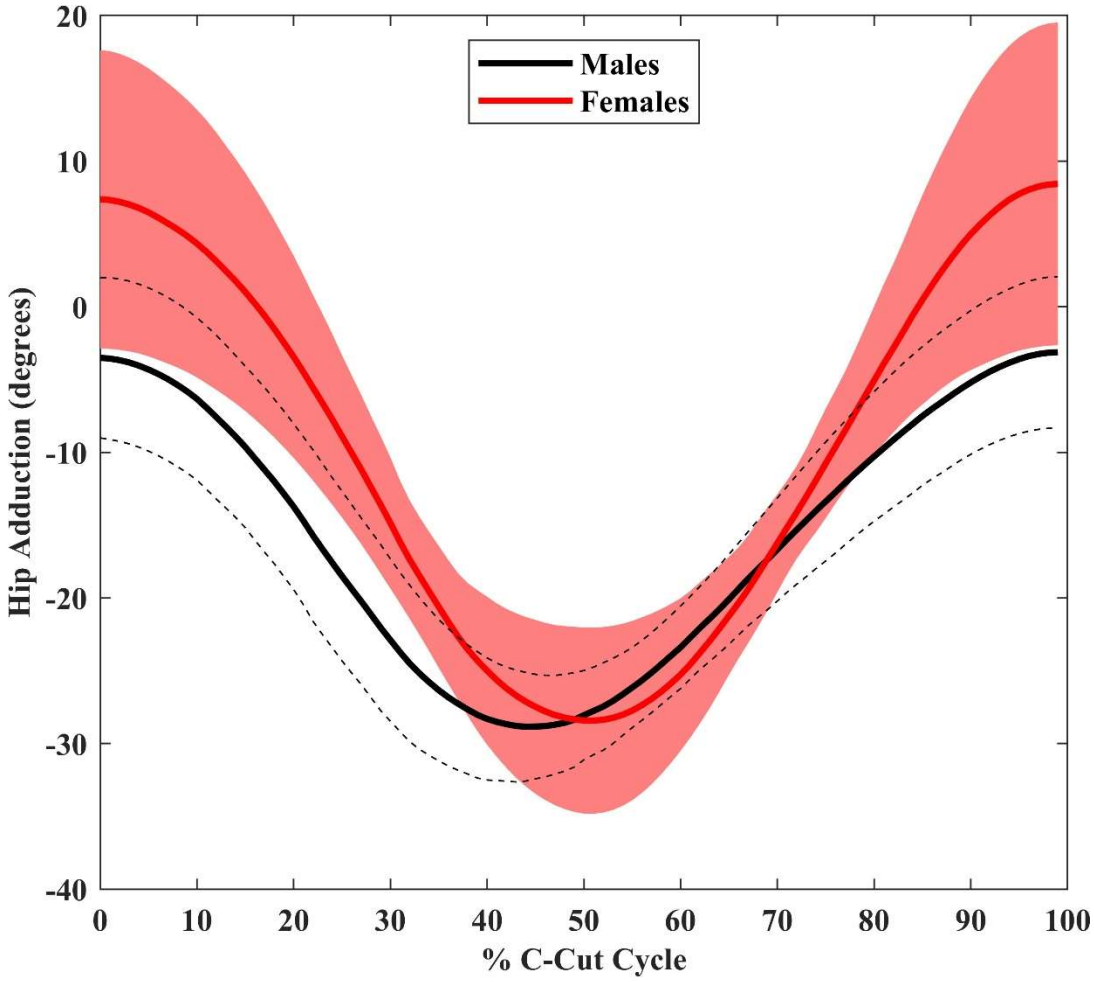
Introduction

Sex differences have been found during forward skating in ice hockey players,[1,2] but has not been investigated during backwards skating. New skate blade designs may impact backwards skating. The objective was to compare joint angles and plantar pressures between males and females when using different skate blades during backwards skating c-cuts.

Methods

Sixteen players (7 males, 9 females) were recruited for this cross-sectional study. They completed backwards skating c-cuts using four skate blades that had different radii of curvature (ROC): standard (10 foot radius), Quad (four different radii), Zuperior (three different radii), Ellipse (ellipse shape). Kinematics were measured with 17 inertial measurement units (Xsens) at 120 Hz. Lower extremity joint angles were calculated using Carden XYZ, and hip angles were used to segment c-cuts into push and recovery phases. Joint angle waveforms were compared between sex and blade conditions using statistical parametric mapping. Plantar pressures (Xsensor) were measured at 120 Hz, and feet were split into six regions (medial and lateral hindfoot, midfoot, forefoot). Hierarchical linear models assessed relationships between mean plantar pressure during c-cuts with sex, blade, and their interaction.

Results



There were no significant blade effects for joint angles. However, females had greater hip adduction during push phase (Figure 1) and less knee flexion during recovery. For plantar pressures, there were significant regression coefficients ($p<0.001$ to 0.033) for blade and sex-blade interactions in all regions. Males had lower plantar pressures with the Quad (four radii) and Zuperior (three radii) blades in five and three regions, respectively, compared to

the standard blade. Plantar pressures did not differ substantially between blades for females.

Discussion

Greater hip adduction and less knee flexion during backwards c-cuts in females was consistent with forward skating studies and may be due to anatomical and strength sex differences.[1,2] Males and females had different responses to non-standard blade designs. Designs for non-standard blades were a larger departure from standard blade for males and they were unable to adapt to ROC changes. Results indicate that sex should be considered when designing equipment.

SHOULDER OR ELBOW: THE BETTER AXE-THROWING STRATEGY?

Graduate Student Shelby Schober, Undergraduate Student Brady Holcomb, Dr. Amber Chelette, Dr. Jeremy Stovall

Stephen F. Austin State University, Nacogdoches, Texas, United States

Introduction

Axe throwing is an increasingly popular timbersport. Due to little prior research, there is limited understanding of the upper-body biomechanics involved in effective axe throwing techniques. This study seeks to identify the most accurate axe throwing techniques and determine if throwing strategies differ by sex. An analysis of shoulder and elbow biomechanics was conduced in male and female collegiate timbersport athletes.

Methods

Ten subjects (5 females, 5 males with average age of 20.4) were recruited from a collegiate timbersports team. The axe had a head weight of 1.35 kg, an edge length of 15 cm, and a wood handle length of 52 cm. Athletes stood ~4.6 m from a wood plank target 70.5 cm wide with a 0.25 cm wide dot for a bullseye at 1.23 m above the ground.

Axes were thrown two handed and were recorded only if the axe successfully stuck in the target. Accuracy was measured as the distance between the center of the bullseye of the target to the closest point of the axe bit.

A Matlab script was utilized to calculate functional range of motion (FROM) in the sagittal plane. Spearman's Rho determined the relationship of shoulder and elbow functional range of motion with accuracy. Mann-Whitney U was conducted to analyze differences between males and females.

Results

Spearman's Rho illustrated a moderate correlation between accuracy and FROM in both shoulder (r=.28) and elbow (r=.52) flexion. Elbow FROM significantly differed between male (25.8±, 19.8) and female (10.3±, 5.78) (p = .01), but not shoulder FROM or accuracy. Examination of a shoulder and elbow FROM scatter plot demonstrates females tend to use more elbow and less shoulder compared to the male subjects.

Discussion

Males and females use different strategies for throwing an axe but their differing strategies did not affect their accuracy of throwing. This difference may be attributable to size or strength which should be studied further.

Comparison of Ankle Kinetic Estimates During Badminton Lunge Using a Custom Inertial Sensor-Based System vs. an Optical Motion Capture System With OpenSim

Mr Shifin A S[1], Mr Apoorv Shrivastava[1], Mrs Saranya Navratnarajah[2], Mr Jeevaraaj N[2], Mrs Siew Li Goh[2], Mr Darshan S. Shah[1]

[1]Indian Institute of Technology Bombay, Mumbai, Maharashtra, India. [2]Universiti Malaya, Kuala Lumpur, Wilayah Persekutuan Kuala Lumpur, Malaysia

Introduction

Inertial measurement units (IMU) have been widely used to estimate joint kinematics considering the advantages of cost-effectiveness, lower setup times and out-of-lab capabilities when compared to optical motion capture systems (OMC).[1,2] Musculoskeletal models based on custom-IMU systems could provide hardware frugality and model versatility to estimate joint kinetics; although, efficiency of custom-IMU systems in estimating kinetic parameters needs validation against benchmarked OMC-based approaches. Therefore, the current study aims to compare the ankle joint moments during badminton lunge estimated from kinematics captured using a custom-IMU system against those obtained from OpenSim using OMC-derived kinematics.

Methods

Custom IMUs (MPU9250, InvenSense, USA) and retroreflective markers were attached to the foot and shank segments of five recreational badminton players, following institutional ethical approval. Ankle kinematics were captured using an eight-camera OMC system (Qualisys, Sweden), while ground reaction forces were measured using force plates (AMTI, USA). Each subject performed five cycles of ankle plantar-dorsiflexion (PDF) for the functional calibration of custom IMUs,[3] followed by three trials of forward badminton lunges. A custom subject-specific musculoskeletal model of the lower limb was developed (MATLAB R2025a, Mathworks, USA) to estimate ankle joint moments using the custom-IMU-derived kinematics. Root mean square error (RMSE), Pearson correlation (R) and paired t-test were used to compare aforementioned normalised ankle joint moments with OpenSim estimates based on OMC-derived kinematics.

Results

Custom-IMU-based peak PDF moment and inversion-eversion moment were higher than those obtained from OpenSim ($p<0.02$) with high correlation in overall trends ($R=0.94$)

(Figure 1). RMSE for custom-IMU-derived method with respect to OpenSim was 0.06 N.m/kg.m and 0.04 N.m/kg.m for PDF and inversion-eversion moments, respectively.

Discussion

Efficacy of the custom-IMU system to estimate joint kinetics was exhibited through the good correlation of joint moments with OpenSim values; however, overestimations in ankle joint moments observed in custom-IMU-based model could be incorrectly interpreted towards injury prediction. Better functional calibration protocols of the custom-IMU sensors could improve joint kinetic estimations using custom-IMU systems coupled with custom subject-specific musculoskeletal modelling.

P1-363

Agreement between Marker-Based and Markerless Motion Capture for Knee Work Asymmetry Assessment after ACL Reconstruction

Mrs. Sierra Hastings PT, DPT, SCS[1], Ms. Katelyn Campbell MS[1], Dr. Eric Dugan PhD[1,2]

[1]Texas Children's Hospital, The Woodlands, Texas, United States. [2]Baylor College of Medicine, Houston, Texas, United States

Introduction

Markerless motion capture (Theia) offers a practical alternative to marker-based systems in sports rehabilitation, but its suitability for joint-level variables used in return-to-sport testing after ACL reconstruction (ACLr) remains uncertain. Positive knee work asymmetry during countermovement jump propulsion reflects limb loading strategy and recovery status. This pilot study evaluated whether Theia produces knee work asymmetry estimates comparable to a marker-based system after ACLr.

Methods

Six participants, 5 males and 1 female, post-ACLr (109 to 1218 days post-surgery) with mean age of 17.5 ± 3.83 years completed six countermovement jumps recorded simultaneously with marker-based and Theia systems. For each system, positive knee work during the concentric phase computed for the involved and uninvolved limbs and normalized to body mass (J/kg). Knee work asymmetry calculated using a bilateral asymmetry index that expresses the percent difference between limbs relative to their sum, consistent with recommendations for bilateral tasks [1]. Agreement between systems evaluated using a linear mixed-effects model with a random intercept for subject, ICC(3,k), and Bland Altman analysis.

Results

Knee work asymmetry ranged from approximately 2% to more than 23%, representing symmetric, moderately asymmetric, and highly asymmetric loading patterns. The mixed-effects model showed no significant difference between systems (Estimate=−1.44%, SE=1.13, p=0.21). Agreement based on subject-level values was high (ICC(3,k)=0.971, 95% CI: 0.83 to 1.00). Bland Altman analysis indicated small bias of −1.44% with limits of agreement from -1.00% to 3.88%(Figure 1).

Discussion

Knee work asymmetry measured with Theia closely aligned with values from the marker-based system across a range of recovery stages and asymmetry magnitudes. Between-system differences were small relative to a commonly used clinical target of 10% asymmetry[2] and were smaller than the asymmetry typically observed in healthy athletes[3]. Although preliminary, these findings suggest that Theia may provide clinically comparable information for knee work asymmetry after ACLr. Larger studies are needed to confirm these results and evaluate performance across a range of tasks and populations.

Images (Optional)

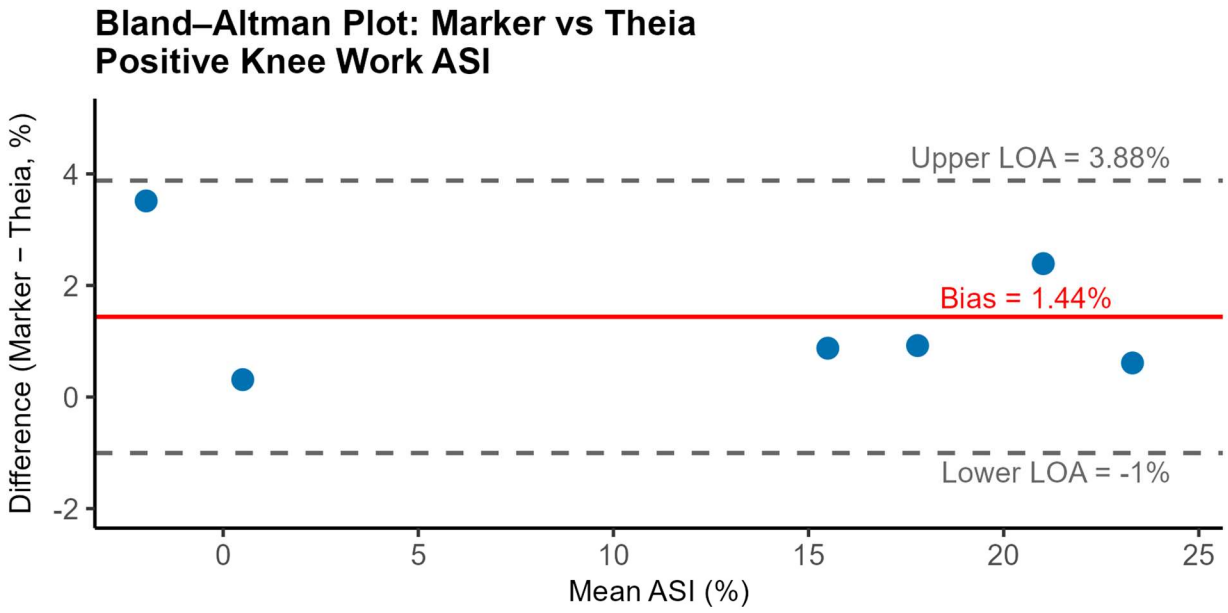

Figure 1. Bland–Altman plot comparing positive knee work asymmetry measured using marker-based and markerless (Theia) systems. Bias between systems was 1.44 percent, and the 95 percent limits of agreement ranged from −1.00 to 3.88 percent.

P1-364

Accuracy of Vertical Force Estimation by DARI Marker-less Motion Capture System

Ms Silvia Zanini[1], Mr Wenpei Liu[2], Mr Mark Lenhoff[1], Mr Snehal Patel[1], Dr Howard Hillstrom[1]

[1]Hospital for Special Surgery, New York, New York, United States. [2]Philadelphia College of Osteopatic Medicine, Philadelphia, Pennsylvania, United States

Introduction

Force plates (FP) are the gold standard for measuring ground reaction forces. However, they are expensive. DARI is an 8-camera marker-less motion-capture system that acquires videos of patients. It extracts 3D volumetric silhouette of each body segment to track and scale a model representing the patient and their movements. This information, combined with body weight, is used to estimate vertical ground reaction force.

This study determined the accuracy of vertical ground reaction force estimation for DARI, to determine its utility and limitations in clinical and research evaluation of patients.

Methods

Twenty healthy individuals (10M+10F; 34.2±8.9years; 171.8±8.9cm; 74.4±13.4kg) participated in this IRB-approved validation study. Participants performed 3 trials of double-leg vertical jump on FP while simultaneously being recorded with DARI.

Accuracy was established from: (1) root mean square error (RMSE) between DARI and raw FP and (2) Pearson correlation coefficient (R) from a regression of DARI onto raw FP vertical forces at each jump frame. All variables were calculated for right leg, left leg, and combined sum.

Frame rates between systems were resampled to match and data was synchronized using the minimum RMSE.

Results

The average RMSE in vertical force (N) during the jump was 62±17, 63±17, and 100±33 for right, left, and combined force, respectively.

Linear regression of DARI onto FP vertical forces (figure-1b) shows good agreement, with discrepancies at 0 (where timing was off) and at high forces (when landing occurred), as seen on the force-time graph (figure-1a). The average R was 0.95±0.03, 0.96±0.02, and 0.97±0.01, and R^2 was 0.91±0.05, 0.92±0.03, and 0.93±0.03 for right, left, and combined force, respectively.

Discussion

DARI provides a good estimate of vertical ground reaction forces in the absence of FP.

The greatest discrepancies occurred 1) for timing of the jump possibly due to camera views and 2) at landing possibly due to DARI data processing and filtering (proprietary algorithm).

Additional exercises and synchronization and filtering techniques will be explored next.

These kinetic measures are clinically valuable and useful outcomes in performance and rehabilitation when addressing a patient's ability to load their lower limbs.

Neurofencing - Study of the Physiology and Biomechanics of a Fencer's Movement

Neurofencing - Study of the Physiology and Biomechanics of a Fencer's Movement Supriya Nair Undergraduate

Stanford Online High School, Redwood City, California, United States. Backyard Brains, Ann Arbor, Michigan, United States. Mount Sinai, New York, New York, United States. CoRE Lab, Seattle, Washington, United States

Introduction

Fencing is a permanent fixture at the Olympics. Agile footwork and bladework are hallmarks of a successful fencer. Based on sword fighting, fencing demands speed, patience, and good reflexes. Warm-ups improve performance. A typical fencing attack technique involves the lunge - an explosive extension of the fencer's body propelled by the non-dominant leg (ND) in which the dominant leg (D) is kicked forward. We study the physiology, underlying kinematics, and healthy range of joint movements to prevent injuries.

Methods

Six fencers, participated in Mount Sinai (STUDY2201661) over the course of two days. One day included a 15-minute warmup of predetermined exercises. All fencers performed ten lunges towards a fixed target 6ft away each day. Delsys Trigno sensors were placed on various muscle groups to collect electromyogram (EMG). Two-minute recordings of electrocardiogram (EKG) and electroencephalogram (EEG) at baseline and post-lunge timepoints was taken. EEG data w/ Neuroelectrics Enbio to assess band power across eight channels. EKG data was collected w/ Polar H10, HRVElite.

Fifty fencers participated in UW (STUDY00019084). Fencers conduct five standard lunges (SL) and five advanced lunges (AL) towards a dummy target 6ft away. These lunges were captured using VICON motion capture system w/ 60 markers on each subject. The second part of the experiment involved playing two games (G1) & (G3) on a Favero fencing target and scoring their discomfort level with nine wrist tendon injury rehabilitation exercises.

Results

A 9.4% faster touch speed was observed after 15-minute warmup (p=0.01). Biomechanics findings relate to ground reaction forces and analysis of dominant knee joint angle. During the extended lunge motion, their dominant foot lands with more force than the standard*

lunge in a shorter period of time. Both the hamstring and rectus femoris play critical roles in regulating the knee's flexion and extension, as the rectus femoris gets the dominant leg moving forward and the hamstring slows it down preventing knee over flexion.

Discussion

The rapid and repetitive fencing lunges along with rapid extension and flexion produces strenuous impact loading on the lower extremities particularly the knee, hip & ankle joints.

Total-Body Motion and Lower-Body Power Generation Strategies in Relation to Baseball Pitching Ball Velocity

Biomechanical Analyst Takato Ogasawara, Associate Professor Brian Knarr

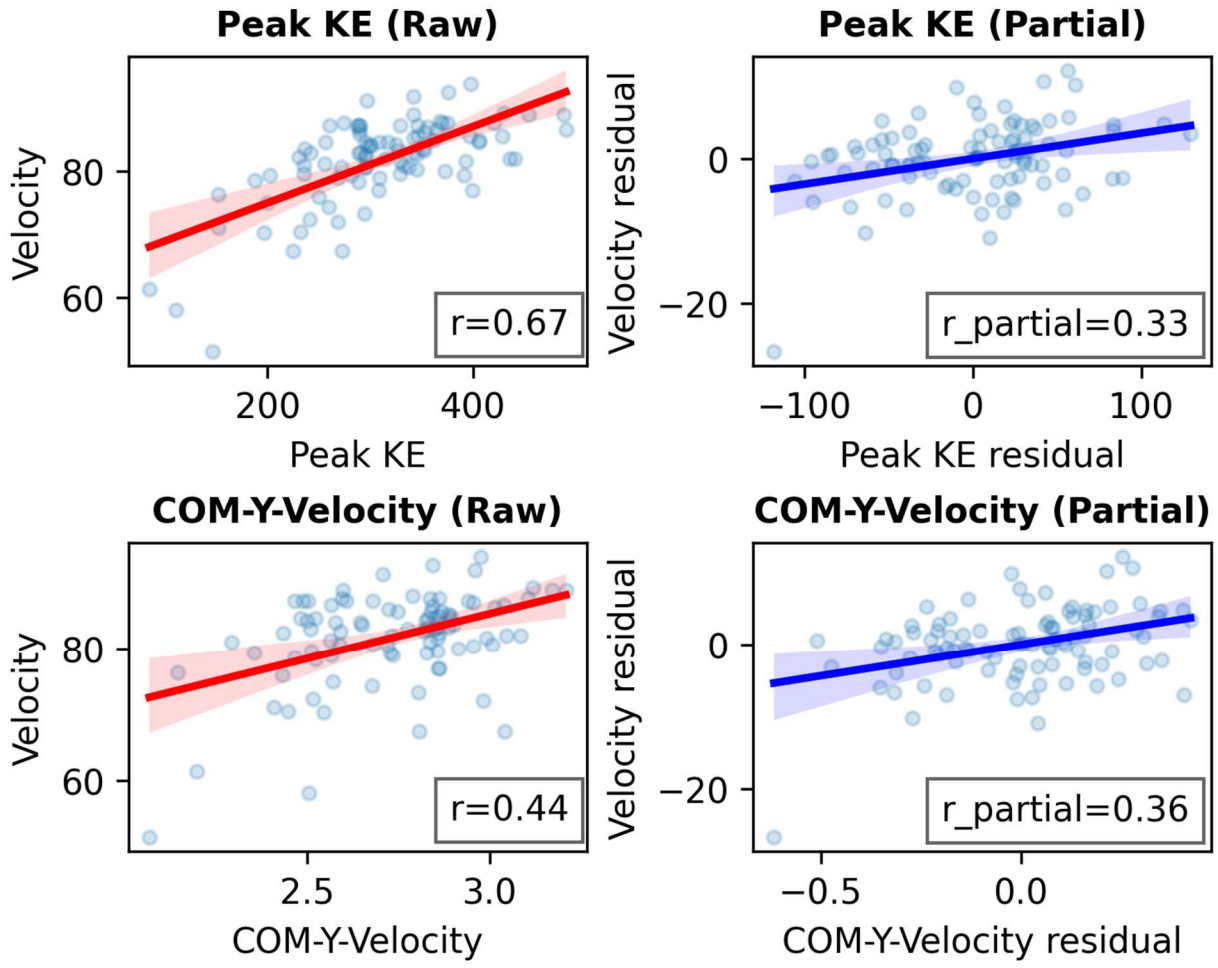
University of Nebraska at Omaha, Omaha, Nebraska, United States

Introduction

Pitching performance depends on efficient energy generation from the lower extremities. Stride-leg ground reaction forces often predict ball velocity (BV), but drive-leg contributions are less consistent, suggesting whole-body movement during the drive phase may better indicate performance and capture mechanical efficiency. Lower-body strength and anthropometry influence BV, highlighting the need to control body mass. This study examines whether total-body movement during the drive phase predicts BV, and how different lower-body strategies contribute to generating that movement.

Methods

Ninety-two pitchers (age 11–24) threw from a mound with force plates while 3D marker-based motion capture. Total-body drive-phase mechanics were quantified using Center of Mass (COM) motion and whole-body energy metrics (kinetic, potential, and total energy, both peak and time-integral). Pearson and partial correlations (weight as covariate) and hierarchical mixed-effects regressions tested relationships with BV, controlling for body mass and height. Lower-body strategy was quantified as time-integrated ankle, knee, and hip positive joint torque power, expressed as fractional contributions to total lower-body work. Pearson correlations assessed relationships between lower-body strategy, total-body mechanics, and BV.



Results

Peak kinetic energy (KE) and COM-Y-velocity (forward) were strongly correlated with ball velocity ($r=0.67$ and 0.48, $p<0.01$), with correlations reduced when controlling for body weight ($r_{partial}=0.33$ and 0.39, $p<0.01$), shown in Figure. Hierarchical regression showed that adding peak kinetic energy, COM-Y-velocity, and COM-Y-acceleration to a weight/height-only model increased R^2 from 0.44 to 0.56 ($\Delta R^2=0.13$, $p<0.05$). Lower-body strategies, as fractional positive work, showed ankle negatively ($r_{partial}=–0.38$, $p<0.01$) and hip positively ($r_{partial}=0.28$, $p<0.01$) correlated with BV, while knee was not significant, and none correlated with peak COM-Y-velocity.

Discussion

Peak KE and COM forward velocity were associated with BV, indicating that greater whole-body output during the drive phase predicts faster pitches. Partial correlations controlling for body weight reduced effect sizes, highlighting anthropometry's influence, while hierarchical regression confirmed total-body motion contributes independently to BV. Lower-body strategies were related to BV, but not reflected in COM velocity, suggesting translational COM metrics alone miss rotational motion, pelvis tilt, and timing differences. Evaluating both mechanics and strategy is critical to optimizing pitching performance.

Novel Inertial Sensor-Based Methods Provide Valid and Reliable Countermovement Jump Force Measures

Dr Therese Parr[1,2], Mr Leutrim Mehmeti[1,3], Dr Justin Reed[1,4], Lt Col Robert Briggs[1], Dr Peter Le[1]

[1]711th Human Performance Wing, Air Force Research Laboratory, Wright Patterson Air Force Base, OH, United States. [2]Innovative Element, Washington, DC, United States. [3]Reef Systems, Cary, NC, United States. [4]KBR, Inc., Houston, TX, United States

Introduction

The countermovement jump (CMJ) is utilized to monitor lower-body performance and guide training/rehabilitation. While force plates (FPs) are the standard to quantify CMJ metrics, they are expensive and resource intensive. Inertial measurement units (IMUs) have been shown to accurately measure CMJ height [1-2], offering a more accessible alternative to FPs. However, research remains limited regarding IMUs ability to quantify metrics that provide insight into the rate, magnitude, and strategy of muscle force production [1-2], limiting their utility in sports, military, and clinical performance monitoring. This study aims to validate IMU-based methods for computing CMJ force metrics: eccentric impulse, concentric force/power/impulse, jump height and modified Reactive Strength Index (RSI-mod).

Methods

Twenty-five participants (9F/16M, 29±6 yrs, 75.9±12.4 kg, 173.7±7.4 cm) performed three CMJs on FPs (VALD, Queensland, Australia) while wearing a sacral-mounted IMU (Movella, Enschede, Netherlands) recording at 500 and 60 Hz, respectively. IMU acceleration and orientation were filtered with a 4th order low-pass Butterworth filter with cutoff frequencies of 6.5 and 10 Hz, respectively [2]. IMU-derived metrics of force, power, and impulse were calculated over the appropriate phases based on physics principles. Jump height and RSI-mod were estimated using literature-based flight-time [1], and impulse-momentum methods [2]. Validity between systems was assessed using mean absolute percent error (MAPE), and Pearson correlation coefficient (r). Reliability was assessed with an intraclass correlation coefficient (ICC).

Results

IMUs-derived metrics demonstrated strong agreement with FPs ($r > 0.9$; $MAPE < 10\%$). Reliability was excellent across all variables for FPs and IMUs ($ICC > 0.9$).

Discussion

A sacral-mounted IMU can accurately and reliably compute force metrics captured from commercial FPs. This is a novel advancement, as previous research has had limited success in deriving force, impulse, and power metrics from inertial sensors [2]. These inertial-based methods enable more accessible and comprehensive jump performance monitoring for applied sports, miliary, and clinical settings.

Effects of Real-time Peak Impact Force-based Augmented Feedback on Running Patterns of Novice Recreational Runners

Professor Thomas Kernozek PhD, FACSM[1,2], Ms. Nora Stroh[1], Mr. Drew Rutherford MS[1,2], Mr. C. Nathan Vannatta DPT, SCS[3,2], Professor Sherwin Toribio PhD[1]

[1]UW La Crosse, La Crosse, WI, United States. [2]La Crosse Institute for Movement Science, La Crosse, WI, United States. [3]Gundersen Sports Medicine, La Crosse, WI, United States

Introduction

Running-related injuries may be related to aspects of ground reaction forces (GRF). Training to reduce GRF resulted in a lower incidence of running-related injury [1]. The purpose was to determine if novice runners lowered their peak GRF via receiving concurrent GRF feedback while running on a treadmill.

Methods

28 healthy male and female novice runners ages 19-23 years were examined. 54 retro-reflective markers were placed on selected body segments. After a standardized warmup, running data were collected on baseline peak GRF to determine 5% and 10% reduction goals. Runners received concurrent GRF-augmented visual feedback indicating whether they were above or below their 5% and 10% peak GRF reduction goals. Feedback was removed, and a short-term retention within that running bout was examined. All analyses examined the stance phase of running at a standardized running speed (3.68 m/s). 3-D kinematics (180 Hz) and kinetics (1800 Hz) on an instrumented treadmill were measured. A repeated-measures analysis of variance compared kinematic and kinetic variables at baseline, after 5% and 10% GRF reduction feedback (α=0.05).

Results

Overall, novice runners reduced their peak GRF compared to baseline ($p<0.05$). Table 1 depicts means, standard deviations, effect size, and percent change for each kinematic and kinetic variable from baseline running, 5% and 10% reduction goals. Most runners successfully reduced their GRF forces in response to feedback; 21.4% (6/28) and 42.9% (12/28) did not achieve the 5% and 10% reduction goals. A regression analysis was used to determine the kinematic or kinetic strategies used to reduce peak GRF. At 5%, foot reach explained about 15.3% of this reduction in peak GRF. At 10%, ankle plantarflexion power, hip extension moment, and hip extension angle explained about 61.1% of the reduction.

Discussion

Providing augmented feedback may be effective in reducing GRF in novice runners. Ankle and hip strategies appear to be employed to reduce GRF in some variables relevant to running injury.

Mechanical Hysteresis Performance of Athletics Track Spikes

Professor Todd Stewart PhD, BSc, Doctor Graham Askew PhD, BSc., Professor Andy Brown PhD, BSc.

University of Leeds, Leeds, West Yorkshire, United Kingdom

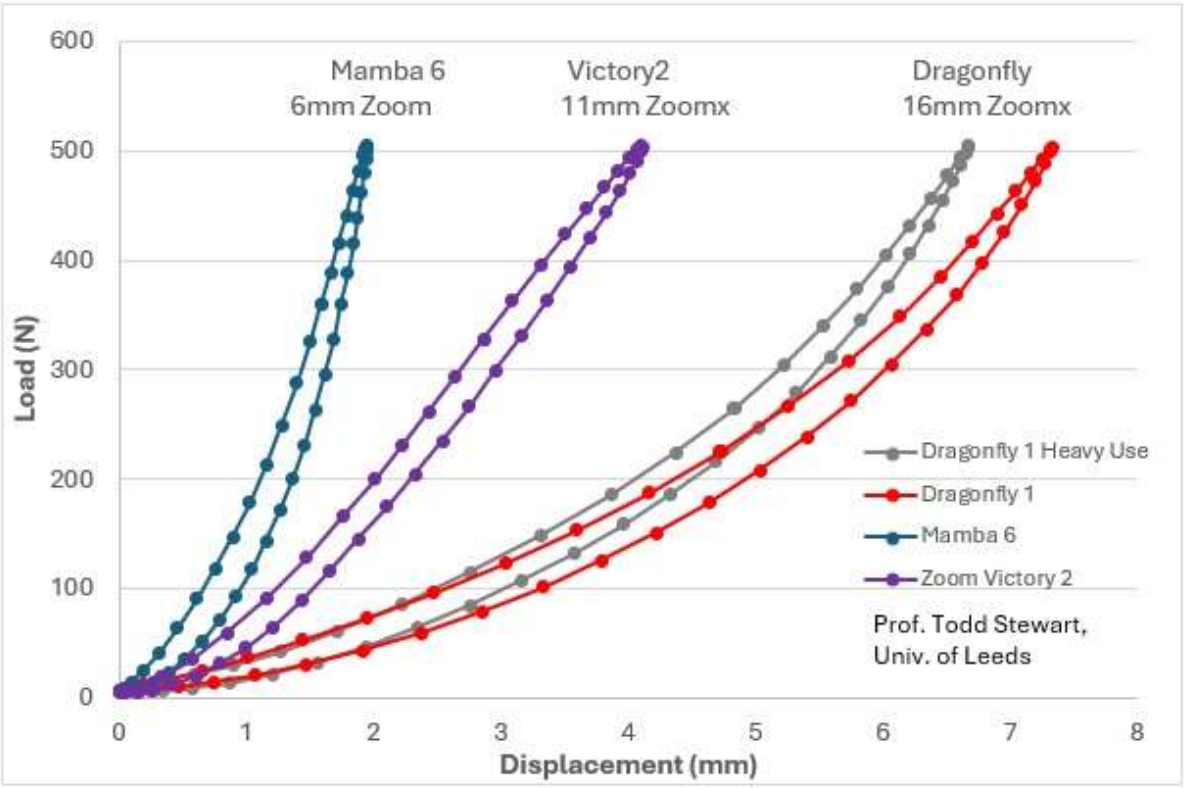
Introduction

Evidence suggests that modern track spikes with advanced footwear technology produce faster running times [1]. These spikes typically feature lightweight, compliant midsole foams and increased longitudinal bending stiffness; there is often substantial variation within a single brand. This study reports the results of biomechanical testing of midsole compliance and bending stiffness using cyclic loading to focus on mechanical hysteresis and energy losses.

Methods

Four Nike running spikes were compared: All shoes had a single Pebax spike plate outsole, Zoom MambaV6 (2023), ZoomX Dragonfly (2021), ZoomX Dragonfly (heavy use). The Air ZoomX Victory2 (2024) had a carbon insole. For the evaluation of midsole compliance a 36mm diameter cylindrical indenter was applied centrally across the MCP joint. A 0-500N force was applied sinusoidally at 4Hz replicating a 185ms ground contact [1]. Bending tests applied 16 degrees of flexion across the MCP joint.

Results



Compliance testing was validated with a steel spring producing negligible energy losses. Figure 1 shows the load/unload response of Track Spikes with the gradient giving the stiffness of the sole in N/mm. A large variation in deformation from 1.9 to 7.3mm was observed suggesting a broad range of comfort. Victory2 produced an uncharacteristically linear loading pattern. Under bending most shoes required a force of 30-40N to flex the toe to 16 degrees (stiffness 1.6N/mm), except the carbon Victory2, that required a force of 87N (stiffness 3.7N/mm).

Discussion

There was a 3-fold variation in midsole compliance across the range of spikes likely linked directly to the thickness of the foam (and shoe weight). In flexion stiffness may be more related to the number of layers within the sole than the specific layer material. A single

layer outsole spike plate shoe is only as stiff as the spike plate, whereas the addition of an internal carbon plate insole increases the moment of inertia proportional to the square of the distance between the plates. Hysteresis was inversely proportional to foam thickness. Victory2 results indicate additional potential for energy storage/return. The interaction and combination of plate layering and a resilient foam affects a shoe's performance.

P1-370

The Examination of Upper Body Mechanics in Women Softball Pitch Count to Prevent Arm Injury

Dr. Tong-Ching Tom Wu Professor, Ph.D.

Bridgewater State University, Bridgewater, MA, United States

Introduction

In baseball, pitch count regulations are established for pitchers to prevent overuse arm injury. In softball, the ball is pitched in an underhand motion, and research has shown that women softball pitchers also experience significant arm injury. The purpose of the study was to examine the upper body joint mechanics to establish and advocate softball pitch count regulations to prevent arm injury from fatigue due to pitching multiple games.

Methods

Three college and one elite high school female pitchers participated in the study. Each pitcher threw five fastballs, five changeups, and five curveballs. After the participant threw 15 pitches, the participant rested for 10 minutes and then threw another 15 pitches. This pitching process repeated seven times to mimic seven innings of a game. After one game, the participant rested for 20 minutes and then pitched for another game. Each participant threw a total of 210 pitches during the two games. A high-speed video camera (120 Hz) was used to capture the upper body joint kinematics. A one-way repeated measure ANOVA test was conducted at $\alpha = 0.05$ and followed by t-test with Bonferroni adjustment if a significant difference was found.

Results

The results showed there was no statistically significant difference in shoulder, elbow and wrist joint angles for all three different types of pitch. It was found that the elbow joint showed some differences, particularly for change up and curveball but not statistically significant enough, Table 1.

Discussion

Wu et al. (2019) showed pitchers started to show signs of fatigue after approximately165 pitches because a significant decrease in fastball velocity (25.4 ± 2.5 m/s decreased to 24.3 ± 2.7 m/s) was observed. In this study, the changes in upper body mechanics were not observed. Thus, this study suggested that the pitchers may experience physiological muscle fatigue, but it was not substantial enough to cause the changes in pitching mechanics. This study provides an important preliminary understanding of the effects of

pitch count on upper body pitching mechanics, and future studies are warranted with the increase of sample size and pitch count to examine the changes in pitching mechanics.

Comparison of Sagittal-Plane Knee Biomechanics Between Upright and Recumbent Cycling

Mr. Tsung-Lin Lu MS, Mr. Alejandro Ovispo-Martinez MS, Ms. Yufei Sun MS, Mr. Jacob Rygielski, Mr. Davin Gleaves, Ms. Quinn Wilson, Dr. Songning Zhang PhD

The University of Tennessee, Knoxville, TN, United States

Introduction

Recumbent bicycles have gained popularity for both exercise and rehabilitation. Several studies have reported lower or similar peak knee extension moments compared with upright bicycles; for example, a recent study discussed reductions in peak knee extension moments during recumbent cycling based on a comparison with an earlier upright-cycling study [1]. However, such cross-study comparisons may not yield meaningful results, as they involve different populations and/or work rates. To address this limitation, this study directly compared sagittal-plane knee biomechanics between upright and recumbent cycling using a within-subject design at matched power outputs.

Methods

Ten healthy participants (6 males, 4 females; age 25.1±3.8 years; height 1.75±0.07 m; weight 72.2±12.8 kg) were recruited. Participants cycled on both an upright cycle ergometer (Excalibur+Sport, Lode BV, Groningen, The Netherlands) and a recumbent ergometer (RE7, Kettler, Germany) equipped with instrumented 3D force pedals at 100 W and 80 rpm for 2 minutes. The last 10 seconds were recorded and truncated into five consecutive crank cycles. 3D Kinematic (240 Hz) and kinetic (1,200 Hz) data were collected using a 12-camera Vicon system and analyzed in Visual3D. Paired-sample t-tests ($\alpha = 0.05$) were conducted to compare knee variables between upright and recumbent cycling.

Results

Knee extension ROM (73.80±6.42° vs. 72.26±5.61°; $p = 0.26$), peak knee extension moment (32.69±5.38 vs. 33.98±7.16 Nm; $p = 0.52$), and peak knee power (167.39±25.54 vs. 161.61±37.76 W; $p = 0.62$) did not differ significantly between upright and recumbent cycling (Table 1).

Discussion

No significant differences in knee biomechanics were observed between upright and recumbent cycling. These findings contrast with prior reports that noted lower peak knee extension moments in a recumbent cycling study compared with results from a separate

upright cycling study [1], which involved different populations and work rates rather than within-subject measurements at matched power outputs. Therefore, the present controlled, within-subject study suggests that sagittal-plane knee loading is comparable between bike types, providing evidence to support the use of recumbent cycling in exercise or rehabilitation without concern for overloading the knee joint.

Accuracy and Precision of Kinematic Methods for Determining Ball Release in Baseball Pitching

Dr. Tsutomu Jinji PhD[1], Dr. Glenn Fleisig PhD[2], Dr. Jon Slowik PhD[2]

[1]Kokugakuin University, Shibuya, Tokyo, Japan. [2]American Sports Medicine Institute, Birmingham, Alabama, United States

Introduction

Accurate identification of ball release is fundamental for baseball biomechanics. Standard fixed-offset methods lack validation across diverse pitch types, while emerging markerless systems rely on unvalidated assumptions. Therefore, this study determined which kinematic event most accurately and precisely identifies release without fixed offsets. We evaluated the systematic bias (accuracy) and random variability (precision) of three detection methods.

Methods

Forty-eight pitchers threw fastballs (FB) and other pitches among curveballs (CB), sliders, change-ups, and splitters. Kinematic data (1000 Hz) defined Actual Release (t_{actual}) based upon ball-fingertip separation (+0.5 cm margin). Three events were identified: wrist passes elbow (Wrist Pass), metacarpal passes wrist (MCP3 Pass), and MCP3 Peak Velocity. Time offset from actual release was calculated for each event. Differences in Accuracy (mean offset) and Precision (mean absolute deviation) were analyzed by pitch type ($p < 0.05$).

Results

MCP3 Pass showed the highest accuracy (offsets ≈ 0 ms) but lowest precision across all pitch types. Wrist Pass and MCP3 Peak Velocity exhibited systematic offsets but significantly higher precision. For FB, MCP3 Peak Velocity demonstrated the highest precision. However, for CB, its precision deteriorated, whereas Wrist Pass maintained high precision. While Wrist Pass precision was consistent, time offsets varied significantly by pitch type.

Discussion

Time offsets for Wrist Pass and MCP3 Peak Velocity varied by pitch type, necessitating pitch-specific offsets. However, precision is the critical determinant of reliability. With angular velocities reaching ~7,000 deg/s (shoulder) and ~2,500 deg/s (wrist) near release [1,2], random variability of just 1 ms may cause errors exceeding Minimal Clinically Important Difference (MCID) thresholds [2]. MCP3 Pass demonstrated low precision due to

finger variability, and MCP3 Peak Velocity deteriorated for CB. In contrast, Wrist Pass maintained high precision across all pitch types. Thus, to ensure kinematic data validity within MCID limits, we recommend using the Wrist Pass method; 7 ms after the wrist passes the elbow for fastballs, change-ups, and splitters, and 3 ms for breaking pitches (curveballs and sliders). This minimizes random timing errors and accommodates the biomechanical diversity of a pitcher's full repertoire.

Performance Asymmetry during a Single-Leg Jump does not Influence Performance during a Bilateral Countermovement Jump in Naval and Marine Corps Aviation Servicemembers

Assistant Professor Tyler Cardinale M.S.[1], Assistant Professor Tatiana Djafar M.S.[1], Biomechanist Andrew Plows M.S.[2], Assistant Professor Benjamin Cuddy DPT[1], Biomechanist Gaervyn Salverda M.S.[2], Lab Director Trevor Kingsbury M.S.[2], Assistant Specialty Leader Eric Infante Commander, DPT[3], Associate Professor Joshua Winters PhD[1]

[1]University of Kentucky, Lexington, Kentucky, United States. [2]Naval Medical Center San Diego, San Diego, CA, United States. [3]Naval Special Warfare, San Diego, CA, United States

Introduction

Assessing unilateral jumping tasks can expose inter-limb force production differences. However, it remains unclear whether unilateral performance asymmetries meaningfully influence bilateral jump mechanics or overall jump performance. This study examined how single-leg jump (SLJ) asymmetry relates to bilateral countermovement jump (CMJ) performance and inter-limb asymmetries across key phases of the movement. Understanding these relationships may clarify whether asymmetry expressed in isolation during unilateral tasks translates to bilateral performance deficits or reflects an independent characteristic of performance.

Methods

A total of 90 servicemembers completed a standardized biomechanical assessment using dual force plates. Testing included three SLJ's on each limb and five CMJ's. Participants were classified into two groups based on SLJ jump-height asymmetry: a low-asymmetry group ((<5%), (n=29; age=29.0yrs± 5.8)) and a high-asymmetry group ((>10%), (n=35; age=31.5 yrs±6.4)). Variables of interest derived from the countermovement jump (CMJ) included jump height, peak power, concentric impulse asymmetry, concentric peak force asymmetry, and peak landing force asymmetry. Independent T-Tests determined group differences ($\alpha = 0.05$).

Results

No significant differences were observed between SLJ asymmetry groups for CMJ performance metrics, including jump height ($p = 0.221$) and peak power relative to body weight ($p = 0.341$). The high-asymmetry group exhibited significantly greater CMJ concentric impulse asymmetry compared to the low-asymmetry group ($p = 0.008$), despite

not seeing significant differences in peak concentric force asymmetry (p = 0.245). The lower asymmetry group landed significantly more asymmetric (P = 0.041).

Discussion

Servicemembers classified in the >10% SLJ asymmetry group demonstrated clear unilateral performance deficits; however, these asymmetries did not translate to reductions in bilateral CMJ jump height. Though CMJ performance was unaffected, concentric impulse asymmetries were observed, suggesting that compensatory strategies may occur during the entire phase of concentric force production. How these asymmetries influence overall performance warrants further investigation. Interestingly, the <5% asymmetry group landed significantly more asymmetric, indicating that landing mechanics may operate independently of propulsive strategies. These findings suggest that bilateral performance may be independent of unilateral performance, highlighting the importance of utilizing a more comprehensive assessment strategy to uncover and address inter-limb differences.

Understanding The Role of Biological Sex, Barefoot Walking and PA in Foot Core Development

Mr Umar Yousufy MSc, Mrs. Nicole J Chimera PhD

Brock University, St.Catharines, Ontario, Canada

Introduction

The foot is vital in establishing a base of support during physical activity (PA). The "foot core" (FC) system encompasses passive, active, and neural subsystems that stabilize the foot and attenuate force. The passive subsystem maintains foot arch; the active subsystem provides foot stabilization through intrinsic foot muscles (IFM). Males and those who engage in barefoot walking (BFW) exhibit greater arch height and IFM cross-sectional area (CSA), which may reflect greater foot stability and force attenuation. Additionally, the role of PA on the passive and active subsystems is less known. However, PA is important to consider since low PA correlates with ankle instability and may play a role in foot instability. The purpose of this study was to examine the relationship of biological sex, PA, and BFW on the passive and active FC subsystems.

Methods

This cross-sectional design determined whether sex, PA, and BFW were predictors of the passive and active subsystems. The predictor variables were sex, PA, and BFW, while the criterion variables were the passive and active subsystems. The Physical Activity Questionnaire-Adults (PAQ-A), a 5-point Likert scale was used to measure PA. A BFW questionnaire determined if participants were habitually barefoot, scored based on a 3-point Likert scale. To measure the passive subsystem, Arch Height Index (AHI) was assessed at 10% and 90% of total body weight in both feet; the active subsystem was measured with IFM (abductor hallicus, flexor digitorium brevis, and abductor digiti minimi) CSA (cm^2) (Clarius Ultrasound L15 HD3 probe) for both feet. A Shapiro-Wilks Test ($p < .050$) examined normality and preliminary analysis was conducted using Pearson's Correlation (r) in SPSS (v.29). Regression analysis will evaluate the variance in AHI and IFM CSA based on predictors with additional participants.

Results

A significantly strong negative correlation was observed between sex and abductor hallicus (ABH) CSA (r = - .882, *p* = .015). No other significant correlations were found.

Discussion

To date, ABH CSA is significantly larger in males, which highlights an emerging relationship between biological sex and the active FC subsystem. This study will highlight how sex, PA, and BFW relate to foot structure and IFM size.

P1-375

Understanding the Role of the Foot Core System in Countermovement Jump Performance

Mr. Umar Yousufy MSc, Mrs. Nicole Chimera PhD

Brock University, St.Catharines, Ontario, Canada

Introduction

The “foot core” (FC) system encompasses passive, active, and neural subsystems that stabilize the foot and attenuate force. The passive subsystem maintains foot arch; the active subsystem provides foot stabilization through intrinsic foot muscles (IFM); thus, force attenuation, stabilization, and force production during jumping may be influenced by the FC. The countermovement jump (CMJ) examines lower limb power and neuromuscular function and may be influenced by the FC function. The purpose of this study was to determine the relationship between the passive and active FC subsystems and CMJ performance.

Methods

This cross-sectional design determined the amount of variance explained in jump height (JH), foot acceleration and stiffness during repetitive CMJs based on the passive and active subsystems. The predictor variables were the passive and active subsystems, and the criterion variables were JH, take-off acceleration (TOA), impact acceleration (IA), and qusai-joint stiffness. The passive subsystem was measured with the Arch Height Index (AHI) at 10% and 90% of total body weight in both feet, while the active subsystem was measured with abductor hallicus (ABH), flexor digitorium brevis (FDB), and abductor digiti minimi (ADM) CSA for both feet (cm^2) (Clarius Ultrasound L15 HD3 probe). Participants performed 5 repetitive CMJs in instrumented insoles (Plantiga accelerometers, Vancouver, British Columbia, Canada) to quantify JH (cm), TOA (m/s^2), and IA (m/s^2). Stiffness (N/m) was computed using body weight (lbs), flight time (secs), and ground contact time (secs). A Shapiro-Wilks Test ($p < .05$) examined normality and preliminary analysis was conducted using Pearson’s Correlation (r) in SPSS (v.29). A regression analysis will determine the JH, TOA, IA, and stiffness variance based on AHI and IFM CSA with additional participants.

Results

A significant, strong positive correlation was observed between right (r = .806, *p* = .029) and left (r = .825, *p* = .023) ABH CSA and left FDB (r = .804, *p* = .029) CSA with stiffness. No other significant correlations were found.

Discussion

To date, participants with greater ABH and left FDB CSA exhibit greater stiffness, suggesting the FC may contribute to neuromuscular function during CMJ performance. This study may inform targeted foot training interventions based on preliminary evidence.

Entry-phase biomechanics in hammer throw: differences between 3gr and 4gr techniques

Dr Gian Mario Castaldi[1], Dr Sebastiano Conci[1], Dr Filippo Goi[1], Dr Silvia Camboni[2], Dr Alessandro Di Gregorio[3], Prof. Valentina Camomilla[1]

[1]University of Rome Foro Italico, Italy, Rome, Italy, Italy. [2]Vibram Spa, Bergamo, Italy, Italy. [3]Washburn University, Topeka, Kansas, United States

Introduction

The hammer-throw entry links preliminary swings to the first turn and helps organize posture, foot support, and early implement acceleration, yet it is less quantified than later phases [1]. Two common techniques differ in preparation and initial pivot. In 3gr, there is no hammer pre-start, no right-foot displacement at the end of preliminaries, and rotation begins on the left heel. In 4gr, a hammer pre-start and right-foot displacement precede rotation initiation on the left forefoot. Kinetic and kinematic differences were compared between 3gr and 4gr during the entry phase to inform their potential impact on subsequent phases.

Methods

Six trained throwers (3 women; 21.0±4.9 years; 1.78±0.08 m; 80.7±13.5 kg) provided informed consent (CAR 194/2024) and performed three 3gr and 4gr entry trials. Data were collected using stereophotogrammetry (200–250 Hz) and force plates (1000 Hz). A CGM v2.5 marker set was used; 4-markers tracked the hammer centroid. Five instants were identified from kinematics and forces: I1 hammer farthest left (frontal plane), I2 hammer aligned with metatarsal markers, I3 hammer passing in front of the right foot, I4 hammer lowest point, I5 right toe-off. Outcomes at I1–I5 included: (1) left/right GRF components (AP, ML, VERT), normalized to body-weight; (2) ankle plantar/dorsiflexion; and (3) hammer centroid tangential velocity relative to athlete COM. Normality and variance were tested to eventually use non-parametric alternatives. Significance was set at $p<0.05$.

Results

Technique differences were mainly in left-foot GRF, with 4gr generally higher than 3gr. At I1, left-foot AP and VERT GRF were higher in 4gr; ML and VERT at I2; and AP at I4–I5. Hammer

tangential velocity modulus differed only at I3, with higher values in 4gr. Ankle plantar-/dorsiflexion showed no consistent difference.

Discussion

Overall, 4gr imposed greater left-foot kinetic demands across the entry and showed a localized velocity increase at I3, indicating phase-specific technique effects. Limitations include small sample size and entry-only analysis without performance outcomes. Future work will expand cohorts and link entry mechanics to release variables.

Images (Optional)

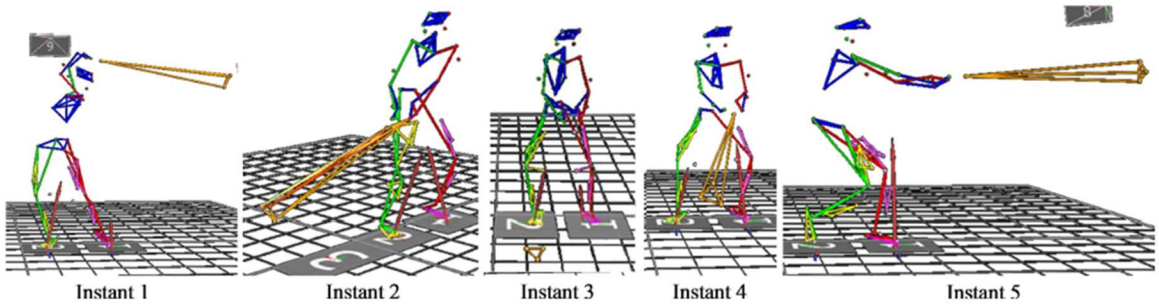

Figure 1: Key instants of the entry phase: the beginning of the active phase after the last preliminary turn Instant 1), the descending phase of the hammer on the right side of the thrower (Instant 2), the passage of the hammer in front of the thrower's right foot (Instant 3), the reaching of the low point of the hammer's path (Instant 4), and the end of the entry phase with the landing of the right foot from the ground (Instant 5).

Functional Usability and User Satisfaction of the Optical Screening for Injury Resilience (OSCIR) System

Ms. Vianey Hortencia Ocampo[1,2], Mr. Joshua Kline[3,4], Ms. Nicole Donahue[3,4], Mr. Nikolas Lamb[3,4], Mr. Dan Clapp[3,4], Ms. Helene Huang[3,4], Dr. Serge Roy[3,4], Mr. Gianluca De Luca[3,4], Ms. Bhawna Shiwani[3,4], Ms. Amy Silder[2]

[1]Leidos Inc, San Deigo, CA, United States. [2]Naval Health Research Center, San Deigo, CA, United States. [3]Altec Inc, Natick, MA, United States. [4]Delsys Inc, Natick, MA, United States

Introduction

The Optical Screening for Injury Resilience (OSCIR) system was developed to aid in the prevention and recovery of musculoskeletal injuries. It is a portable, markerless motion feedback system that provides offline, real-time feedback on technique during commonly performed exercises. The software displays real-time body tracking (e.g., joint angles, body/equipment alignment), repetition counts, and error indicators then stores the metrics locally, without relying on cloud services. The system is portable and can be set up in ~10 minutes. In this study, the System Usability Scale (SUS) was used to understand the functional usability of OSCIR at military fitness facilities.

Methods

Active-duty participants (n=33) were recruited from local U.S. Navy and Marine Corps fitness facilities. Participants were asked to select and perform a minimum of three exercises, then complete the SUS and provide open-ended feedback. Options included plank, pushup, forward lunge, deadlift, double-leg squat, overhead press, jump squat, side hop, and single-leg balance. Questions from the usability section of the SUS (8-of-10 questions, excluding Q4 and Q10) were considered [1].

Results

Open-ended feedback was positive and the mean (SD) SUS score was 80.77 (12.93), indicating “excellent” usability (>80) [2]. Most answers suggested users would “use this system frequently”, that it “was easy to use”, and that “most people would learn to use this system very quickly.” Negative feedback included comments like, “certain exercises [worked] better than others” and comments focused on tuning the software to provide more intuitive cues like, “Keep chest up” rather than a “Trunk-tibia alignment” error.

Discussion

The mean SUS score met the universal benchmark for a good experience and suggests excellent usability. Questions related to frequency of use, complexity, and the learning curve for system usability received the highest scores. Participants noted the system was great for correcting 'technique' and posture. They appreciated the readily available quantitative movement metrics and could see this system being incorporated into their typical unit training activities. We are currently working to integrate OSCIR for clinical care and to provide feedback during normal training.

Concurrent Validity of an Inertial Measurement System for Evaluating Energy Fluctuation in Pole Vaulting

M Victor RESTRAT PhD student[1,2], M Guillaume Nicolas PhD[2], M Georges Dumont Full Professor[1], M Bideau Nicolas PhD[2]

[1]IRISA, Rennes, Bretagne, France. [2]M2S, Rennes, Bretagne, France

Introduction

Pole vault performance is strongly influenced by mechanical energy generated and transferred during the run-up and take-off phases [1]. While 2D video approaches are commonly used to estimate these parameters, they have notable limitations [2]. Inertial measurement units (IMUs) have emerged as alternative tools in sports biomechanics, but their accuracy in quantifying pole vault energy dynamics remains unvalidated. This study aims to assess the concurrent validity of embedded IMUs by comparing them with a reference optoelectronic marker-based system to evaluate energy exchanges under realistic, in situ conditions.

Methods

In this ongoing study, four pole vaulters (2F, 2M) each performed six vaults (soft and medium poles; bar heights: 3.30 m for females, 4.30–4.50 m for males). Kinematics were recorded simultaneously with Xsens MVN Awinda (17 IMUs, 60 Hz) and Qualisys motion capture (20 cameras, 240 Hz; 42 markers), synchronized via a SyncUnit. Kinetic, potential, and mechanical energies were computed at take-off (TO), maximal pole bend (MPB), and bar clearance (BC) using a full-body model [3].

Results

Results show excellent agreement between IMU and Marker based system for kinetic, potential and mechanical energies with mean differences consistently below 1.2 J/kg. Across all trials, RMS values for KE, EPP and EM were moderate for TO to MPB phase with respectively (1.8 J/kg, 1.1 J/kg and 1.1 J/kg) and for the MPB to BC phase (0.5 J/kg, 1.2 J/kg and 1.1 J/kg).

Discussion

The IMU system provides robust estimates of energetics variables throughout the vaulting cycle, with low absolute error in relation to the observed energy amplitude. The elevated

RMS values for KE during the TO to MPB phase may reflect the system's sensitivity to variations in segmental velocity. The limited magnitude of relative errors and inter-trial variability supports its use in quantitative in situ biomechanical analysis. A kinematic and dynamic analysis could enhance this study by establishing links between the athletes' technical qualities and energy quantities.

Kinematic and Kinetic Modulation of Joint Stiffness Across Sequential Landing Phases in Drop Vertical Jumps

PhD Student Victoria Vandiver MA, Dr. Changki Kim Ph.D, Dr. Timothy Lowe Ph.D

The University of Alabama, Tuscaloosa, AL, United States

Introduction

Drop vertical jumps (DVJs) are widely used to assess rehabilitation progress and sport performance. DVJs include two landings that represent distinct motor tasks with different neuromechanical demands. The first landing primarily reflects pre-planned control strategies, while the second requires adaptive regulation influenced by the preceding jump, including variable timing, trajectory, and center-of-mass dynamics. These task-dependent differences affect how athletes coordinate force attenuation and modulate joint stiffness. Comparing stiffness across landings therefore provides a mechanistic view of how neuromechanical control adapts to changing movement constraints, offering insight into joint function, loading strategies, and potential performance or injury-related compensations.

Methods

Eleven healthy adults with no injury history performed three single-leg DVJs from a 0.30-m platform using their preferred limb. Participants landed on a force plate, jumped vertically as high as possible, and returned to the same plate. Peak vertical ground reaction force (vGRF) was recorded, and peak joint angles, moments, and joint stiffness were calculated for the first and second landings. vGRF and moments were normalized to body weight. Paired t-tests compared biomechanics between landings ($\alpha=0.05$).

Results

No differences were found in max or peak vGRF or in hip, knee, or ankle stiffness between landings (all $p > 0.09$). COM height decreased from the first to second jump (1.29 ± 0.06 m vs. 1.17 ± 0.07 m, $p < 0.01$). Despite similar loading, several kinematic and kinetic variables changed. At the hip, initial angle, peak angle, and initial moment all decreased ($p \leq 0.04$). At the knee, initial angle and peak moment increased ($p \leq 0.05$), while knee excursion decreased ($p < 0.01$). At the ankle, peak angle and peak moment increased during the second landing ($p \leq 0.05$).

Discussion

Joint stiffness was unchanged, however, differences in stiffness components across landings were observed. Suggesting that landing mechanics were altered to preserve joint stiffness. Peak COM was different despite vGRF being unaffected. The observed differences in the second landing produced an increased vGRF, despite peak height differences. This suggests, that changes in landing mechanics diminish force attenuation. These findings demonstrate the importance of analyzing the second landing to offer insight into joint function, loading strategies, and illuminate performance and injury-related compensations.

Lower-Limb Intracellular Water Is Associated With Glucose Rate-of-Change During Moderate-Intensity Running

Master's Student Wooyoung Park, Professor Sukyung Park

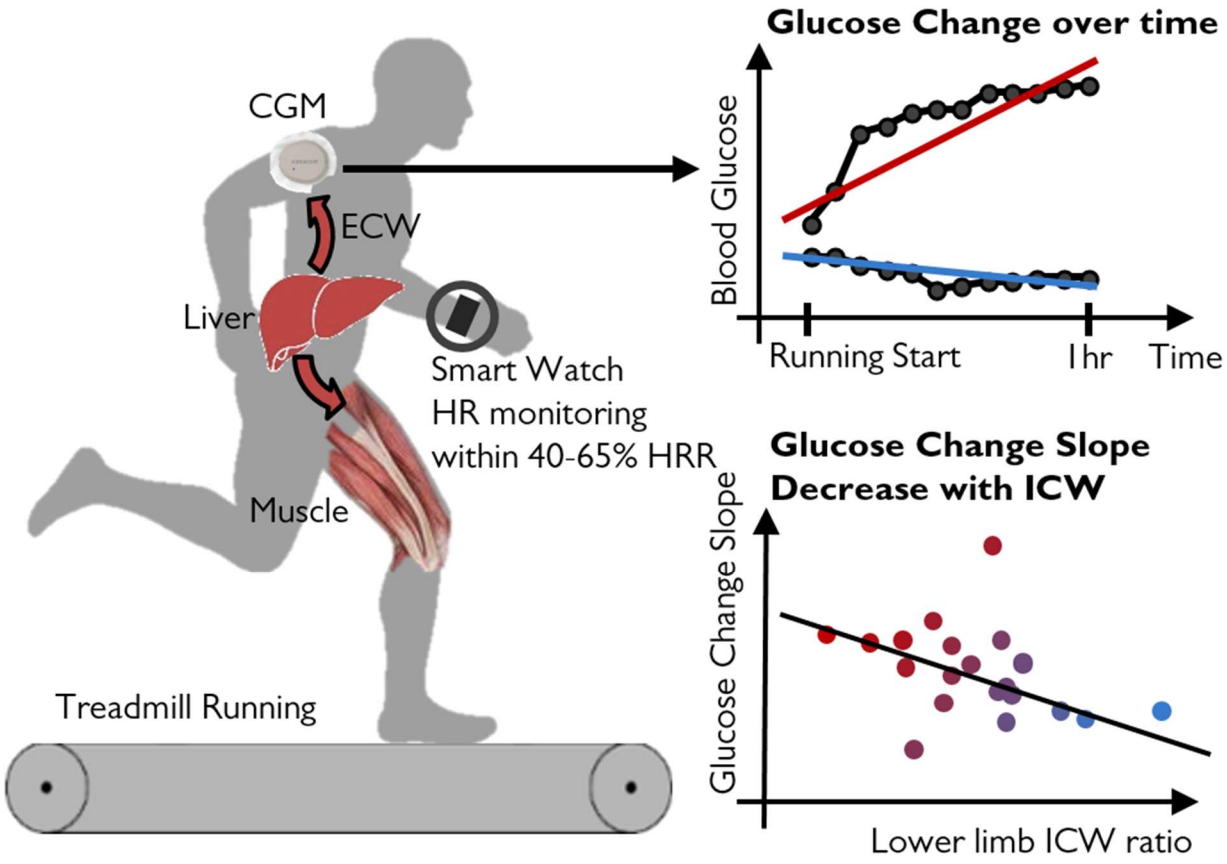
KAIST, Daejeon, Daejeon, Korea, Republic of

Introduction

Maintaining stable glucose regulation during exercise is essential for sustaining performance, as it is tightly linked to energy metabolism. Previous studies using continuous glucose monitoring (CGM) have focused mainly on exercise-related factors such as intensity and duration. Yet glucose responses still vary considerably across individuals under identical loads, suggesting that intrinsic skeletal muscle characteristics—including muscle mass, fiber composition, and cellular hydration—may influence glucose dynamics. However, the relationship between these muscle properties and glucose change rates during exercise remains unclear. This study investigated the association between lower-limb intracellular water (ICW), a proxy for active muscle cell volume, and glucose change rate during aerobic exercise.

Methods

A total of 21 adults (20–58 years) participated. Body composition was measured before exercise using the InBody BWA 2.0 system, and glucose levels were recorded via a Dexcom G7 CGM attached to the upper arm. All participants completed a 60-minute treadmill run in a fasting state (>8 hours), maintaining 40–65% heart-rate reserve. Heart rate was continuously monitored with a smartwatch, and HRmax was estimated using the age-predicted formula (220 – age). Treadmill speed was adjusted throughout the session to ensure the target HRR range was maintained. The glucose change rate was calculated using linear regression on CGM data collected at 5-minute intervals. Each participant completed two to three sessions, and the average glucose slope was used for analysis. The relationship between glucose change rate and lower-limb ICW ratio was examined.



Results

Across all participants running at moderate intensity based on HRR, a weak negative association was observed between glucose slope and lower-limb ICW ratio ($R^2 = 0.120$, $p = 0.12$), suggesting that muscle cellular properties may partially contribute to individual differences in glucose responses during exercise. This relationship appeared more pronounced in recreational runners, whereas no significant association was found in more experienced runners.

Discussion

These findings indicate that intracellular hydration and muscle/body composition may be related to glucose stability during exercise. This relationship has potential implications for assessing hypoglycemia risk during physical activity, designing hydration and nutrition strategies, developing personalized exercise prescriptions that consider body composition, and improving predictive models of glucose dynamics.

Dynamic Foot Perception: Differences in Sensory Sensitivity Between Marathon and Basketball Athletes Under Simulated Motion States

Bachelor Rongxi Lan[1], Dortor Fan Yang[2], Associate professor Xianyi Zhang[1]

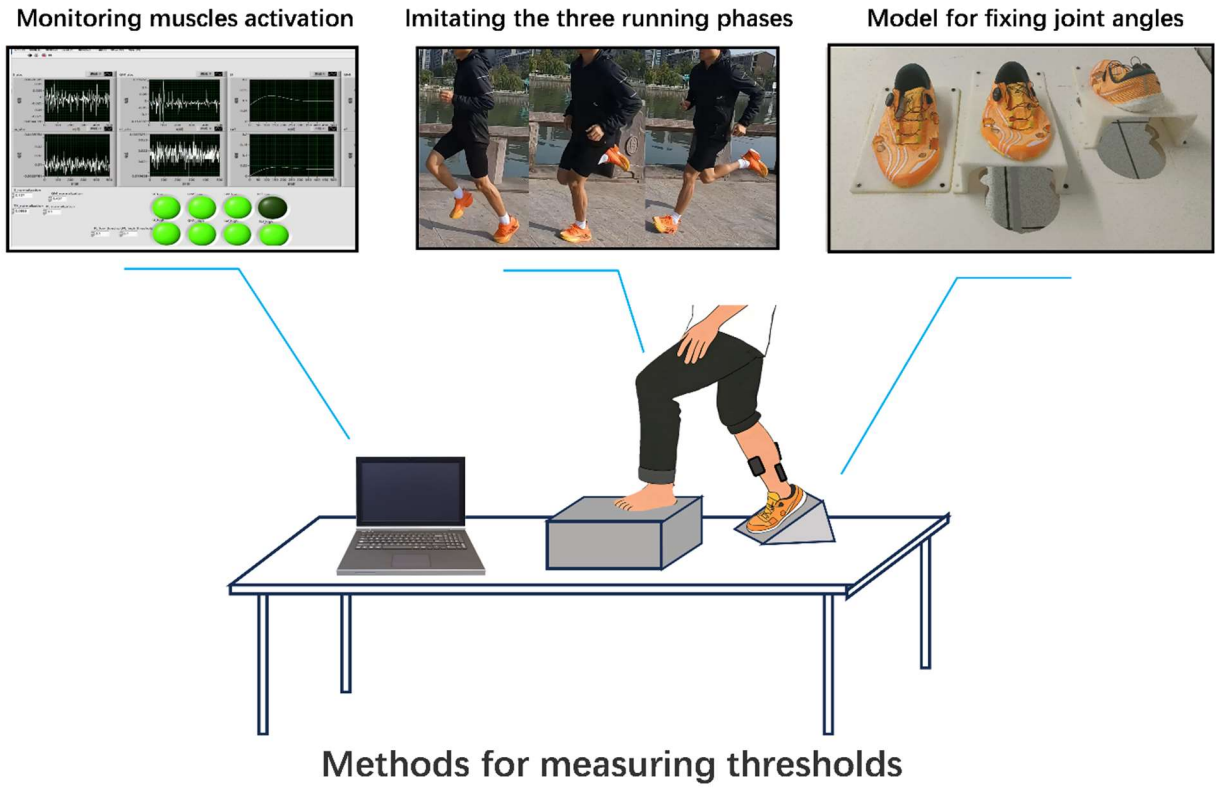
[1]SunYat-sen university, Shenzhen, Guangdong, China. [2]Li Ning Sports Science Application Research Center, Tongzhou, Bejing, China

Introduction

Research on physiological plantar perception threshold, specifically tactile, vibration, and pressure pain threshold, is largely limited to static conditions, failing to reflect the dynamic demands of active sports. This study aims to bridge this gap by quantifying sensory thresholds under static versus simulated motion states. The primary objective is to evaluate how simulated motion states affects plantar sensitivity and to determine differences in plantar sensory thresholds between marathon runners and basketball players.

Methods

Twenty male athletes (10 marathon runners and 10 basketball players) were recruited. Sensory thresholds were measured at 6 anatomical locations on the foot sole using Semmes-Weinstein filaments (tactile threshold), a neurothesiometer (vibration threshold), and a digital force gauge (pressure pain threshold). Simulated running phases (heel strike, mid-stance, and toe-off) were achieved by fixing the foot at specific joint angles using custom 3D-printed devices while participants adopted corresponding joint positions. Measurements were conducted only when participants actively replicated certain percentage of the specific muscle activation patterns associated with each motion phase, monitored via real-time electromyography (EMG).



Results

Dynamic simulations revealed significant shifts in sensory thresholds. For marathon runners, plantar vibration thresholds were significantly higher in motion states compared to static conditions; specifically, the heel region showed a marked reduction in vibration threshold during the heel-strike phase ($p = 0.005$). For basketball players, plantar tactile thresholds were significantly higher in dynamic states compared to static conditions ($p < 0.001$). In inter-group comparisons, basketball players demonstrated significantly higher overall plantar pressure pain thresholds than marathon runners ($p < 0.001$).

Discussion

The findings confirm that static assessments do not accurately reflect plantar perception during athletic activity, as thresholds generally change under dynamic load, exhibiting distinct variation patterns across different plantar regions. The significantly reduced sensitivity observed in basketball players compared to runners suggests sport-specific physiological adaptations, such as callus formation. These physiological differences indicate that marathon runners may maintain higher sensory acuity for ground feedback, whereas basketball players may rely more on impact protection, providing a fundamental basis for differentiating athletic footwear design.

Decreased Intra-Foot Coordination Variability on Bilateral Sides of Individuals With Unilateral Chronic Ankle Instability During Landing

Ms Xiaomei Hu[1], Ms Ziwei Zeng[1], Mr Cheukyin Ho[1], Dr Daniel Fong[2], Professor Yijian Yang[1]

[1]The Chinese University of Hong Kong, New Territories, Hong Kong, China. [2]Loughborough University, Loughborough, Leicestershire, United Kingdom

Introduction

People with unilateral chronic ankle instability (CAI) have been found to display lower limb coordination dysfunction during landing. Landing, a movement associated with the risk of ankle sprain, is widely used to detect altered motor patterns. In recent years, there were studies observed that people with unilateral CAI may present bilateral dysfunction, suggesting that the injury may influence the contralateral function. Additionally, some studies found that the ankle sprain may also affect foot function; however, little is known about the bilateral intra-foot coordination and variability in individuals with unilateral CAI. Therefore, this study aimed to investigate the intra-foot coordination and variability in bilateral sides of people with unilateral CAI. We hypothesized that individuals with unilateral CAI would exhibit decreased coordination variability in bilateral sagittal planes and increased coordination variability in bilateral frontal planes compared to healthy controls.

Methods

Forty unilateral CAI and 40 control participants aged between 18 and 40 years old were enrolled. Landing task was executed to explore the intra-foot coordination patterns and variability calculated by modified vector coding. A 2 (group) × 2 (limb) mixed-model ANOVA was applied to analyze the differences between groups and injured/uninjured sides on coordination patterns and variability.

Results

Compared to the healthy controls, participants with unilateral CAI displayed reduced coordination variability in rearfoot-midfoot (48.73 ± 2.95 vs. 50.03 ± 2.21, $p = 0.012$) and rearfoot-forefoot (49.39 ± 3.25 vs. 50.92 ± 2.29, $p = 0.005$) sagittal plane coordination bilaterally. For rearfoot-forefoot sagittal plane coordination pattens, both sides of unilateral CAI participants showed higher frequency of in-phase with proximal dominance pattern (36.24 ± 6.48 vs. 33.56 ± 6.10, $p = 0.021$) and lower frequency of in-phase with distal dominance pattern (19.35 ± 2.95 vs. 20.71 ± 3.10, $p = 0.017$) in comparison with the controls.

Discussion

Individuals with unilateral CAI exhibited an increased rearfoot-dominance coordination pattern and decreased coordination variability in sagittal planes bilaterally, suggesting a more rigid intra-foot coordination pattern. These findings also suggest that the rehabilitation regarding unilateral CAI may not only target at injured side, but also focus on contralateral side and foot. Central function evaluation and functional connectivity analysis may help elucidate the underlying mechanisms in individuals with unilateral CAI.

Running Economy and Kinetics in Rocker and Flat Carbon-Plated Shoes

Dr Yasushi Enomoto[1], Dr Yasuko Hirono[2], Ms Masako Nishihira[3]

[1]University of Tsukuba, Tsukuba, Ibaraki, Japan. [2]University of Tsukuba, Tsukuba, Ibaraki, Japan. [3]YONEX, Tokyo, Tokyo, Japan

Introduction

The purpose of this study was to compare the O_2 cost and running kinetics at faster speeds while wearing two types of carbon-plated shoes among competitive runners, and to get insight into how carbon plates contribute to improving running speed efficiently at a competitive level.

Methods

Eleven competitive distance runners belonging to a university team participated in this study. Two types of shoes equipped with a carbon plate—one with a rocker-shaped plate and the other with a flat-shaped plate (R and F) were evaluated biomechanically and physiologically. Running kinetics at 4.17, 4.76, and 5.56 m/s (low, mid, high) were measured using a motion capture system with integrated force plates on an experimental runway. In a separate experiment, oxygen uptake during treadmill running at low and mid speeds was measured using a metabolic measurement system.

Results

The results are summarized as follows. O_2 cost for F was lower than for R. Ankle torque for F was greater than for R, although no significant difference was observed in vertical ground reaction force between the two shoe types. The one of possible reason of greater ankle torque for F could be a larger anterior–posterior distance between the ankle joint center and the center of pressure (CoP) on the force plate.

Discussion

All participants exhibited a mid or fore-foot strike pattern. Their CoP shifted backward immediately after foot strike and then moved forward toward toe-off. A possible explanation is that greater ankle torque may occur concurrently with smaller knee torque

when ground reaction force remains similar, which is associated with lower energy cost during running [1]. We hypothesize that the rocker-shaped plate may not facilitate forward CoP movement once it shifts backward, compared with the flat plate, although the rocker design may assist forward CoP movement immediately after heel contact. In conclusion, flat carbon-plated shoes may reduce O_2 cost by increasing ankle joint torque in competitive distance runners.

Validity of IMU-based Assessment of Knee Motor Control in Difference Stance Conditions using Angular Velocity Vector Analysis

Dr. Yu Kashiwagi PhD[1], Dr. Jeffery Rankin MSE, PhD[2], Prof. Jill McNitt-Gray PhD[3]

[1]Senshu University Institute of Sport, Kawasaki, Kanagawa, Japan. [2]Pathokinesiology Laboratory and Rehabilitation Engineering, Rancho Los Amigos National Rehabilitation Center, Downey, California, United States. [3]Biological Sciences and Biomedical Engineering, University of Southern California, Los Angeles, California, United States

Dr. Yu Kashiwagi

Dr. Jeffery Rankin

Introduction

Inertial measurement units (IMUs) enable motion analysis in real-world contexts without the spatial constraints of optical motion capture. IMUs reduce preparation burden by eliminating the need for camera calibration, marker placement, and marker detection issues. Although three-dimensional joint motion reflects an individual's multijoint control strategy, its representation is dependent on global and local reference systems that are not consistently defined across platforms. We addressed these challenges by examining resultant joint angular velocity time-series, derived from adjacent segment kinematics[1], to characterize motor control during sit-to-stand (STS) tasks[2]. We hypothesized that the resultant knee angular velocity vector magnitude and direction would be comparable between measurement systems and would differentiate within-participant strategies across three STS conditions.

Methods

One adult male participated and performed ten consecutive STS movements at a self-selected tempo using three stance conditions: preferred, ankle posterior to knee, and toe-out. Movement data were collected simultaneously using a marker-based motion capture system and a seven-sensor IMU system (Vayu Technology). Forty-seven reflective markers defined the model, and each IMU was fitted with three markers to maintain spatial registration. Local segment coordinate systems were aligned to a static standing posture

and transformed into IMU frames using quaternions, which were differentiated to obtain angular velocity vectors. Five stable cycles were selected for analysis, and cross-correlation coefficients were computed for knee angles and angular velocity vectors. Three-dimensional vectors were visualized for velocity magnitudes exceeding 50% of the peak extension-phase value.

Results

Knee angular velocity vectors showed differences across stance conditions in direction, distribution, and variability, indicating altered motor strategies. Time-series patterns of quaternions and segment angles matched between collection systems (Cross-correlation coefficients: resultant angular velocity magnitude (0.925 to 0.984), direction (.158 to 0.873), knee angles (0.44 to 1.00). Correlations increased with greater rotational amplitude .

Discussion

IMU-derived angular velocity vectors demonstrated high validity compared to optical motion capture and were sensitive to differences in multijoint coordination across stance conditions. Findings support the use of IMU-based resultant angular velocity vectors to characterize joint control in diverse stances.

Biomechanical Analysis of Compression Garment During Running

Yun-Bae Jeong M.S.[1,2], Jae-Won Kang M.S.[1,2], Jung-Min Yoon M.S.[1,2], Prof. Sihyun Ryu Ph.D.[1,2], Prof. Sukhoon Yoon Ph.D.[1,2], Prof. Sang-Kyoon Park Ph.D.[1,2]

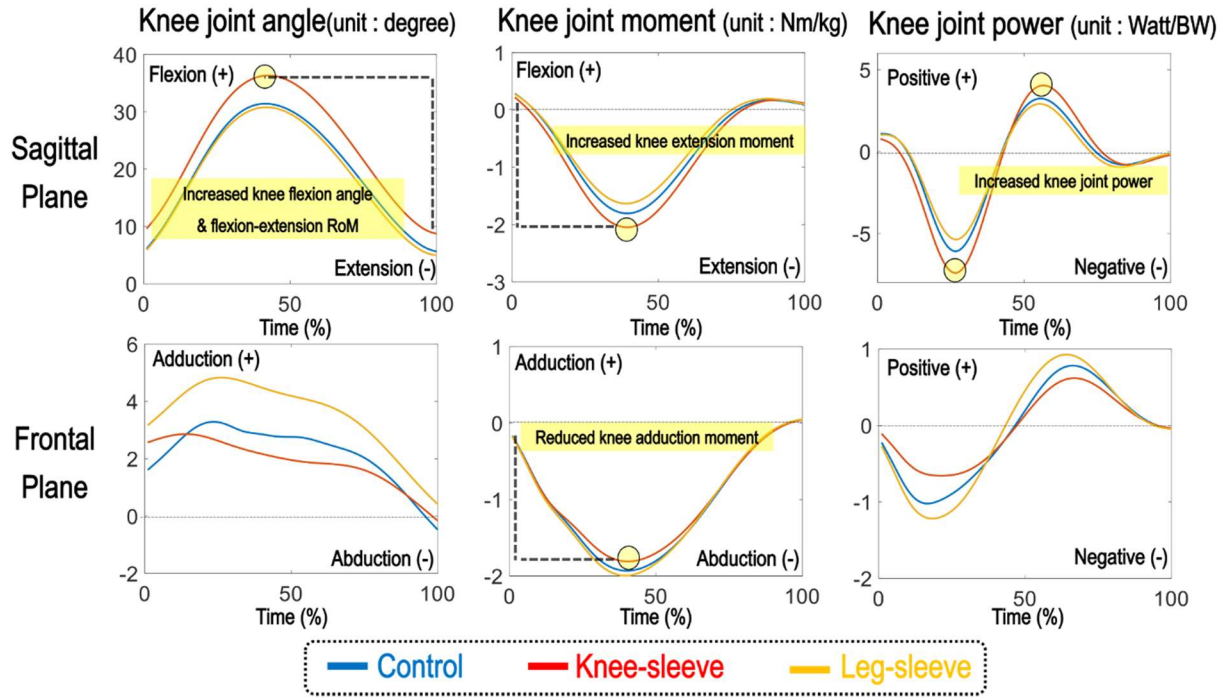
[1]Korea National Sport University, Seoul, Seoul, Korea, Republic of. [2]Motion Innovation Center, Seoul, Seoul, Korea, Republic of

Introduction

Compression garments are widely used in sports to reduce muscle oscillation during impact without restricting movement[1]. For the lower extremities, these are typically categorized as knee sleeves (joint-targeted) and leg sleeves (muscle-targeted). While previous research has focused on vibration-dampening effects, comparative analyses of how biomechanical variables differ based on the application area remain insufficient. This study investigated the effects of joint-supporting knee sleeves and muscle-supporting leg sleeves on key biomechanical variables during running.

Methods

Fifteen healthy males participated in this study. Participants performed treadmill running for three minutes at a speed of 3.6 m/sunder three conditions: Control (C), Knee sleeve (K), and Leg sleeve (L). Kinematic and kinetic data were collected using nine infrared cameras (100 Hz) and an instrumented treadmill (1000 Hz). A one-way repeated measures ANOVA with Bonferroni post-hoc tests was used to examine differences between conditions (α=.05).



Results

No significant differences were observed in spatiotemporal variables (contact time, stride length, and cadence) among the three conditions. However, the K condition showed a significant increase in peak knee flexion angle, flexion-extension range of motion, extension angular velocity, extension moment, and negative power in the sagittal plane compared to C and L. Conversely, in the frontal plane, the K condition significantly decreased the knee adduction angle and adduction moment compared to C and L conditions.

Discussion

The knee sleeve enhanced knee frontal plane stability while increasing sagittal plane knee joint forces, whereas the leg sleeve showed no significant biomechanical changes. Given that compression garments primarily contribute to muscle protection and improved energy economy by reducing muscle oscillation during prolonged exercise, the short running duration in this study likely limited the observability of leg sleeve effects. Future studies should verify the long-term implications of increased sagittal plane loading from knee sleeves and further investigate the specific benefits of leg sleeves regarding muscle protection and energy efficiency over extended durations.

Joint Stiffness During the Landing Stage in Table Tennis Footwork

Asst. Prof. Yuqi He[1,2], Assoc. Prof. Daisuke Takeshita[2], Asst. Prof. Ping Yeap Loh[3], Prof. Guopeng Hu[1]

[1]Huaqiao Univesity, Quanzhou, Fujian, China. [2]The University of Tokyo, Tokyo, Tokyo, Japan. [3]Kyushu Universiy, Fukuoka, Kyushu, Japan

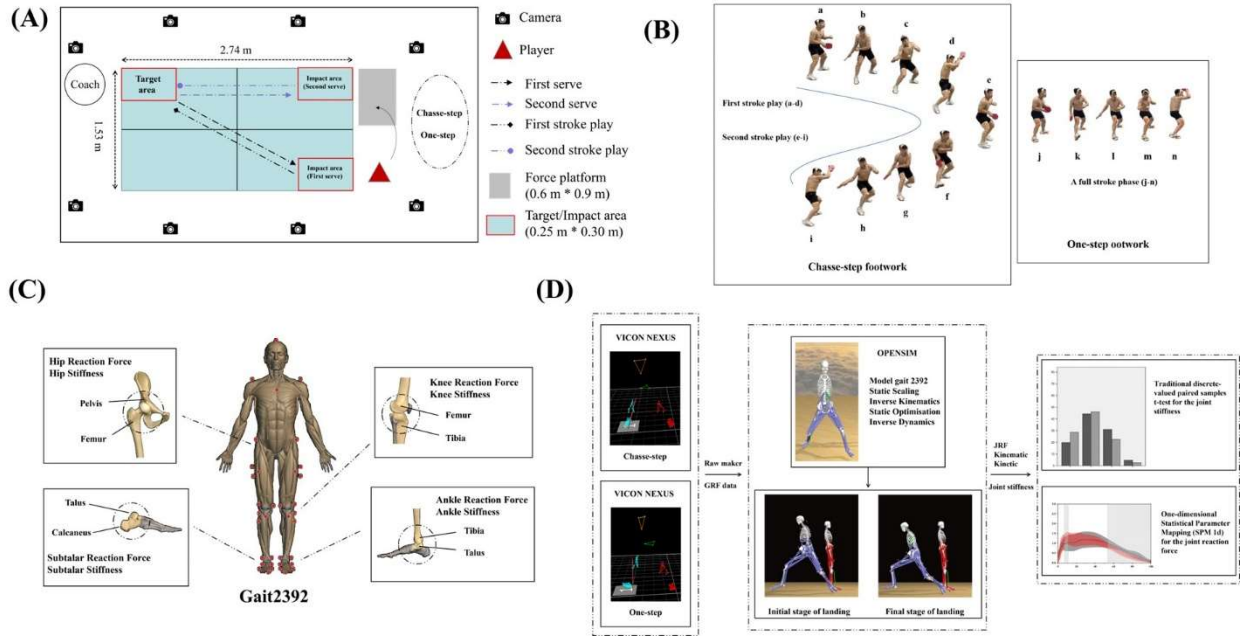
Introduction

The joint reaction force (JRF) and stiffness are important indicators to evaluate the mechanical performance of joints during movement. The purpose of this study is to explore the JRF and joint stiffness of the chasse-step (CS) and one-step (OS) footwork during the landing phase to further reveal the intrinsic mechanical mechanism of table tennis footwork and provide a theoretical basis for the prevention of joint injury.

Methods

Sixteen male table tennis athletes (height: 171.98 ± 4.97 cm; weight: 68.77 ± 7.86 kg; experience: 10.67 ± 1.86 years; age: 22.50 ± 1.64 years) performed CS and OS footwork to return the ball from the coach by topspin forehand stroke. The kinematics, kinetics, and muscle activity of the lower limb were recorded by the motion capture, force platform, and Electromyography (EMG) system. Statistical parametric mapping (SPM) analysis was used to investigate any difference between the CS and OS footwork during the stroke.

Results



During landing, the subtalar joint exhibits the greatest joint stiffness (0.242±0.078 in CS, 0.338±0.185 in OS). Compared with OS, the stiffness of the knee and hip's transverse plane in the CS was significantly greater (Knee: CS = 0.072 ± 0.011 N·M·KG-1·Deg-1, OS = 0.038 ± 0.010 N·M·KG-1·Deg-1, $t = 9.487$, $p = 0$; Hip: CS = 0.119 ± 0.037 N·M·KG-1·Deg-1, OS = 0.073 ± 0.027 N·M·KG-1·Deg-1, $t = 3.934$, $p = 0$).

The results shows that 1) in the knee, the JRF in CS was significantly greater than in OS in the percentage of 30.89-35.83% ($p = 0.035$) and 36.19-100% ($p < 0.001$) but lower than in OS in the percentage of 8.74-14.05% ($p = 0.034$). 2) in the subtalar, the JRF in CS was significantly greater than in OS in the percentage of 24.24-30.15% ($p = 0.028$) and 41.14-100% ($p < 0.001$).

Discussion

The results of this study can be applied to movement control and injury prevention in table tennis footwork.

Leveraging Biomechanics for Rugby Player Safety: Insights from the FIR

Dott.ssa Fabiola Spolaor[1], PhD Student Federica Beghetti[1], Ing. Federica Cibin[2], Mr. Davide Bruschi[1], Dott. Giovanni Biondi[3], Associate Professor Zimi Sawacha[1]

[1]Department of Information Engineering, University of Padova, Italy, Padova, ITA, Italy. [2]BBSoF - Beyond Biomechanics Sport on Field, Padova, ITA, Italy. [3]FIR (Federazione Italiana Rugby), Roma, ITA, Italy

Introduction

Rugby is a high-contact sport with frequent collisions and rapid directional changes, leading to a high risk of lower-limb injuries, especially ACL ruptures [1]. Traditional prevention relies on general functional tests, which partially capture sport-specific mechanical demands and lack ecological validity [2]. The Italian Rugby Federation implemented a rugby-specific cutting task after an up-and-under reception, combining video and pressure-insole analysis to assess joint kinematics and kinetics. through ACL Quick Check® [3] method. Multi-technique clustering was applied to identify subgroups with similar biomechanical deficits and guide targeted exercises.

Methods

Ninety-two rugby players (17 ± 5 years, 27 ± 3 kg/m^2) were assessed on-site using seven synchronized cameras (GoPro Hero, 30–240 Hz) and a wireless plantar pressure system (X Sensor, 200 sensors, 100 Hz). Each player performed four sidestep cuts (two per side) with randomly assigned direction and the following variables were computed: hip, knee, ankle angles and torques, joint ranges of motion, vertical ground reaction forces, each variable peak occurrence within the task duration. A subgroup of athletes with no history of injuries was selected to define the normative bands. Unsupervised machine-learning analysis (K-means, Hierarchical Clustering, DBSCAN) was applied to the remaining 42 athletes, using grid-search and Silhouette scores to select optimal parameters and cluster counts. The resulting clusters were used to assign athletes to exercise groups, and an expert trainer's independent assignments served as the benchmark for validation.

Results

Results revealed four distinct clusters: two (3, 0) characterized by altered hip and knee biomechanics. Cluster 3 was characterized by increased hip adduction and reduced hip flexion moments. Cluster 0 displayed a similar pattern but with a deeper squat strategy, further accentuating these biomechanical alterations. In contrast, Cluster 2 grouped

athletes demonstrating more efficient joint coordination and overall better management of the task.

Discussion

A good agreement was found between personal trainer assignment and clustering based one. Identification of recurrent hip-driven deficits underscores the importance of proximal control in ACL-risk biomechanics. The variability in compensatory strategies highlights the need for biomechanics-based interventions.

Images (Optional)

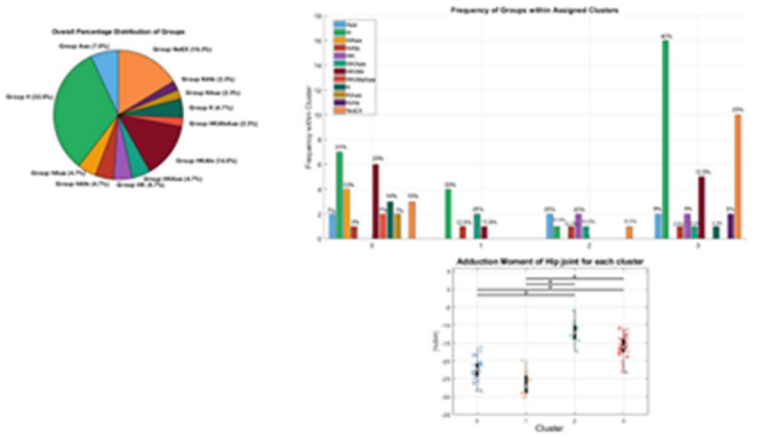

Fig. 1: *Left:* Pie chart illustrating the proportion of athletes assigned to each exercise group according to the personal trainer's classification. The NoEx group includes athletes with no detected alterations; HIP represents hip-related alterations (H); KNEE indicates knee-related alterations (K); and ANKLE corresponds to ankle-related alterations (A), with subgroups distinguishing dorsiflexion/plantarflexion issues (Afe) and adduction/abduction deficits (Aaa). Mixed groups reflect combinations of two or more of these biomechanical alterations.
Top Right: Histogram showing the distribution of athletes across the four clusters identified through the k-means analysis. The comparison provides insight into the differences between practitioner-based and data-driven groupings.

Acoustic Microfluidic Confinement Elucidates the Photoshock Response of Light-Sensitive Microswimmers

Prof. J. Mark Meacham[1], Mr. Advaith Narayan[1], Dr. Mingyang Cui[1,2], Prof. Susan Dutcher[3], Prof. Philip Bayly[1]

[1]Washington University in St. Louis, St. Louis, MO, United States. [2]Massachusetts Institute of Technology, Cambridge, MA, United States. [3]Washington University School of Medicine in St. Louis, St. Louis, MO, United States

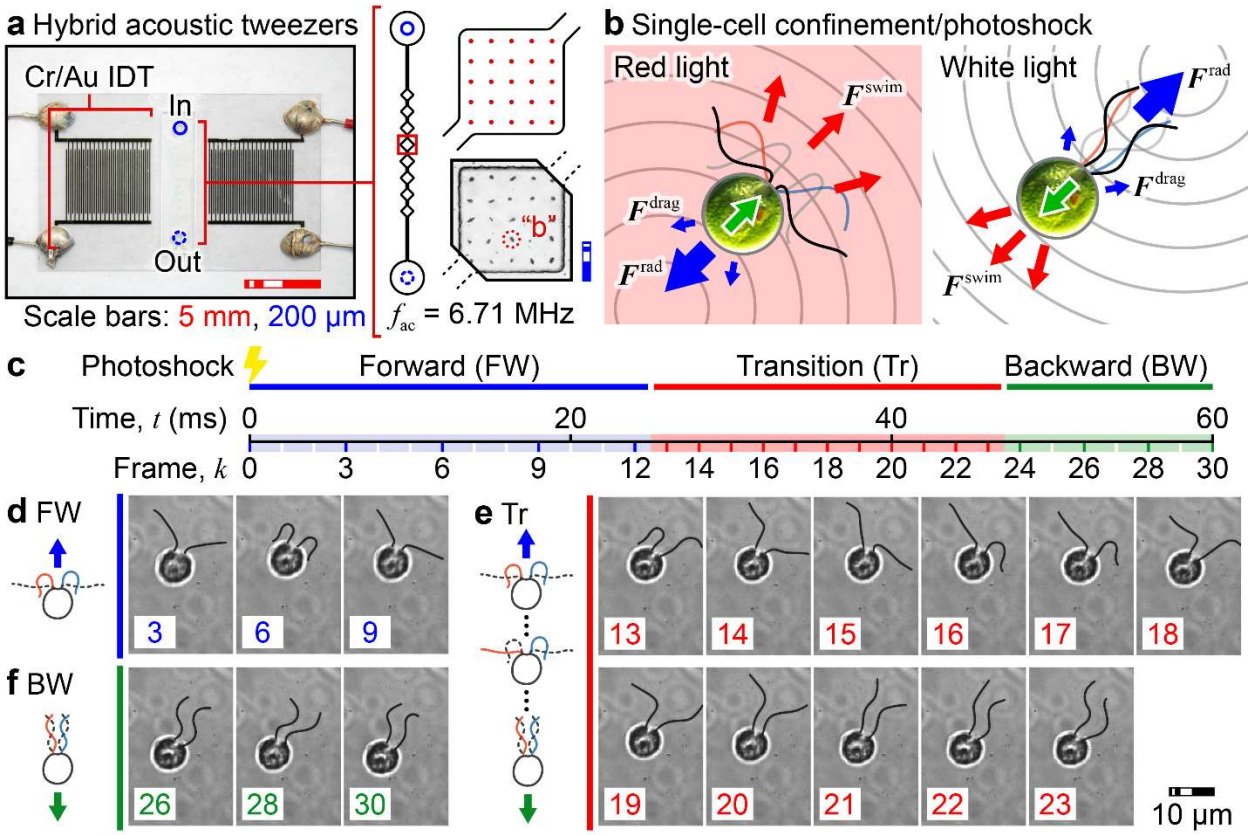
Introduction

Conventional studies of sustained cilia motion in microswimmers are laborious, time-intensive, and overconstrained as rapidly swimming cells must be immobilized to observe their behavior over time. Alternatively, acoustic tweezers are able to trap the (microscale) cell body without affecting the natural motion of the (nanoscale) cilia. This capability enables detailed investigation of photoshock in wild-type *Chlamydomonas reinhardtii* cells.

Methods

Two acoustic tweezers were developed: (i) a circular chamber with a central node for population-based trap-and-release motility assessment and (ii) a square chamber with an array of traps for studying cilia dynamics in individual cells (see figure panel **a**). Both devices used Cr/Au interdigital transducers (IDTs) on $LiNbO_3$ piezoelectric substrates to generate standing acoustic waves within fluid-filled glass channels. Photoshock was induced using a red-to-white-light illumination change. For trap-and-release experiments, ultrasound removal was synchronized with photoshock; cell trajectories were used to determine swimming speed and linearity of the cell populations. For single-cell analyses, the trap remained on during and after photoshock (panel **b**).

Results



Slightly more than half of the light-treated cells (13 of 22 over two experiments) exhibited backward swimming based on a low median speed u = 26.7 μm/s. Some treated cells (4 of 22) maintained a forward swimming presentation (less linear, significantly higher u = 77.4 μm/s). The remaining cells were unidentifiable. The median speed of untreated control cells was 88.2 μm/s (12 cells). Acoustic confinement enabled high-resolution imaging of the two cilia during the transition from forward to photoshock-induced backward

swimming (panels **c-f**). The asymmetric mode that propels cells in forward swimming was observed for ~12 frames (two beat cycles at ~80 Hz) after the photoshock stimulus (panel **d**). The two cilia transitioned independently with one (right cilium, panel **e**) accelerating before both cilia extended to take on the symmetric, undulatory beat pattern indicative of backward swimming (panel **f**).

Discussion

Acoustic tweezers are versatile tools for exploring microswimmer behavior at the multi-organism-, organism-, and organelle-scales. Cilia behavior is consistent with prior studies using uniciliated mutants or cells held rigidly on micropipettes; however, acoustic tweezers do not rely on rigid immobilization, thus allowing locally free, three-dimensional swimming.

A Study on Vascular Endothelial Cell Mechanobiological Responses to Disturbed Flows Around Narrow Vessels Based on Vessel-on-a-Chip Model

Dr. Jifeng Ren, Ms. Dong Ma

Capital Medical University, Beijing, Beijing, China

Introduction

Atherosclerosis is a leading global cause of mortality and disability worldwide. This progressive condition, which leads to vascular narrow and triggers severe cardiovascular events. Narrow vessel regions existing in most atherosclerosis cases, therefore abnormal flow conditions such as disturbed flow usually occur. Since traditional cell culture methods struggle to replicate physiological functions of blood vessels, novel research methods should be applied. Vessel-on-a-chip systems not only replicate specific mechanical conditions of diseased regions but also allow real-time observation of cellular behaviors and molecular mechanisms. In this study, vessel-on-a-chip models with different cell mechanical properties were built to unveil mechanobiological clues in the progression of atherosclerosis.

Methods

Microfluidic device design and fabrication: A straight vessel containing partial narrow regions was designed to mimic the pathological condition of atherosclerosis. The microfluidic devices were fabricated by following standard soft lithography process.

Cell culture: Human umbilical vein endothelial cells (HUVECs) were used in this study. Cells were first cultured in flasks and resuspended using trypsin-EDTA before seeding into microfluidic chips.

Cell viscoelasticity measurement: Cell viscoelasticity can be quantified using a previously developed microfluidic cytometer (see *ref*[1,2]).

Abnormal viscoelasticity cell model: High viscoelasticity HUVECs can be induced by using an actin polymerization inducer Jasplakinolide.

Results

By considering cells as standard linear solid materials, higher viscoelastic parameters (i.e. viscosity, instant elasticity & relaxed elasticity) were discovered in Jasplakinolide treated HUVECs using microfluidic cytometer measurement.

Disturbed flow streamlines can be observed around narrow vessel regions, indicating abnormal flow condition is realized in our vessel-on-a-chip devices.

Epithelial mesenchymal transition marker vimentin was discovered to have higher expression level in Jasplakinolide treated vessel-on-a-chip model.

Discussion

Our current results indicate abnormal high cell mechanical property is an important factor in the progression of atherosclerosis, which is consist with the alternations of cell viscoelasticity in senescent HUVEC models (*ref*[2]). The limitation of the study is shortage of protein types to reflect HUVEC epithelial mesenchymal transition. In the future, we are planning to involve more protein types such as alpha-SMA to solidify findings in this study.

Development of Microfluidic Devices to Generate Oxygen and pH Heterogeneity

Mr. Taishi Nakamura B.Eng., Prof. Kenichi Funamoto Ph.D.

Tohoku University, Sendai, Miyagi, Japan

Introduction

Heterogeneous hypoxic and acidic (pH < 7.4) conditions are generated in cancer and inflammatory microenvironments due to massive O_2 consumption and lactate release during glycolysis. Hence, elucidation of the effects of O_2 and pH on cell dynamics and functions is essential to develop novel therapeutic strategies for these diseases. However, conventional cell culture systems have had difficulties in reproducing in vivo microenvironments with spatiotemporal changes of O_2 and pH. Here, we introduce microfluidic devices to rapidly and precisely control dissolved gas concentrations around cells.

Methods

The microfluidic devices were fabricated from polydimethylsiloxane (PDMS), a polycarbonate (PC) film, and a glass coverslip [1]. Cell culture channels were located on the glass coverslip, and gas channels were formed above them. By supplying gas mixtures with adjusted components (O_2, CO_2, and N_2) to the gas channels, O_2 and CO_2 concentrations were controlled by gas exchange through the gas-permeable PDMS layer between the channels. Subsequently, the chemical equilibrium of $NaHCO_3$ supplemented in the cell culture media was shifted by dissolved CO_2, enabling pH control. A low gas-permeable PC film was embedded in the device covering the channels to reduce infusion of ambient gas components. The steady-state and transient characteristics of dissolved gas control were investigated by numerical simulations and validated experimentally using materials that exhibited O_2-dependent phosphorescence or pH-dependent fluorescence. Device feasibility was examined by observing migratory behaviors of MDA-MB-231 breast cancer cells.

Results

The devices generated arbitrary uniform or gradient conditions (0.3%–21% O_2 and pH 6.5–7.9) in cell culture channels filled with DMEM cell culture medium. Temporal characterization revealed that steady-state conditions could be achieved within 15 min after switching gas mixtures. Cell experiments showed changes in migratory behaviors of MDA-MB-231 cells. Migration speed tended to increase under hypoxic conditions. Moreover, it increased under alkaline conditions but decreased under acidic conditions,

with cells exhibiting directional migration toward regions with pH 7.6 (5% CO_2 concentration).

Discussion

Our microfluidic devices can generate arbitrary O_2 and pH conditions covering both physiological and pathological ranges. These devices are expected to be useful tools for cell experiments and drug screening.

Hydrophilic Macromolecule Transport into Deep Skin via Sweat Ducts: Quantitative 3D Imaging and Diffusion Simulation

Assoc. Prof. Kenji Kikuchi Doctor of Engineering[1], Researcher Keisuke Kikuchi Doctor of Pharmaceutical Sciences[2], Researcher Sanae Hirota[2]

[1]Tohoku University, Sendai, Miyagi, Japan. [2]Maruho Co.,Ltd., Kyoto, Kyoto, Japan

Assoc. Prof. Kenji Kikuchi

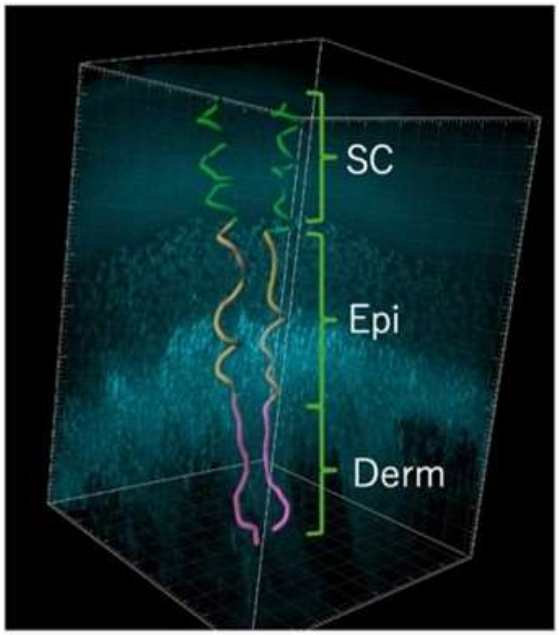
Researcher Keisuke Kikuchi

Introduction

Hydrophilic macromolecules and polymers with molecular weight well above 500 Da and very low log P are generally regarded as incapable of crossing the stratum corneum barrier by passive diffusion. Yet clinical experience with mucopolysaccharide polysulfate (MPS) ointments suggests pharmacological actions in deep skin, raising the question of which pathway enables such water-soluble drugs to reach dermal targets. We hypothesised that sweat ducts provide a dominant shunt route and aimed to visualise and quantify MPS transport via this pathway.

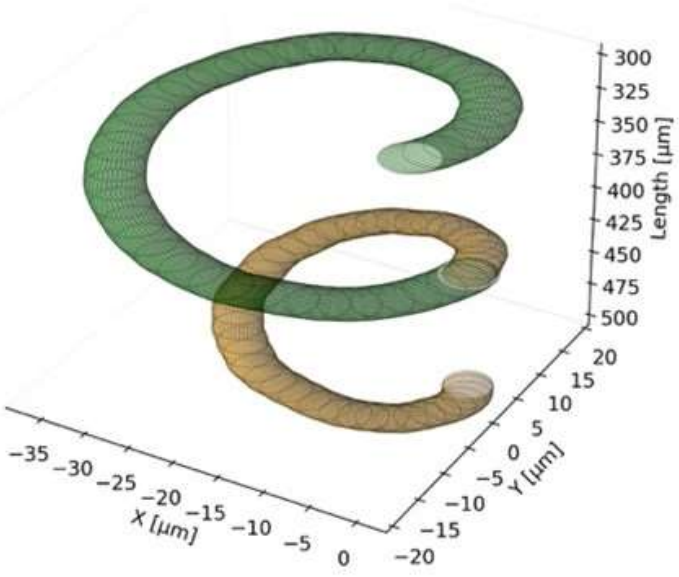
Methods

Fluorescein-labelled MPS cream was topically applied to the plantar skin of hairless regions of C57BL/6J mice. After defined application times, tissue clearing with a high-refractive-index medium enabled three-dimensional confocal imaging of individual sweat ducts and surrounding tissue. Duct morphology was characterized and parameterized as helical segments in the stratum corneum, epidermis, and dermis. Depth-dependent fluorescence attenuation was calibrated by immersing skin in solutions of known concentration and fitting a three-layer (SC/Epi/Derm) exponential attenuation model using nonlinear least-squares optimization. Fluorescence recovery after photobleaching (FRAP) provided the diffusion coefficient of MPS in the formulation. One-dimensional finite-volume simulations of diffusion along the duct, with a Michaelis–Menten sink at the secretory portion, were used to interpret the spatial distribution of drug mass.



Results

Cleared-tissue imaging revealed intense MPS accumulation along the intra-epidermal duct extending several hundred micrometers below the surface. The calibrated attenuation model enabled quantitative three-dimensional maps of local drug concentration in and around sweat ducts. FRAP yielded diffusion coefficients, consistent with rheological measurements. Simulated time-evolution of duct concentration profiles reproduced the experimentally reconstructed depth-dependent accumulation and total drug amount with good qualitative agreement.



Discussion

These findings demonstrate that, in the absence of sweating, highly water-soluble, high-molecular-weight polymers such as MPS can reach deep skin layers predominantly through sweat ducts via diffusion-dominated transport. Preliminary experiments under controlled sweating conditions, which are currently ongoing, qualitatively confirm that MPS can also penetrate along sweat ducts even in the presence of outward sweat flow. The combined framework of 3D microscopic visualization, quantitative fluorescence reconstruction, and transport simulation provides a general strategy for rational design and evaluation of sweat-duct-mediated transdermal drug delivery.

Rheological Comparison of Resting and Stimulated Saliva in the Context of Phonation in Ectodermal Dysplasia

PD Dr.-Ing. Marion Semmler[1], Ms. Jamina Holbach[1], Dr. med. Maximilian Eckhardt[1], Dr.-Ing. Bogac Tur[1], - Sophie Wolfsteiner[1], MSc Samuel Schlicht[2], Prof. Dr.-Ing. Dietmar Drummer[2], Dr. rer. nat. Olaf Wendler[1], Prof. Dr. med. Holm Schneider[3]

[1]University Hospital Erlangen, Medical School, Division of Phoniatrics and Pediatric Audiology at the Department of Otorhinolaryngology – Head and Neck Surgery, Friedrich-Alexander-Universität Erlangen-Nürnberg, Erlangen, Bavaria, Germany. [2]Institute of Polymer Technology, Friedrich-Alexander-Universität Erlangen-Nürnberg, Erlangen, Bavaria, Germany. [3]Division of Molecular Pediatrics at the Department of Pediatrics, Friedrich-Alexander-Universität Erlangen-Nürnberg, Erlangen, Bavaria, Germany

Introduction

Patients with the rare condition Ectodermal Dysplasia (ED), a group of inherited disorders in the development of ectodermal structures, display a significant lack of skin appendages as well as a reduced function of some eccrine glands. Previous studies showed significantly reduced saliva production and impairment of the acoustic outcome in male ED patients compared to healthy male controls. ED offers a unique chance to study the fundamental role of laryngeal mucus in the phonation process. The aim of this study was a thorough rheological analysis of saliva samples serving as a non-invasively obtainable substitute for the laryngeal mucus.

Methods

This study included 36 ED patients and 96 controls. Samples of resting and stimulated saliva were obtained for a period of 5 min. The samples were measured with a plate-plate rheometer (plate diameter: 25 mm, slit width: 120 µm). Frequency was varied between f=1-10 Hz in 15 steps at τ=0.01 Pa, and the amplitude of the applied shear stress was systematically varied between τ=0.01-20Pa at 0.5 Hz in 30 steps. Storage modulus G’ and loss modulus G” were determined in both frequency and strain sweeps and were analyzed statistically with regard to differences between stimulated and resting saliva for ED patients and controls.

Results

The present study shows significantly lower values for G' und G" at lower frequencies and at lower strains for stimulated saliva compared to resting saliva in controls and female ED subjects, but not for male ED patients. With increasing frequency and strain, mean G' and G" of stimulated saliva were slightly higher than in resting saliva. Male ED subjects displayed only minor differences between resting and stimulated saliva.

Discussion

Our data suggest that resting and stimulated saliva do not differ to the same extent for male ED subjects compared to controls. The changed rheology in stimulated saliva might result from the altered concentration or molecular weight of hyaluronic acid and mucins, or overall protein concentration. The differences in the viscoelasticity between resting and stimulated saliva for the quasi-static range of lower frequencies and amplitudes indicate reduced resistance against external forces in controls, which would influence the retention rate.

Microfluidic-Enhanced Size-Based Cell Separation for Biomedical Applications

Mr Mohsen Hassani, Dr Amir Sanati Nezhad

University of Calgary, Calgary, AB, Canada

Mr Mohsen Hassani

Introduction

Efficient size-based separation of cells and sub-cellular particles is essential for accurate biomedical analysis and diagnostic workflows. Conventional techniques such as ultracentrifugation and precipitation method often require bulky equipment, generate shear stress, or deliver inconsistent size selectivity [1]. Microfluidic systems offer a compact, controllable alternative by leveraging laminar flow and engineered channel geometries to achieve precise, label-free separation [2]. This work presents a microfluidic-enhanced platform optimized for size-dependent cell separation, aiming to improve separation performance, purity, recovery rate, and reduce operational complexity for a range of biomedical applications.

Methods

A microfluidic platform was designed with size-selective constriction zones and a hydrodynamic filtration membrane optimized to separate cells based on their effective diameter. Devices were fabricated using Polyethylene Terephthalate (PET) film and bonded to create enclosed microchannels. Cell suspensions of defined size ranges were introduced through a single inlet under controlled capillary-driven flow, and separation was achieved as the filtration membrane selectively allowed smaller cells to pass while retaining larger ones. Outlet fractions were collected and analysed using Dynamic Light Scattering (DLS) and Nanoparticle Tracking Analysis (NTA) to quantify size distribution and recovery. Purity assessment will be conducted in the next phase of evaluation.

Results

The microfluidic platform effectively separated particles based on size using its integrated hydrodynamic filtration membrane. Filtration of ~90 µL PBS containing 500 nm particles was completed in under 5 minutes, demonstrating rapid processing capability. Tests with sweat and saliva showed consistent size-selective performance, though saliva required

slightly longer filtration due to higher viscosity. As a proof of concept, a urine sample from a cancer patient was processed, and Nanoparticle Tracking Analysis confirmed successful enrichment of particles below 100 nm with reduced larger-particle content.

Discussion

Results indicate that membrane-based microfluidic filtration provides rapid, consistent size selectivity without external pumping. Performance remained stable across fluids of varying viscosity, supporting broad applicability. Successful enrichment of sub-100 nm particles from urine highlights potential for downstream diagnostic workflows, including extracellular vesicles analysis, pathogen detection, and other size-dependent assays. The platform's simplicity positions it well for point-of-care use.

Transfection of Suspension Cells Using a Microbubble Generator That Combines Mechanical and Electrical Stimuli

Dr. Nobutoshi Ota, M.S. Kei Tateishi, Prof. Yoko Yamanishi

Kyushu University, Fukuoka, Fukuoka, Japan

Introduction

Modification of cellular functions can be achieved by delivering desired genetic materials into cells, called transfection. Physical methods of transfection shows high reproducibility due to precise control of physical parameters while one type of physical stimulation is applicable for limited cell types. To explore transfection to broader cell types, we have developed a core-shell structured microbubble generator, which performs a transfection method called electromechanical poration (EMP). EMP uses mechanical and electrical stimuli to perforate the membrane of cells. Although EMP has been applied to adherent cells [1], its capability has not been investigated for suspension cells.

Methods

Figure 1 illustrates transfection via EMP. EMP uses electric pulses, which induce electric stimulation to the suspended cells. Simultaneously, electric pulses are applied to a microbubble generator to form microbubbles at the tip of the generator. The microbubbles oscillate their volume based on applied electric pulses and provide mechanical stimulation to suspended cells.

The experimental setup is shown in Figure.2. A core-shell structured microbubble generator was consisted with a tungsten wire inserted to a glass capillary and was connected to a high-voltage power source for EMP. During EMP, target cells and plasmids were suspended in culture medium. After EMP, perforated cells were allowed to recover for 24 h. Recovered cells were evaluated by expression of a reporter gene such as green fluorescent protein (GFP), which indicates successful transfection.

Results

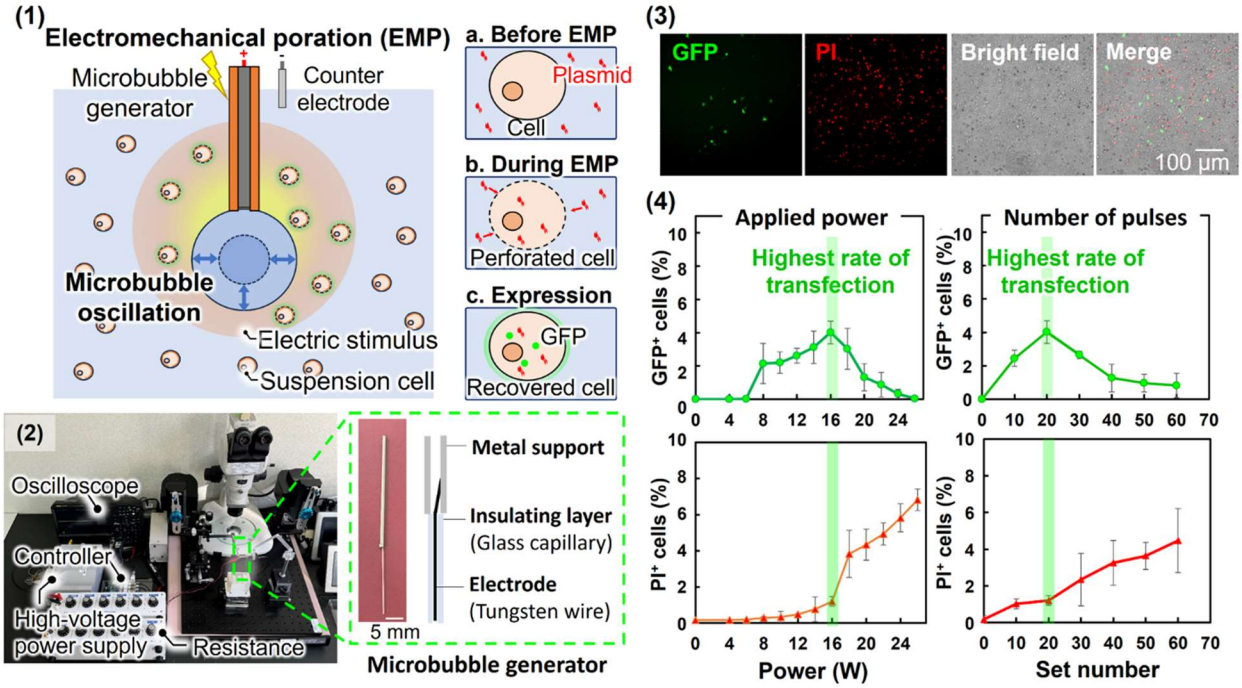

Figure 3 shows bright field and fluorescence images of transfected cells under microscope observation. Green fluorescence given by GFP indicates successful transfected cells. Red fluorescence given by propidium iodide (PI) staining indicates dead cells. Changes in physical parameters, applied power and pulse number, resulted in various rates of

transfection and cell death (Figure 4). When the cells are perforated appropriately, transfection rate was as high as 4% and cell death was kept as low as <10%.

Discussion

In this study, we have succeeded transfection of suspension cells by EMP. Further improvement of transfection can be achieved by modifying other physical parameters, such as frequency of electric pulses, for successful transfection to broader types of suspension cells.

Optimization of Microchannel Geometry for Efficient Sorting of Highly Motile Sperm Using a Microfluidic Device

Prof Toru Hyakutake

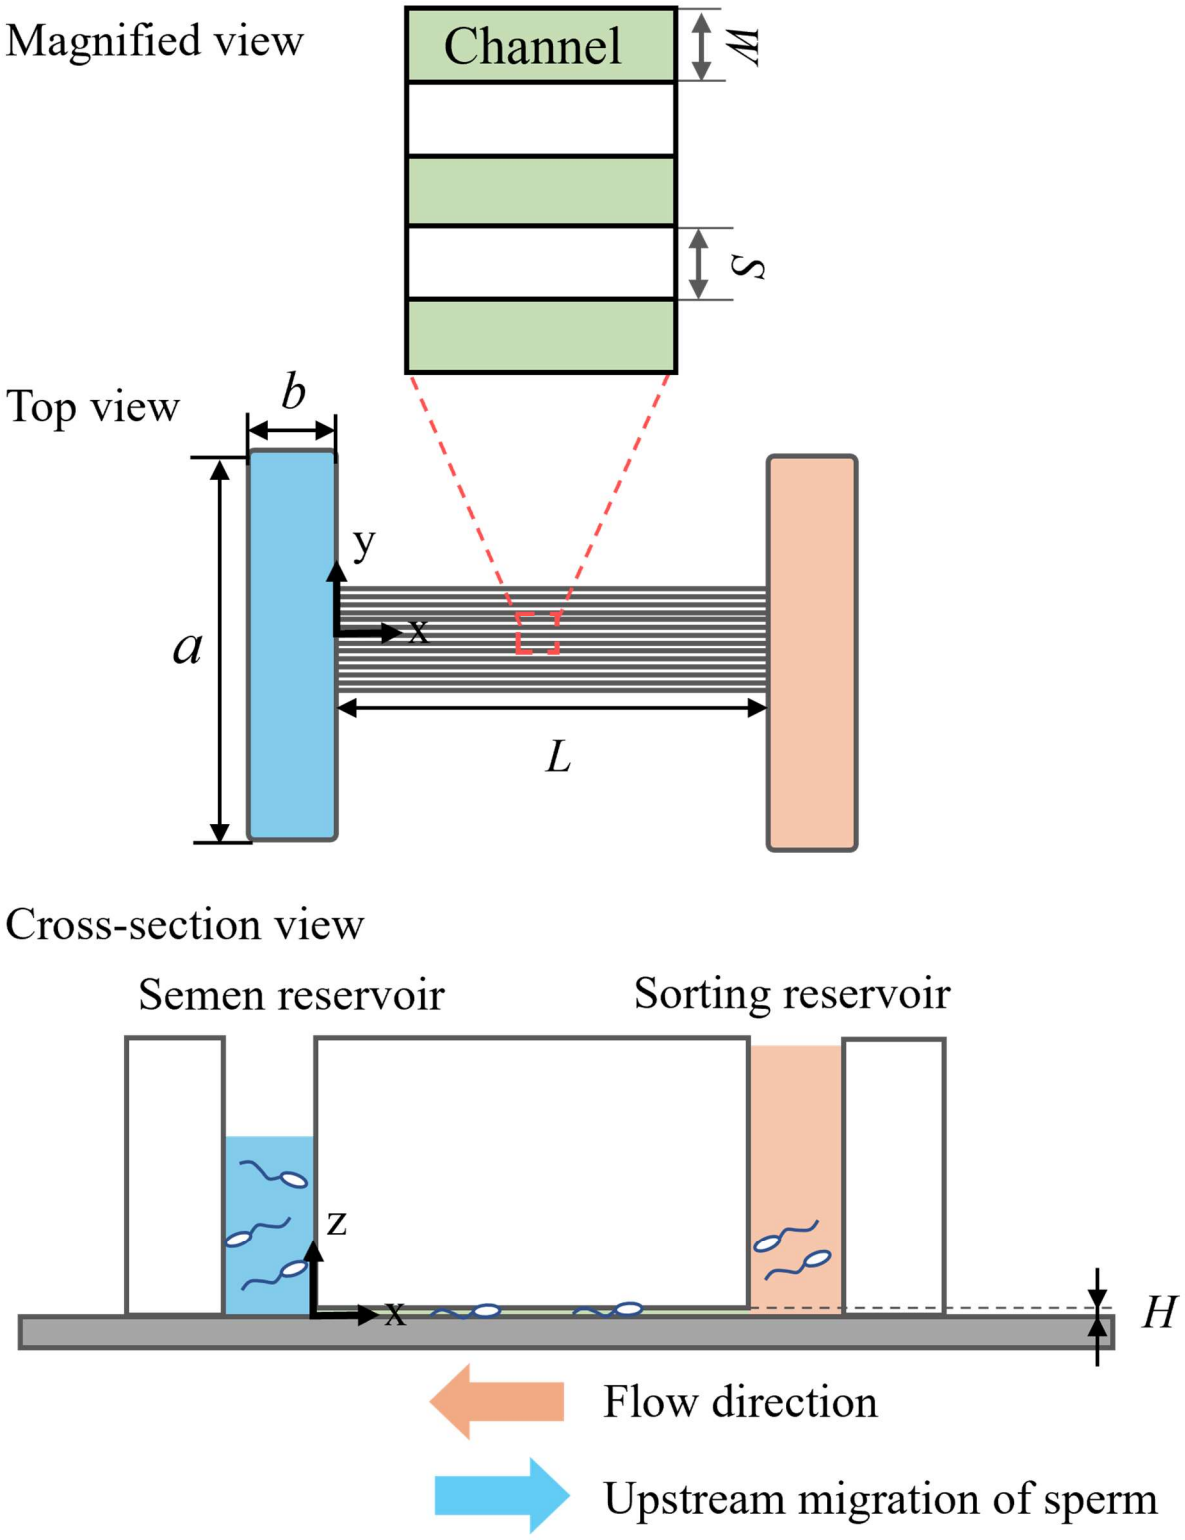
Yokohama National University, Yokohama, Kanagawa, Japan

Introduction

In Japan, the declining birthrate has become a serious social concern, and infertility is considered one of its major contributing factors. Current treatment methods—artificial insemination (AI), in vitro fertilization (IVF), and intracytoplasmic sperm injection (ICSI)—are selected based on the patient's condition. However, the commonly used density-gradient centrifugation method may cause DNA damage to sperm. Microfluidic devices, which use gentle microscale flow, offer an alternative approach by sorting sperm with minimal mechanical stress and in a shorter processing time. Against this background, we developed a microfluidic device composed of multiple parallel microchannels with widths comparable to sperm length. By creating flow through a hydraulic head difference between two reservoirs, the device allows sperm exhibiting rheotaxis and thigmotaxis to swim upstream, enabling selective collection of highly motile sperm. The aim of this work was to investigate how microchannel geometry affects sorting performance and to identify design guidelines for optimizing the device.

Methods

The microfluidic devices were fabricated in polydimethylsiloxane (PDMS) using standard soft lithography techniques. Each device included several parallel microchannels connected to a sorting and a semen reservoir. Japanese cattle semen cryopreserved in 0.5-mL straws was used. Flow in the channels was generated by the hydraulic head difference, and sperm swam upstream under these conditions. After incubation, sperm were collected from the sorting reservoir and evaluated for sperm concentration and motility.



Results

The results showed that the number of sorted sperm increased as the number of channels increased. Sperm in the sorting reservoir had higher motility than those in the semen reservoir, confirming that highly motile sperm were selectively sorted. Larger channel spacing reduced the number of collected sperm, and reservoir geometry also affected sorting: devices with smaller aspect ratios showed higher sperm concentrations.

Discussion

These findings suggest that the proposed microfluidic device is a promising alternative to conventional sperm-selection methods used before IVF. In future work, we will use the sperm collected by this device for embryo transfer (ET) and evaluate the resulting conception rates. The outcomes of this study are expected to contribute to improved reproductive efficiency in both livestock production and human assisted reproductive technologies.

Relative Velocity of Red Blood Cells to a Surrounding Continuous Fluid in a Microchannel with an Abrupt Change in its Cross Sectional Area

Ms. Yi Li[1], Mr. Takayuki Osawa[2], Dr. Satoru Kuriu[2], Dr. Marie Shinohara[2], Dr. Soo Hyeon Kim[2], Dr. Yukiko Matsunaga[2], Prof. Yosuke Hasegawa[2]

[1]Department of Mechanical Engineering, School of Engineering, The University of Tokyo, Tokyo, Tokyo, Japan. [2]Institute of Industrial Science, The University of Tokyo, Tokyo, Tokyo, Japan

Introduction

The transport of red blood cells (RBCs) in surrounding fluids plays critical roles in nanoparticle margination, which in turn influences drug delivery. Because of the strong interaction between RBCs and the surrounding fluid, simultaneous measurement of both phases is essential for understanding their coupled dynamics. Although previous studies have reported RBC–fluid slip, most studies focus only on fluid velocities measured from nanoparticles (NPs) and cannot capture RBC velocities simultaneously with the background flow. As a result, quantitative dual-phase velocimetry in microchannels remains limited.

Methods

A dual-phase micro-PIV system was developed to measure RBC and nanoparticle (NP) velocities simultaneously using LED volume illumination and laser fluorescence. A U-Net model is developed to segment micro-PIV images. It locates RBCs from the input image, therefore segment the input images into NPs image and RBCs image separately. Then, the velocities of NPs and RBCs are calculated through particle image velocimetry and Lagrangian trajectories, respectively.

A 40-μm-high PDMS microchannel with 100 μm inlet and outlet widths and a 400 μm width middle section was fabricated, with expansion and contraction structures. A suspension consists of 0.5% hematocrit RBC and 0.05% volume fraction fluorescent NP (0.5 μm) in phosphate-buffered saline (PBS) is used with a flow rate of 1 μL/min. This condition was selected to enable simultaneous visualization of both phases while maintaining low hematocrit to prevent channel clogging.

Results

Clear cell-free layers were observed in both expansion and contraction regions, consistent with existing studies [1]. RBC velocities were generally lower than the background fluids

represented by NPs. RBC slip velocity increases both toward the channel center and toward the constriction throat, suggesting regulation by transverse velocity gradients and axial acceleration, although further investigation is required to confirm these effects.

Discussion

The observed increase in slip velocities toward the channel center and constriction throat suggests competing effects between RBC deformability, local shear gradients, and axial acceleration of the surrounding fluid. These factors can alter RBC–fluid momentum exchange, leading to spatially varying slip. Further experiments under different hematocrit and flow-rate conditions are needed to isolate each contribution.

Quantitative and Time-Resolved Analysis of Macrophage Responses to Fine Particles Using a Continuous-Exposure Micro-Gap Chamber

Prof. Yoshitaka Nakanishi PhD, Dr. Yukio Fujiwara MD, Prof. Yuta Nakashima PhD

Kumamoto University, Kumamoto, Kumamoto, Japan

Introduction

Fine particles such as asbestos and diesel exhaust particulates are well-known health hazards, and recent concern has expanded to micro- and nanoplastics dispersed in the environment and wear debris from artificial organs. Understanding how such particles interact with biological systems remains both a longstanding challenge and an urgent issue. Macrophages internalize foreign particles and secrete pro-inflammatory cytokines, serving as key indicators of particle-induced biological effects. However, conventional well-plate exposure assays are limited by particle sedimentation, unstable local concentrations, the need for numerous independent cultures, and difficulty reproducing continuous or cumulative exposure. These limitations hinder quantitative evaluation of exposure–response relationships and long-term effects.

Methods

To address these issues, a large-area, low-ceiling Micro-gap Exposure Chamber was developed to reproduce macrophage–particle interactions under continuous, stable conditions suitable for quantitative and time-resolved analysis. The chamber incorporates a ceiling height of 50–200 μm to limit particle floating and maintain proximity to the cell layer. A 15-mm culture area accommodates 1.5–2.5 × 10^5 macrophages, enabling quantitative measurements and qualitative imaging. Particle suspensions are introduced at a constant low flow rate of 0.05–0.10 mL/h, and six inlet ports reduce flow velocity to achieve uniform circulation and sufficient phagocytosis time. A motor-driven micro-syringe ensures stable medium retention and allows periodic sampling for cytokine quantification. An integrated vertical-motion mechanism minimizes mechanical stress while maintaining homogeneous particle distribution.

Results

Using this system, particles of identical size produced distinctly different acute macrophage responses depending on polymer type. Cytokine production also varied with particle size for the same polymer. Under continuous exposure, macrophages exhibited a

characteristic temporal pattern: gradual cytokine elevation, a defined peak, and subsequent decline. This nonlinear response was not observable with conventional well-plate assays.

Discussion

The observed dynamics cannot be explained solely by mechanical stimuli related to particle size or morphology. The findings indicate that physicochemical surface properties regulate organic molecule adsorption and subsequently influence phagocytosis, intracellular degradation, and signaling pathways. The exposure platform provides a robust basis for advancing research on particle–cell interactions and supports applications in environmental science, biomaterials evaluation, and toxicology.

Simulation of the Swimming Behavior of Magnetic Bacteria Near the Wall in a Magnetic Field

Mr. Akihiro Kawasaki, Prof. Yuji Shimogonya PhD

Nihon University, Koriyama, Fukushima, Japan

Introduction

Bacteria swim through water by rotating their flagella, which serve as motility organs. Near surfaces, hydrodynamic interactions between bacteria and surfaces cause them to trace circular trajectories. Magnetic bacteria, a type of bacterium, possess magnetic particles within their bodies and swim along the direction of external magnetic fields. However, the swimming behavior of magnetic bacteria near walls remains poorly understood. Therefore, this study aims to analyze the swimming behavior of magnetic bacteria near walls when the surrounding magnetic field is altered, using numerical simulations.

Methods

Using the same method as our previous study[1], we created a three-dimensional model of a bacterium composed of a prolate ellipsoidal cell body and elongated flagella (Fig. 1(a)). The interaction between the magnetic moment of the bacterial cell and the external magnetic field was formulated as a magnetic torque to represent the characteristics of the magnetic bacterium. In this case, the flow field has an extremely low Reynolds number, allowing the assumption of Stokes flow. Therefore, the boundary element method[1], the most reasonable and highly accurate numerical simulation technique for this case, was employed to analyze the swimming behavior near the wall.

Results

Figure 1(b) shows the swimming behavior of magnetic bacteria near a wall. The external magnetic field was applied perpendicular to the wall. The values in the figure represent how many times the applied external magnetic field strength exceeds that of the Earth's magnetic field. These results indicate that up to an external magnetic field approximately twice the strength of the Earth's magnetic field, the bacteria remain near the wall and exhibit nearly circular swimming trajectories. However, when the external field exceeds this strength, the swimming trajectories change significantly, and the bacteria swim away from the wall.

Discussion

Additional simulations revealed that controlling swimming direction parallel to the wall requires an external magnetic field over 100 times stronger than the Earth's magnetic field (figure omitted). Thus, this study clarified that while controlling magnetic bacteria to move away from the wall is relatively easy, controlling movement along the wall requires a much stronger magnetic field.

Mr Pratik Mitra

Mr Archer A French

Dr. Satish C Muluk

Dr. Mark K Eskandari

Associate Professor Seungik Baek

Introduction

Abdominal Aortic Aneurysm (AAA) is a dilation of the abdominal aorta greater than 3 cm. Wall shear stress (WSS) is thought to play a significant role in AAA development. To this end, we investigated the use of spectral analysis and the power spectrum density (PSD) of WSS as potential hemodynamic descriptors of the AAA flow environment.

Methods

Abdominal computed tomography scans of five saccular (S1–S5) and one fusiform (F1) AAAs were collected retrospectively and segmented using MIMICS. SimVascular was used to perform pre-processing and volume meshing, while the blood flow simulations were performed using the svSolver. Dynamic mode decomposition (DMD) was performed using the linear operator $X'=AX$, where $X = [u_1,u_2,u_3,\ldots u_{n-1}]$ and $X' = [u_2,u_3,u_4,\ldots u_n]$, and u_1,u_2,u_3 are the velocity vector components. The PSD in the vicinity of the AAA sac was computed from the temporal WSS distributions.

Results

DMD yielded differences in the temporal and spatial hemodynamic signatures for S1–S5 compared to F1. For all AAAs, the mode frequency plots (Fig. 1a) showed a small number of dominant modes with larger amplitudes, indicating that unsteady sac flow is governed by strong low-frequency coherent structures. Growth/decay (real component) revealed localized regions of persistent hemodynamic phenomena, particularly along recirculation zones within the sac (see Fig. 1b). Oscillation frequency (imaginary component) highlighted concentrated high-frequency fluctuations in shear-layer regions, suggesting complex vortex dynamics (see Fig. 1c). The PSD of WSS, extracted from sac point data, showed distinct peak amplitudes (see Fig. 1d).

Discussion

The DMD and spectral analyses collectively demonstrated that AAA sac shape has a substantial impact on the underlying flow physics. The saccular AAAs (S1–S5) exhibited stronger low-frequency coherent structures and more pronounced high-frequency oscillatory content, reflecting an overall unsteady flow environment inside the sac. These features corresponded to regions of recirculation, shear-layer interaction, and vortex trapping. In contrast, the fusiform AAA (F1) exhibited fewer energetic modes and a narrower spectral bandwidth, indicating a more stable flow regime. The dominant WSS frequency range in saccular AAAs was 1–3 Hz, whereas the fusiform AAA exhibited frequencies in the range of 3–8 Hz at the lumen wall.

Images (Optional)

[3]Institute of Fluid Mechanics and Heat Transfer, TU Wien, Vienna, Vienna, Austria. [4]Carl Reiner GmbH, Vienna, Vienna, Austria. [5]Institute of Chemical, Environmental and Bioscience Engineering, TU Wien, Vienaa, Vienna, Austria

Introduction

In this work, a 7-generation Computational Fluid Dynamics (CFD) domain of the respiratory system is utilized to estimate the oxygen delivery efficiency during High-frequency Jet Ventilation (HFJV) at 300 pulsations per minute.

Methods

CFD is used to model the oxygen transport in the respiratory system. The domain is extracted from the dimensions provided by Weibel [1]. Unsteady Reynolds-Averaged Naiver-Stokes (URANS) k-ω SST turbulence model is used to simulate the flow field with a mesh of y+ around 1. Dynamic pressure outlet boundary conditions that include the resistance and compliance of the lung after each outlet (gen.7) are utilized in the CFD model (total lung compliance = 0.05 L/cmH_2O). The CFD model is validated against our in-house Particle Image Velocimetry (PIV) experimental results, utilizing a refractive index-matched fluid and 3D-printed test pieces.

Results

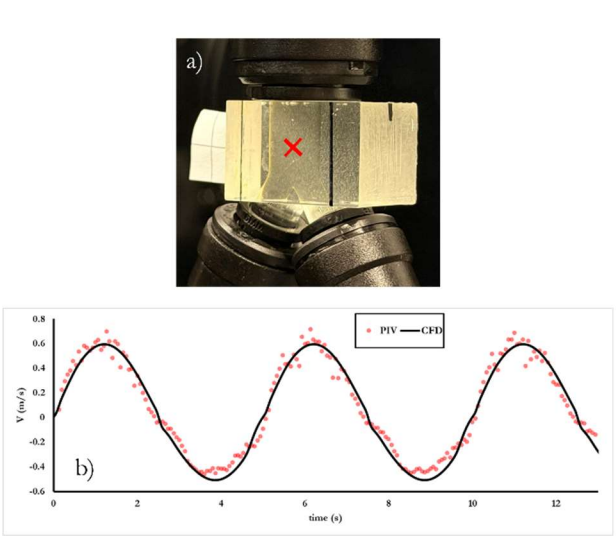

Figure 1 a and b show the test piece used in PIV measurements, with a comparison of the vertical velocities on the mid-plane 4.5 mm above the junction between the PIV and CFD. Figure 1c, d and e depict the resultant flow rate, volume and oxygen delivery behavior in the 7-generation model respectively. Each pulsation delivers some portion of the oxygen provided to the lung to the deep lung.

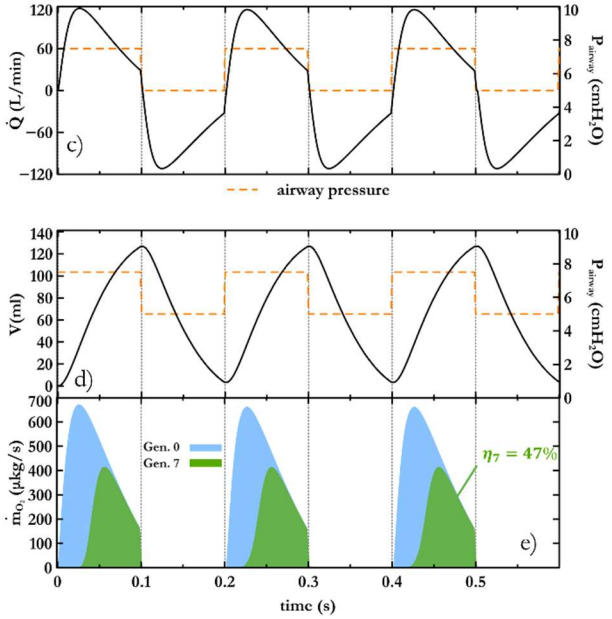

Discussion

CFD results strongly agree with the PIV (maximum Re = 1763, Wo = 3.82). At a frequency of 300 per minute, the tidal volume of around 125 ml is achieved while only 47% of oxygen

delivered to generation 7 per pulsation. In further studies, turbulent PIV will be used in validation, and different frequencies will be examined.

Hemodynamic Analysis of Patient-Specific Coarctation of Aorta Model via Two-way Fluid-Structure Interaction Modeling

Mr. Mashrur Muntasir Nuhash, Dr. Victor K. Lai, Dr. Ruihang Zhang

University of Minnesota Duluth, Duluth, Minnesota, United States

Introduction

Coarctation of the aorta (CoA) is a congenital cardiovascular defect characterized by a narrowing of the aortic arch and accounts for approximately 6-8% of congenital heart disease cases at birth. Even after successful surgery, some patients will still have a high possibility of cardiovascular complications, such as hypertension. To study the hemodynamics, we developed a fluid-structure interaction (FSI) model to replicate the patient-specific coarctation of the aorta (CoA) and flow dynamics in the ascending and descending aortic wall.

Methods

Structural simulations were conducted in Ansys Mechanical APDL, and fluid dynamic simulations were performed in Ansys Fluent, with the two domains coupled through the Ansys System Coupling module. A pulsatile velocity profile is applied at the inlet, while mass-flow outlet conditions are imposed at the arch branches and descending aorta with prescribed flow percentages. The aortic wall was modeled as an anisotropic hyperelastic material to replicate realistic deformation of the aorta during the cardiac cycle. The non-Newtonian behavior of blood is replicated using the Casson model. The two-way FSI model is run for several cardiac cycles with a time step size of 1e-4 seconds, and the final cycle is used to analyze the results

Results

A high-speed jet alongside complex secondary flows was observed downstream of the coarctation segment, with pronounced recirculation during the diastole at post coarctation region. The asymmetric jet generated high helical flow, which slid along the wall of the aorta. High wall shear stress was observed at the edge of the coarctation at peak systole, and the compliant aortic model depicted large deformation of the walls downstream of the narrowed section of the geometry. Incorporating a hyperelastic model generates mechanical behavior that would be remiss in a rigid wall model.

Discussion

The localization of abnormal hemodynamics downstream of the coarctation region indicated the possibility of hypertension, dilation and aneurysm formation, which also explains why the patients may remain at risk even after reconstructive surgery. However, the current model is limited to a single patient-specific geometry. Extending this work to a larger cohort with varying CoA severities and including both repaired and healthy aortas, would provide a more comprehensive insight.

Simulation of the Swimming Behavior of Bacteria With Two Flagella Near the Wall

Prof. Yuji Shimogonya PhD

Nihon University, Koriyama, Fukushima, Japan

Introduction

Bacteria swim through water by rotating their elongated flagella. *Escherichia coli*, a representative bacterium, swims using a single bundle of flagella and is known to trace circular paths near walls. In contrast, bacterium MO-1, which we are interested in, possesses two flagella[1], yet the swimming behavior of bacteria with two flagella near walls remains unknown. Therefore, this study aims to clarify the swimming behavior of bacterium MO-1 near the wall using numerical simulation.

Methods

A three-dimensional model was created that mimics the actual shape of MO-1, consisting of a prolate ellipsoidal cell body and two helical flagella. Based on preliminary investigations, one flagellum was set as a left-handed helix rotating clockwise, while the other was set as a left-handed helix rotating counterclockwise. Since the flow field around the swimming bacterium can be assumed to be Stokes flow, we analyzed its swimming behavior near the wall using the boundary element method code previously developed by our group[2].

Results

Swimming simulations near the wall were performed considering four flagellar conditions, including MO-1. The results are shown in Fig. 1. Condition (a) represents MO-1, (b) represents a condition where only one flagellum rotates, (c) represents a condition where one flagellum is missing, and (d) represents a condition mimicking *Escherichia coli*. Models under conditions (b), (c), and (d) exhibited circular trajectories near the wall. In contrast, the MO-1 model under condition (a) swam in a straight line without any deflection of its trajectory, even in the presence of a nearby wall surface.

Discussion

The difference in swimming trajectories can be explained by the fluid resistance acting on the cell body and flagella. In conditions (b), (c), and (d), the fluid resistance acting on the cell body and flagella is in opposite directions, causing the trajectory to bend. In contrast,

under condition (a), the presence of two flagella causes the forces bending the trajectory to cancel each other out. This study successfully demonstrated that bacteria with two flagella exhibit significantly different swimming behavior near the wall compared to bacteria with one flagellum.

Characterisation of Tumour Cell Biomechanics using High-Throughput Microfluidic Devices

Ms Orlaith McSweeney[1], Prof María Ángeles Pérez Ansón[2], Prof José Manuel García-Aznar[2], Prof María José Gómez-Benito[2], Dr Eoin McEvoy[1]

[1]University of Galway, Galway, Galway, Ireland. [2]University of Zaragoza, Zaragoza, Aragon, Spain

Introduction

Personalised breast cancer treatment requires a mechanistic understanding of heterogeneous cell behaviour within a patient's tumour material, where increased cell stiffness can be a marker for chemoresistance. In this project, we develop a platform for microfluidic cell aspiration in response to pressure, which, in conjunction with computational modelling, is applied to characterise heterogeneity in active tumour cell biomechanics.

Methods

Micropipette aspiration probes cell biomechanics by aspirating the membrane. We extend this technique for high-throughput microfluidic devices, by controlling pressure gradients ΔP across microchannels. Chips with 5-15μm microchannels were fabricated by casting PDMS onto photo-patterned masks and plasma-bonding to coverslips. We developed computational fluid dynamics (CFD) models to predict how geometry and boundary conditions govern ΔP (Fig.1A). Microfluidic devices were connected to pressure controllers (Fluigent) to control microchannel ΔPs in a 0.6-1kPa range. We seeded T47D cells ($1x10^6$ cells/ml) within the device and monitored short-term aspiration into microchannels (Fig.1B). We utilised ImageJ to measure diameters of calcein-stained cells pre-aspiration, and to identify aspiration lengths, L. We subsequently developed finite element models containing active cortical, cytoplasmic and nucleic regions (Abaqus, Simulia), to derive the non-linear biomechanical behaviour of measured cells.

Results

CFD modelling revealed microfluidic chip design and experimental input conditions to ensure a gradual ΔP was achieved across microchannels (Fig.1A). Subsequently, partial aspiration of T47D cells was achieved in optimal microchannel widths of 6-9μm, where experiments showed that aspiration length increased with channel width and ΔP (Fig.1C).

Variability in results reflected heterogeneity in cell size and stiffness, confirmed by fluorescent imaging (Φ_{mean}: 12.09 ± 3.09μm). Finite element modelling uncovered the interplay between non-linear cortex and nucleus stiffness in governing aspiration length arising from heterogeneous cell biomechanics (Fig.1D). While stiff cells are more readily aspirated at smaller sizes (Fig.1E), interestingly softer cells exhibit greater aspiration lengths when larger due to a transition from an elasticity-limited to a volume-limited response.

Discussion

This study provides a platform to characterise non-linear tumour cell biomechanics using coupled experimental and computational modelling. This framework can readily be extended to provide novel characterisation and insight for biomechanisms of chemoresistance, multicellular spheroids, and patient tissue.

Images (Optional)

Quadratus Lumborum Asymmetry Linked to Hip Abduction Strength and Nonlinear Measures of Unilateral Postural Control

Mr. Sam Vasilounis[1], Mr. Daniel Sheffield[1], Dr. Dan Desroches[1], Dr. Janessa Drake[1]

[1]York University, Toronto, Ontario, Canada

Introduction

Single-leg stance (SLS) demands lumbopelvic coordination, with the quadratus lumborum (QL) serving as one of the critical stabilizers against lateral flexion and pelvic obliquity. Linear measures often overlook complex neuromuscular dynamics, but sample entropy (SampEn) is utilized to measure postural sway regularity. This study examined the relationship between unilateral QL asymmetry, hip abduction force, and centre of pressure (COP) SampEn during SLS. It was hypothesized that asymmetry will correlate with lower SampEn values, reflecting rigid and less adaptable postural control.

Methods

60 healthy, right-hand dominant athletes (aged 18-21y; 28M/32F, height 1.78m ± 0.22, weight 87.2 kg ± 5.4). QL cross-sectional area (CSA) was measured via ultrasound at the L3/L4 vertebral level using a LOGIQ P-series ultrasound system (GE Healthcare, USA). Asymmetry indices for QL morphology were calculated using the formula derived from previous literature. Isometric hip abduction force was quantified bilaterally with a hand-held dynamometer (Hoggan Scientific, USA) during maximum side-lying hip abduction (SLHA). Postural control was assessed during three 30s SLS trials on a force plate (AMTI OR-6 Newton, USA), from which COP and SampEn were derived to quantify sway complexity.

Results

34 (21F/13M) participants exhibited greater than 10% asymmetry. The right QL CSA was significantly larger than the left (567.8mm^2 ± 195.8, 461.6mm^2 ± 150.8; $p < 0.001$, $d = 1.38$), and SLHA force was significantly greater on the right (163.6N ± 43.1, 147.9N ± 42.0; $p < 0.001$, $d = 1.34$). There was a statistically significant main effect of sex on QL CSA (F (1,47) = 15.44, $p < 0.001$) indicating males had larger QL CSA than females. SampEn^{ML} was significantly larger on the right side (Right: 0.034 ± 0.021 vs. Left: 0.018 ± 0.028; $p = 0.004$). Pearson correlations revealed moderate positive associations between QL CSA and SLHA on both sides ($r = 0.42–0.44$), reaching statistical significance on the left ($p = 0.040$).

Discussion

Participants exhibited clear right-sided dominance in muscle size and strength. Furthermore, asymmetry was isolated to the frontal plane, where significantly lower $SampEn^{ML}$ on the weaker left side reflects a compensatory strategy. These findings imply the non-dominant side lumbopelvic-hip complex may be limited not only by force deficits but by a rigid control mechanism.

Images (Optional)

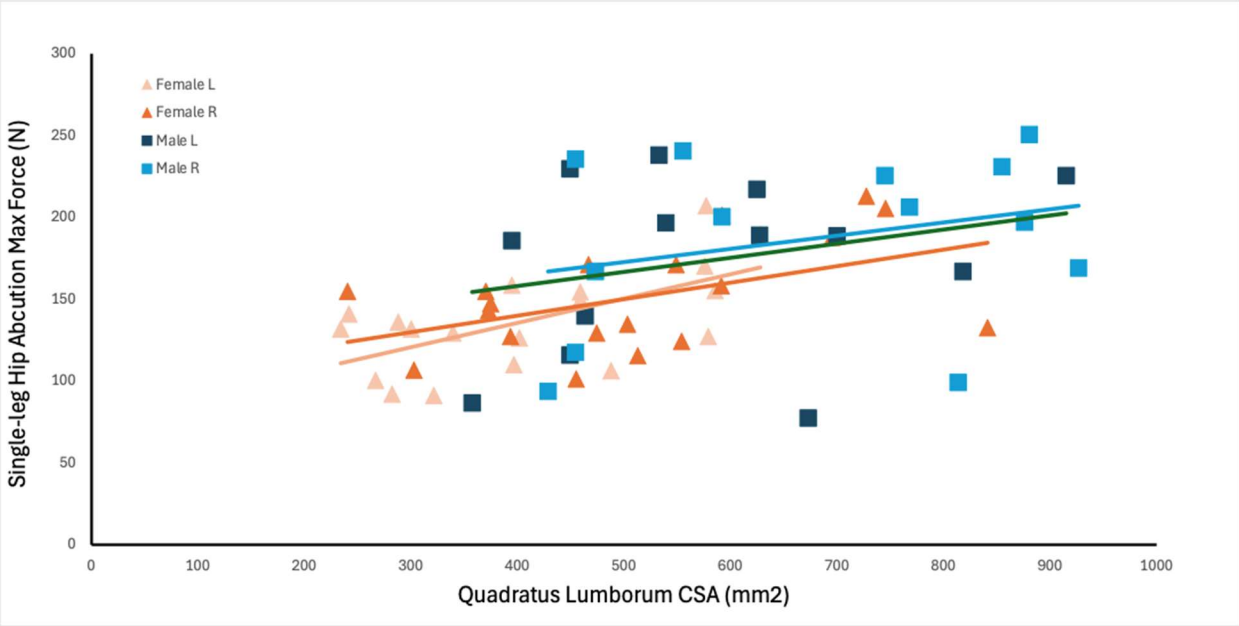

Figure 1. Relationship between quadratus lumborum cross-sectional area (QL-CSA) and single-leg hp abduction maximum force (SLHA) grouped by sex and side. Points show individual right and left measurements for females and males, with lines depicting the linear mixed model. The model indicates a modest positive association between the QL CSA and SLHA, with greater strength on the right versus left and higher SLHA in males versus females after adjusting for QL CSA.

Are Distinct Lamina Cribrosa Collagen Architectures Between Species Adaptations to Different Mechanical Loading Conditions?

Dr. Adam Galloy PhD, Dr. Ian Sigal PhD

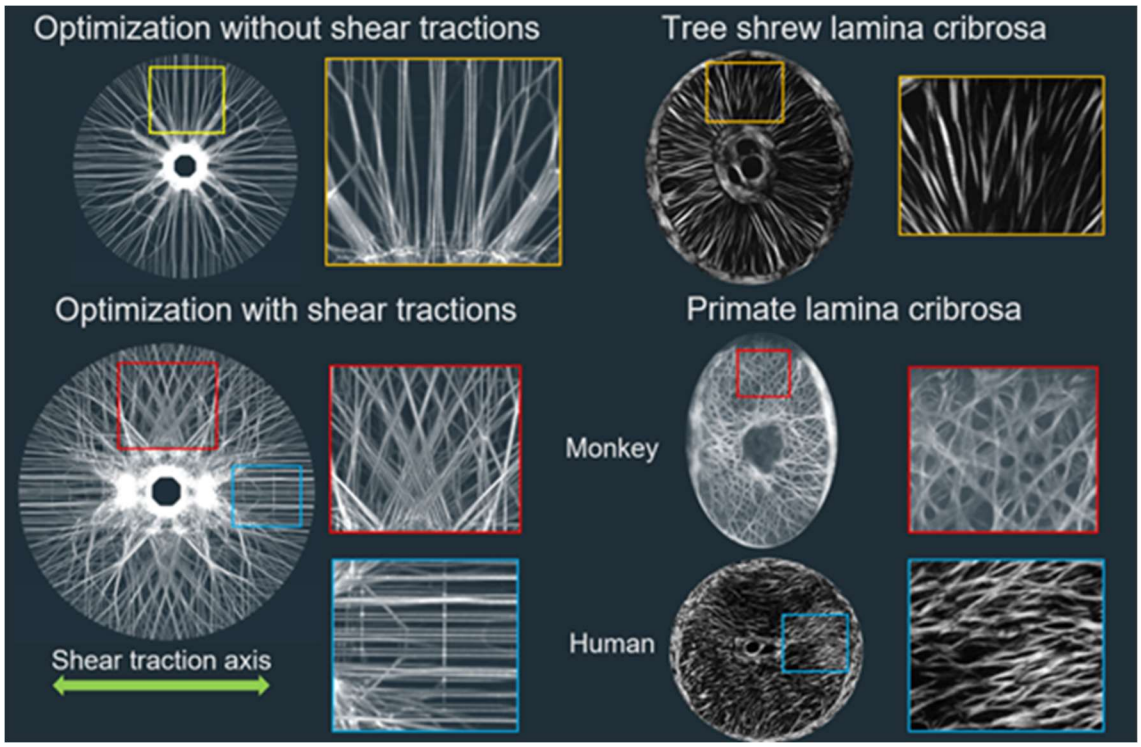
University of Pittsburgh, Pittsburgh, PA, United States

Introduction

Nerve axons are vulnerable to damage from a variety of loads as they exit the eye including translaminar pressure (the drop in pressure from inside to outside the globe) and tractions from eye rotations. The lamina cribrosa (LC) is a complex collagen network that provides protection to the nerve axons at this location. Different species exhibit distinct LC collagen architectures. For example, tree shrew LCs follow a wheel and spoke pattern, human LCs have a nasal-temporal bias in fiber direction and density, and monkey LCs exhibit mesh-like structure. We hypothesize that these diverse architectures are specializations to different loading conditions. To examine the plausibility of this hypothesis, we created topological optimization (TO) models of the LC to contrast optimal fiber architectures for different loading cases.

Methods

A truss network TO algorithm [1] was adapted with a compression penalty to create tension-only fiber networks. The network was optimized within a cylindrical domain (2 mm diameter, 0.25 mm thick) with a small cylindrical obstacle through the center representing the central vessels. Pressures of 15 mmHg and 7 mmHg were applied to the anterior and posterior surface respectively modeling the translaminar pressure. Additional models with shear tractions distributed uniformly to the posterior surface (net 8 mN) modeled eye rotation tractions. A support structure for fiber attachments surrounded the entire circumference of the domain.



Results

When TO models only included translaminar pressure, fibers formed in a radial pattern like the collagen architecture in tree shrew LCs. When models included rotational shear tractions, the fibers skewed towards the applied shear. Super-imposing results with shear tractions pointing in opposite directions resulted in a biased collagen orientation and meshwork crossings capturing aspects of human and monkey LCs respectively.

Discussion

These results suggest that interspecies differences in LC architecture may be understood in terms of adaptations to specialized loading conditions to protect nerve axons. The nasal-temporal biased human LC collagen networks and meshwork monkey LCs could be adaptations to primates' heavy reliance on eye movements. The wheel pattern of tree shrew LCs suggests they are adapted primarily for pressure not large eye rotations.

Improved Muscle Gearing in the Gastrocnemius of Pregnant and Lactating Rats and Its Implications for Locomotor Energetics

Dr. Adrien A. Arias[1,2], Ms. M. Lauren Delargy[1], Dr. Nicole Danos[1]

[1]University of San Diego, San Diego, CA, United States. [2]University of California, Irvine, Irvine, CA, United States

Introduction

Pregnancy and lactation are both energetically expensive for mammals. Basal metabolic rate increases by approximately 2- 6x during gestation and up to 7x during lactation in mammals. However, mammals operate under a 'metabolic ceiling' and cannot support these drastic increases in metabolic rate with increased food intake alone. This suggests that the high energetic demands of pregnancy and lactation may necessitate a reduction in the energetic budgets of other organ systems. Patterns of improved fuel economy in transmission systems with wider gearing ranges combined with previous work on muscle gearing and musculoskeletal remodeling in rats during motherhood suggest that pennate locomotor muscles may improve gearing ability to mitigate the large increases in energy consumption during reproduction.

Methods

We used fixed-end 'isometric' contractions and after-loaded isotonic contractions under maximal stimulation *in situ* to test our hypothesis that remodeling of the medial gastrocnemius muscle-tendon unit during motherhood in rats (*Rattus norvegicus*) leads to an improved ability to vary architectural gear ratio across force conditions (i.e. we expect a wider range of gear ratios and steeper slope across force conditions in pregnant and lactating animals compared to non-pregnant controls).

Results

We found that the medial gastrocnemius has a significantly wider range of AGRs and steeper linear relationship between AGR and muscle force during motherhood (Figure 1). Additionally, we found that pregnant and lactating rats had more compliant muscles.

Discussion

Overall, our findings show that the medial gastrocnemius of pregnant and lactating rats has improved gearing ability compared to non-pregnant animals, which is underpinned by

increased muscle compliance, suggesting a trade-off between gearing ability and maximal contractile dynamics. We propose, like engineered systems, improved muscle gearing ability may improve locomotor energetics during motherhood in rats.

Images (Optional)

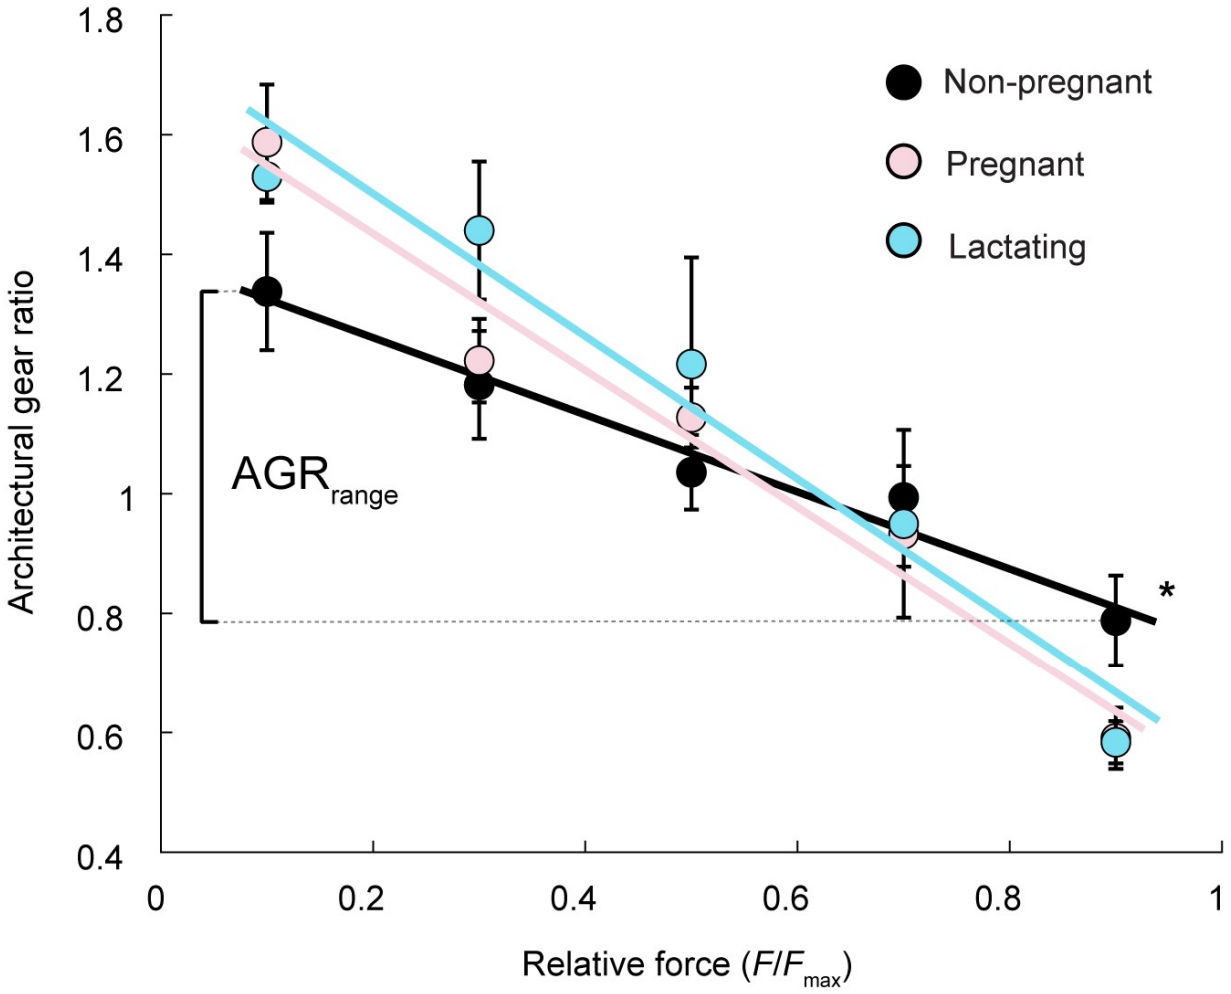

Figure 1: The effect of pregnancy and lactation on architectural gear ratio (AGR). AGR across relative muscle forces is shown for non-pregnant (black), pregnant (pink), and lactating (blue) rats. Pregnant and lactating animals had significantly wider AGR ranges (LME, $p=0.002$) and steeper slopes (LME, $p=0.001$) relative to non-pregnant controls (Tukey's post-hoc, $p<0.05$). Asterisk represents statistically significant difference in AGR slope between non-pregnant animals and the other two conditions.

EMG-Informed Simulation of Bipedal Chimpanzee Walking

Dr. Aravind Sundararajan[1], Dr. Brian Umberger[2], Dr. Matthew O'Neill[3]

[1]Elemance, LLC, Winston-Salem, NC, United States. [2]University of Michigan, Ann Arbor, MI, United States. [3]Midwestern University, Glendale, AZ, United States

Introduction

Optimal control simulations of locomotion using musculoskeletal models allow prediction of muscle activation, but these predictions may fail to replicate some characteristics of electromyography (EMG) measurements. EMG-informed simulations can improve estimation of muscle activation, but may affect dependent quantities, such as muscle energy consumption. Here, we integrate EMG measurements from 32 pelvis and hind limb muscles into three-dimensional (3-D) tracking simulations of bipedal chimpanzee walking and evaluate its effect on the simulated metabolic cost of transport (COT).

Methods

A 3-D musculoskeletal chimpanzee model [1, Fig. 1a] tracked experimental 3-D kinematic and ground reaction force data while minimizing gross COT, determined using a muscle energetics model. For EMG-informed simulations, fine-wire EMG waveforms from 32 pelvis and hind limb muscles per limb [2] were also tracked. The EMG tracking term was iteratively weighted to account for 0 to 51% of the total cost function value (J). All simulations were generated using OpenSim Moco. Correspondence between the predicted muscle activations and EMG was assessed via zero-lag cross-correlations (r) across all 32 muscles.

Results

Excluding EMG from the optimal control problem, the simulated gross COT was 6.2 $J \cdot kg^{-1} \cdot m^{-1}$ and muscle activations agreed moderately well with experimental EMG (r=0.53). Increasing the weight on the EMG tracking term achieved an r=0.80 with only an 8.7% increase in the simulated COT. A near-maximum tracking fit increased the correspondence to r=0.91, but led to a simulated COT ~40% higher than experimental measurements [3, Fig 1b].

Discussion

Using an EMG-informed approach, a Pareto frontier exists where EMG tracking can enhance neuromuscular realism with only a modest effect on the simulated COT [Fig 1].

These results provide an avenue to gain greater insight into chimpanzee biology and important comparative context for understanding hominin walking evolution.

[8]Centre for Nature-Inspired Engineering, City University of Hong Kong, Hong Kong, Hong Kong, Hong Kong

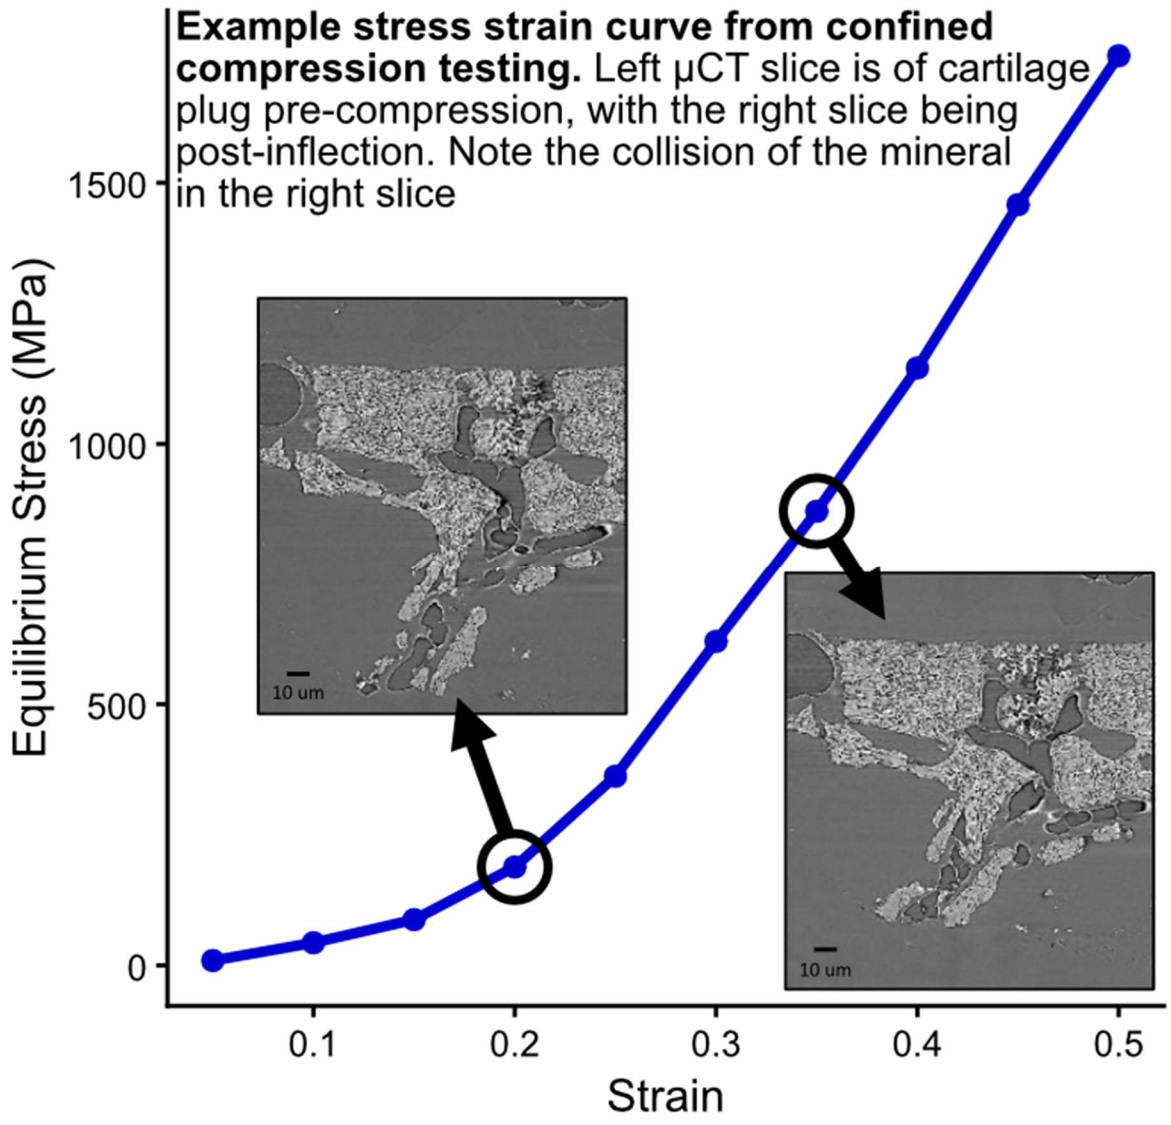
Introduction

Sharks and rays (elasmobranch) possess cartilaginous skeletons. Despite being made of compliant material, the hyaline cartilage cores of elasmobranch skeletal elements are wrapped by a cortex of mineralized tiles (tesserae), imparting dynamic compressive stiffness. Additional reinforcements via mineralized tubes made of tesserae coursing through skeletal elements have been described in numerous stingray species. This study seeks to understand how these mineral struts change the mechanics of cartilaginous tissue.

Methods

19 samples from three cownose ray (*Rhinoptera)* jaws were imaged via conventional μCT, then tested in confined compression. Post-testing, sample composition was analyzed and compared with mechanical properties (Pearson's r). Five samples from two additional cownose jaws were imaged on the PETRA III μCT beamline synchrotron under confined compression.

Results



Mineral content from μCT and confined compression demonstrate that the mechanical properties of tessellated cartilage are directly tied to its mineral content, with highly mineralized cartilage (many trabeculae) having equilibrium moduli up to five times greater

than less mineralized (fewer trabeculae) cartilage. The corresponding stress-relaxation stress-stain curves had two distinct shapes depending on the level of mineralization. Highly mineralized cartilage exhibited a distinct J-shaped curve with an initial low-stiffness toe region, followed by a massive increase in stiffness after an inflection point at around 25% compression. Less mineralized cartilage had only a singular linear curve, similar to stress-strain curves from mammalian cartilage. Synchrotron μCT images showed the trabeculae collapsing under high strains.

Discussion

We hypothesize the J shaped curve is due to the soft/ hard composite nature of trabeculated cartilage, with the toe region being caused by initial compression of soft cartilage, followed by the stiffer region representing collision of tesserae. Images from the synchrotron supported this theory, showing the tesserae colliding only after the inflection point. This is the first time this phenomenon has been described in tessellated cartilage loaded perpendicular to the skeleton surface (previously only seen in parallel loading). Trabeculae therefore demonstrate an additional way that tesserae can reinforce cartilage without adding more cortex layers. These novel mechanical tests on tessellated cartilage create a foundation for future studies on the mechanics of this cartilage-only high-load system.

Stereotypic Behaviours Affect Thoroughbred Racehorse Gait Symmetry and Stride Time

Ms Brittany Davis PhD Cand., PAS, Dr. Zoe Chan, Ms. Karelhia Garcia PhD Student, Ms. Charlotte De Bruyne PhD Student, Dr. Thilo Pfau

University of Calgary, Calgary, Alberta, Canada

Introduction

Stereotypic behaviours (STBs) are repetitive, abnormal behaviours performed for a substantial portion of the day, and are common in Thoroughbred racehorses. Some STBs do involve a significant physical aspect in the performance of those behaviours, and they are associated with clinical sequelae that may increase their risk of injury. However, STBs are typically only considered as a behavioural issue and their potential impact on equine biomechanics is not considered. Previous research has found a difference in race performance between STB horses and control horses, and this study expands more into the biomechanical effect that STB has on racehorses to further our understanding of injury risk and welfare.

Methods

A total of 29 actively racing Thoroughbreds (15 STB and 14 matched controls) were outfitted with 9 IMU EquiGait sensors. Horses were trotted up and down an aisle to analyze their symmetry and gait. All statistical analyses were performed using independent t-tests in SPSS.

Results

STB horses demonstrated a reduced stride time by 24.67ms ($p=0.05$), several head movement asymmetry was increased between 2.01mm to 5.77mm ($p=0.04$ to $p=0.028$). Withers asymmetry in STB horses nearly doubled ($p=0.039$). Pelvic movement asymmetries were higher in STB horses with increases of 2.64mm and 6.5mm ($p=0.05$ and $p=0.033$) when compared to control horses.

Discussion

Horses with STBs have increased gait asymmetry in both the front and hind end as well as an increased difference in forces produced between the left and right forelimbs when compared to matched controls. Increased asymmetries can lead to uneven joint loading and increased risk of injury. The asymmetries may also indicate that sub-clinical lameness

is present. The reduced stride time may indicate that horses are unable to fully extend their bodies, possibly indicating pain, lameness, or muscular fatigue.

Impact Analysis of the Hoof During Walking Using IMU Sensors

Bsc Beatrice poller, Bsc Chiara Steinwender, A. Univ. Prof. Dr. Christian Peham

University of Veterinary Medicine, Vienna, Vienna, Austria

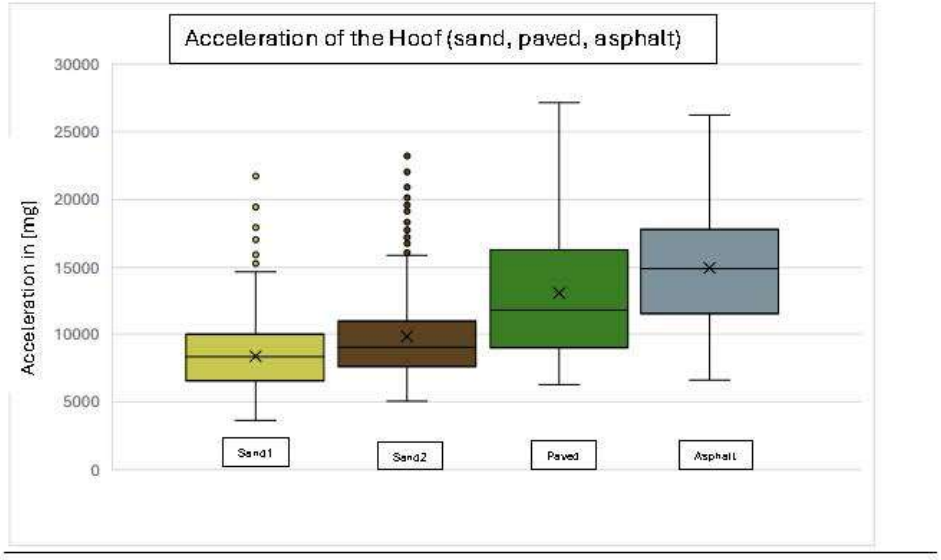
Introduction

Lameness in horses and the condition of the surface/ground of sport arenas are a widespread problem that significantly affects the equine well-being and performance.The aim of the study was to show that accelerometers on the hoof can detect different surfaces (sandy soil, paved path, asphalt) as well as movement asymmetries.

Methods

For this purpose, a total of 30 horses were led at a walk and fitted with IMU sensors (3 axis, 16g, sample rate 833 Hz) on their front hooves. The measured data were evaluated with regard to their maximum acceleration and compared both between the forelimbs and between the different surfaces (sand soil, paved path, asphalt).The length of the 3-dimensional acceleration vector was calculated as follows: $accel3D = \sqrt{ax2 + ay2 + az2}$. The maximum acceleration values during impact and lifted off of the hoof were determined. The data were grouped and tested for normal distribution using the Kolmogorov-Smirnov test.To test the different soil types, a repeated-measures ANOVA was used; for the left-right comparison (asymmetry), a t-test (normally distributed data) or a Wilcoxon rank test (non-normally distributed data) was used.

Results



The results show partially asymmetrical movement patterns as well as significant differences in vertical acceleration values depending on the surface. The study demonstrates that IMU sensors are a suitable instrument for the objective detection of movement asymmetries and for differentiating the mechanical properties of various soils (figure 1).

Discussion

These results suggest that ground conditions play a role in lameness assessment. The results show partially asymmetrical movement patterns and significant differences in acceleration values depending on the surface. The study demonstrates that IMU sensors are a suitable tool for objectively recording movement asymmetries and differentiating the mechanical properties of various surfaces. Furthermore, it shows that combining ground properties and symmetry assessment can be advantageous. Their application thus opens

up promising perspectives for targeted use in training design, as well as in the prevention and diagnosis of musculoskeletal disorders.

How Temperature Tunes Muscle Mechanics During Active Lengthening Contractions: Implications for Muscle Models and Injury Risk

Dr Graham Askew[1], Dr Roger Kissane[2]

[1]University of Leeds, Leeds, West Yorkshire, United Kingdom. [2]University of Liverpool, Liverpool, Merseyside, United Kingdom

Introduction

Eccentric muscle contractions occur when muscles actively lengthen, dissipating energy and stabilising joints. During active stretch, muscle force rises in two phases (Figure 1): an initial rapid increase (phase-1), followed by a slower, sustained rise (phase-2). Phase-1 reflects the strain on attached cross-bridges, while the phase-2 is linked to increased strain of non-contractile elastic elements (e.g. titin). The temperature sensitivity of these responses remains poorly understood, despite its importance for musculoskeletal models that often rely on data collected at non-physiological temperatures.

Aim: to characterise the temperature dependence of the eccentric force-velocity relationship in mammalian skeletal muscle.

Methods

Mouse extensor digitorum longus muscles were subjected to ramp lengthening contractions during tetanic activation at 17, 27 and 37°C. The rate of force development during each phase was calculated.

Results

Phase-1 stiffness decreased at higher temperatures indicating faster ATP-dependent cross-bridge detachment, although mechanical strain-dependent detachment also contributes to the change in stiffness. Phase-2 stiffness increased with temperature, consistent with stronger and faster titin-actin binding. The transition between phases (muscle *'give'*) varied with temperature, with lower temperatures delaying cross-bridges detachment and engagement of the parallel elastic elements.

Discussion

These findings provide new insights into the eccentric force-velocity relationship and its temperature dependence, revealing distinct mechanisms underlying phase-specific responses. The interplay between cross-bridge kinetics and titin engagement highlights an intrinsic tuning of muscle mechanics to potentially reduce the risk of damage under

different thermal conditions. These results have important implications for musculoskeletal modelling, which often relies on data collected at sub-physiological temperatures.

Images (Optional)

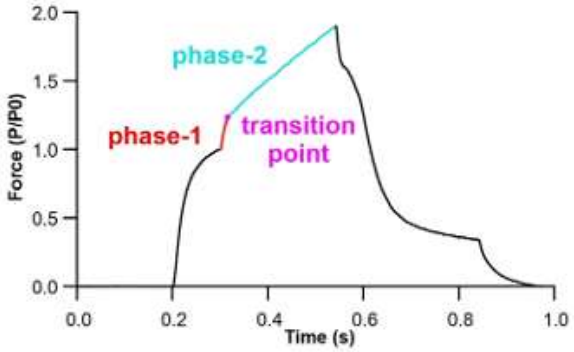

Figure 1. Eccentric lengthening of muscle. The initiation of stretch during an isometric tetanic contraction results in a rapid rise in force (phase-1), followed by a lower rate of force development (phase-2).

Morphological and Bioenergetic Adaptations to Environmental Temperature in Endotherms

Mr. Jason Cullum, Ms. Arianna Lopez, Mr. Peter Niehaus, Mr. Ali Mossayebi, Dr. Audrey Stone Ph.D., Dr. Owen Beck Ph.D.

University of Texas at Austin, Austin, Texas, United States

Introduction

Environmental temperature alters morphological and bioenergetic traits of endotherms, potentially creating a tradeoff in the ability to maintain body temperature versus producing mechanical power. In colder environments, animals typically exhibit a reduced ratio of surface-area-to-volume and fat-to-lean mass, as well as decreased mitochondrial ATP production efficiency with each of these having implications to thermoregulation and mechanical power production (1,2).

We hypothesized that endotherms from colder environments would adapt their physiology for greater heat production. To test this hypothesis, we reared rats in colder (6.5º C) and warmer (30º C) environments and predicted that the colder rats would develop relatively shorter tibias, a higher proportion of fat-to-lean mass, lower electron transport chain (ETC) efficiency, as well as high metabolic flux control though ETC complex I.

Methods

Twenty-four post-weaned Sprague-Dawley rats were equally divided into colder and hotter incubation chambers. Groups were size and sex matched at the start of incubation (85.2 ± 24.7 g for colder; 83.6 ± 26.7g for hotter; 50% female; Mean ± SD). Body composition and dimensions were analyzed using Dual X-Ray Absorptiometry scans one-month post-weaning. We isolated the soleus mitochondria of a room temperature rat and analyzed ETC characteristics.

Results

The tibia lengths of the colder (3.84 ± 0.24cm) and hotter rats (3.86 ± 0.23cm) were similar ($p=0.93$; $d=0.09$). There was no difference between the lean mass percentage ($p=0.06$; $d=1.61$), but colder rats had a lower body fat percentage ($p<0.01$; $d=2.28$) (Fig.1a,b). The coupling efficiency of the room temperature rat's ETC was 66% and synthesis of ATP depended on metabolic flux through complex I, with inhibition of the complex bringing down metabolic flux by 40% (Fig.1c).

Discussion

Our preliminary results indicate that environmental temperature exhibit some morphological adaptation, partially rejecting our hypothesis. Unexpectedly, the tibia length and lean mass percentage were unaffected, though these differences may arise at advanced ages. We expect the ETC characteristics in the colder rats to elicit greater heat production. As further data are obtained, we expect to detect tradeoffs between an animal's capacity to generate heat and mechanical power.

Development and Validation of a Custom Force Treadmill for Small Animal Biomechanics Research

Ms. Jessica Murawski MS, Dr. Derek Jurestovsky PhD, Dr. Stephen Piazza PhD, Dr. Jonas Rubenson PhD

The Pennsylvania State University, University Park, Pennsylvania, United States

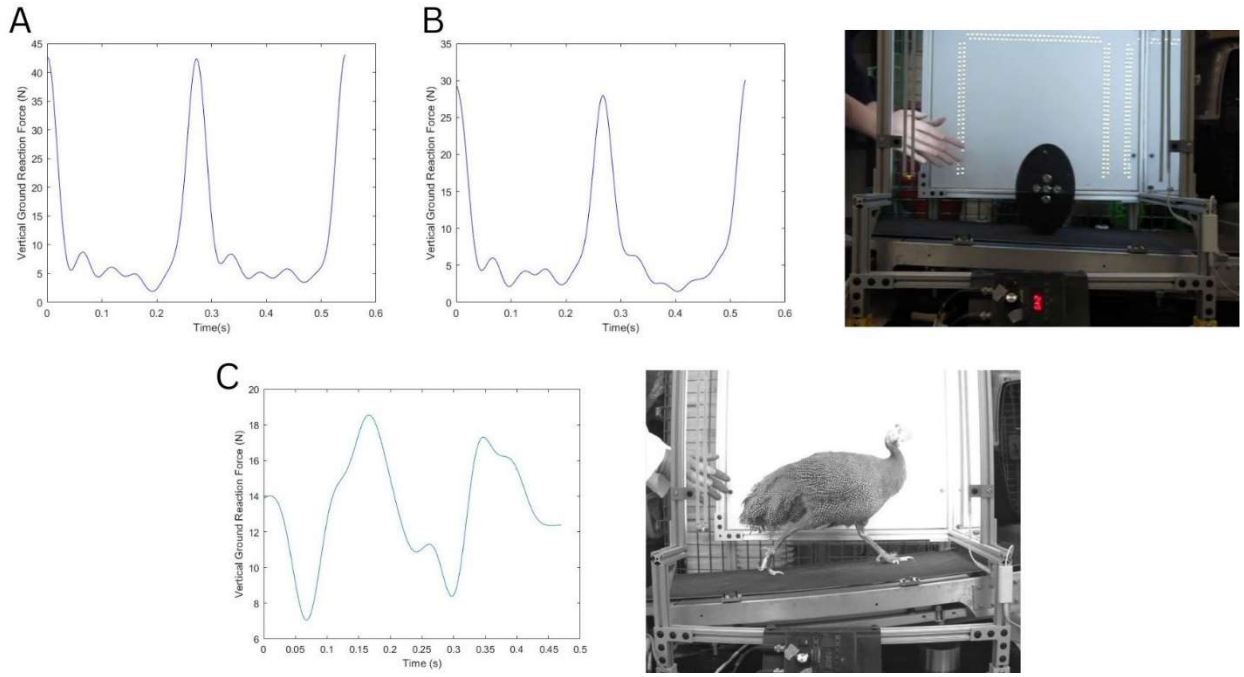
Introduction

Force plates are widely used in biomechanics to measure ground reaction forces during locomotion performed either overground or on a treadmill. While there are commercial force plates available that are sensitive enough for small animal research, they are particularly susceptible to errors and noise when placed in the vibrating environments of a treadmill. To address this problem in ongoing studies of guinea fowl (Numida meleagris) locomotion, we built a treadmill fitted with a customized force platform specifically designed to accommodate small animals and the vibrations of the treadmill.

Methods

The Avian Force Treadmill (AFT) is equipped with a servomotor and controller with a manual dial controller and speed display. The system allows speed adjustment in real time. The AFT has an integrated custom-built high frequency force platform (AMTI; Model Number: BP400600HF-400-CTT). Sitting atop the treadmill without contacting it is an enclosure with a transparent side wall for video recording and the rear aspect open for access to the animal by the handler.

To test the ability of the treadmill to measure ground reaction forces consistent with small animal locomotion, we employed a passive dynamic elliptical cylinder rolling downhill (2.3° decline) under two mass conditions (0.91 kg and 1.18 kg) at 1.10 $m \cdot s^{-1}$. We also conducted trials with a guinea fowl (1.78 kg) running at 1.34 $m \cdot s^{-1}$ up a 6.0° incline.



Results

The AFT was found to make measurements of ground reaction forces that discriminated between the different mass conditions despite the vibrations of the treadmill. Figure 1 shows the larger peak forces for the larger mass condition (Fig. 1A) and lower peak forces for the lighter mass condition (Fig. 1B). Figure 1 also shows representative ground reaction force data (combined from both feet) from a guinea fowl (Fig. 1C).

Discussion

The results of these tests support the ability of the AFT to measure ground reaction forces in a vibrating environment. Ongoing work will make use of additional passive dynamic walking robots to test force measurements and force-derived kinematic measures. This approach may be valuable for researchers working with small animals or where traditional calibration methods are insufficient due to environmental noise.

Investigating the Role of Foot Biomechanics in Load Redistribution for Medio-Lateral Balance and Stability in Ground Birds

Mr. Junhyuck Woo[1], Ms. Alyssa Desamito[1], Ms. Samar Rana[1], Mr. Harish Saravanakumar[1], Prof. Monica Daley Ph.D.[1,2,3]

[1]Department of Ecology & Evolutionary Biology, University of California, Irvine, Irvine, CA, United States. [2]Department of Mechanical and Aerospace Engineering, University of California, Irvine, Irvine, CA, United States. [3]Department of Biomedical Engineering, University of California, Irvine, Irvine, CA, United States

Introduction

Ground birds serve as useful animal models for investigating diversity and shared features for balance and stability in bipedal locomotion. Bipedal ground birds must maintain balance in the face of mediolateral (ML) disturbances when navigating uneven terrain. Although avian bipedal locomotion has been extensively studied, most work has focused on sagittal-plane dynamics [1]. Consequently, neuromechanical strategies for frontal-plane balance remain unclear. Here we investigate the foot and whole limb mechanisms for frontal plane ML balance control in avian bipedal locomotion.

Methods

Helmeted guinea fowl (Numida meleagris, 1.50 ± 0.15 kg, n = 7) were trained to run across a runway with a 15° positive-roll ML perturbation manually triggered just before stance. We collected frontal-view kinematics and ground reaction forces (GRF). Videos were tracked with DeepLabCut [2] to extract limb, foot and body landmarks. The center of mass (CoM) was estimated as the centroid of six tracked points. We analyze the angle of the ground reaction force vector relative to virtual leg (VL) vectors between the medial and lateral toes and the CoM (Fig.1A). The angle between the medial and lateral VL components and the GRF vector was measured to estimate redistribution of load between the medial and lateral digits Stance phases were time-normalized, and angles were evaluated at 10%, 50%, and 90% of stance to represent early, mid, and late contact.

Results

Preliminary analysis suggests that smaller VL-GRF angles reflect greater mechanical contribution of that toe to weight support. Early to mid stance showed a redistribution between the toes, consistent with stabilizing against the perturbation. By end stance, both limbs shift toward greater medial toe contribution, which may reflect preparation for forward propulsion approaching takeoff rather than lateral stabilization.

Discussion

These findings suggest weight redistribution between toes to restore balance following a ML perturbation. In ongoing work, we will analyze how the foot kinematics relate to shifts in GRF over time during both the initial response and recovery from the perturbation.

Images (Optional)

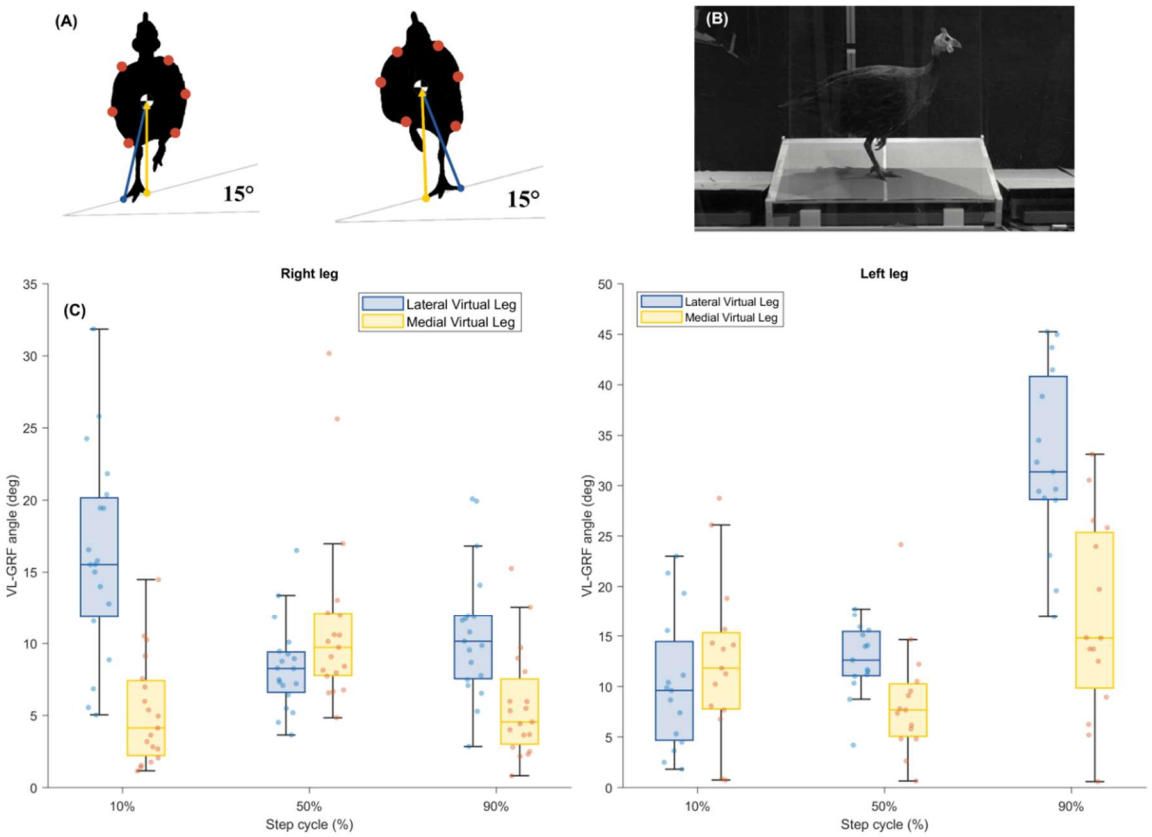

Figure 1. A) Illustraion of frontal kinematic analysis during medio-lateral perturbation, illustrating right leg and left leg contacts. The center of mass (CoM) is estimated from six tracked body points (orange). The medial VL (yellow) connects digit 2 to the CoM, and the lateral VL (blue) connects digit 4 to CoM. **B) Illustration of perturbation device (sagittal-plane view).** A sagittal-plane frame showing the bird encountering the perturbation device as it makes foot contact. **C) VL-GRF angle distributions at three timepoints in stance.** Data are from seven helmeted guinea fowl. The x-axis indicates the fraction of the step cycle, at early (10%), mid (50%), and late (90%) stance. The y-axis shows the angle between the VL vectors and ground reaction force (GRF). The right- and left-limb plots represent independent perturbation trials, illustrating how each limb responds to the perturbation. Each timepoint within stance contains paired boxplots for the medial (yellow) and lateral (blue) VL vectors.

Mechanics of Bipedal Hopping on Uneven Terrain

Ms. Mary Peña[1], Dr. David Lin[2], Dr. Craig McGowan[1]

[1]Keck School of Medicine, Los Angeles, CA, United States. [2]Washington State University, Pullman, WA, United States

Introduction

For animals locomoting on uneven terrain, mitigating abrupt surface changes that can impede forward progression and cause instability can be critical for survival. The mechanisms by which the elements of the musculoskeletal system work together to enable dynamic stability under such conditions are still not thoroughly understood. This study examined how kangaroo rats *Dipodomys deserti* accommodate a decelerating perturbation – a sudden 12-degree upslope. We hypothesized that (1) pitching moments about the center of mass (CoM) would be minimized through changes in limb orientation and (2) the ankle joint would be the primary contributor to increased energy absorption demands caused by the decelerating perturbation.

Methods

Six kangaroo rats hopped bipedally at 1.77 m s^{-1} on a custom variable-terrain rotary treadmill under two conditions: level ground and perturbed. High-speed video (300 fps) and ground reaction forces (GRFs) were collected. An inverse dynamics analysis was used to quantify whole body and joint level mechanical output. A Wilcoxon signed-rank test was used to test differences between conditions. Linear regressions with ANCOVA assessed relationships between net joint work and acceleration.

Results

Peak pitching moments and the rotational impulses about the CoM did not differ between conditions. The relative orientation of the hindlimb to the GRF vector also did not differ between conditions. The perturbation was on average more decelerative than the level condition (-4.34 ± 0.73 m s^{-2}, -1.11 ± 0.79 m s^{-2}, respectively) but similar variability in acceleration was present in both conditions. Distal joint net work did not differ on average; however, for a given acceleration, the ankle absorbed less energy in the perturbed condition.

Discussion

The changes in hindlimb posture observed in accordance with GRF vector orientation support our first hypothesis by maintaining CoM rotational mechanics during decelerative

conditions. Our second hypothesis was not supported; however, the ankle exhibited a perturbation-specific response independent of deceleration. Because our inverse dynamics analysis is limited to rigid segments, it does not include the trunk, whose CoM lies anterior to the whole body CoM and likely produces an extensor moment. We propose that intrinsic ankle mechanisms help counteract the perturbation specific effects from larger body segments to preserve stability.

Kink in the Armor: The Mechanical Properties of Bony Armor in Agonidae Fishes

Ms Megan Vandenberg[1], Dr. Bart Boom[1], Dr. Adam Summers[1], Dr. Cassandra Donatelli[2]

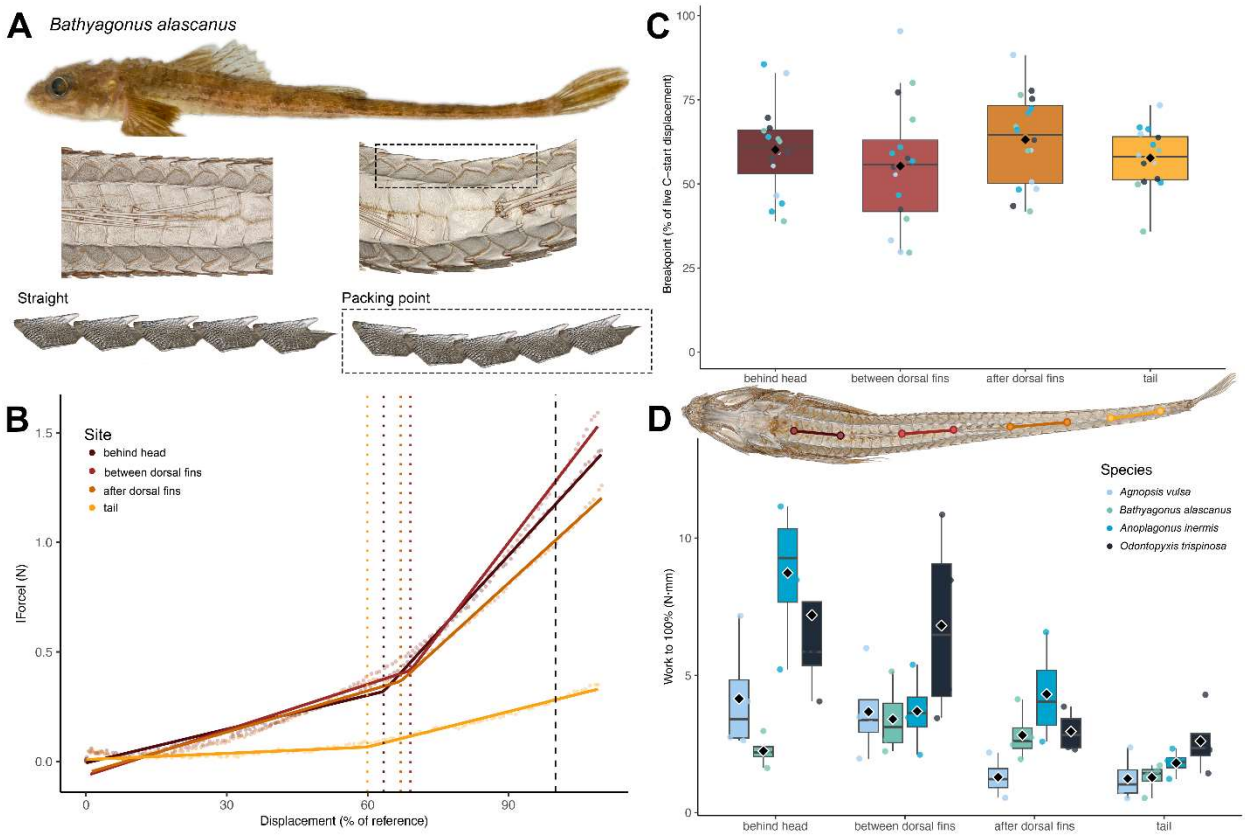
[1]University of Washington, Seattle, WA, United States. [2]University of Washington Tacoma, Tacoma, WA, United States

Introduction

In an aquatic environment, evading predators determines survival. Many fishes use C-starts where the body bends into a tight curve before recoiling to propel away from danger [1]. Armored fishes behave as natural composite systems where added stiffness allows for greater energy storage during bending [2]. Agonidae are a family of fishes with diverse overlapping bony armor plates covering their bodies (1.A) [3]. Their armor features spines which offer protection - covering vulnerable gaps between plates, and hydrodynamic benefits - decreasing drag [4]. Below the spines, ridges provide a packing point which limits motion and potentially stores energy for C-starts. We used kinematic analysis, material testing, and micro-computed tomography to compare how different armor morphologies affect body stiffness.

Methods

We filmed C-starts for four species and extracted maximum bending angle. Specimens were euthanized and subject to cantilever bending tests at four locations to 110% of species-specific curvature. From force-displacement curves, we identified the packing point – interpreted as the onset of scale interlocking – using a linear regression (1.B). We calculated work to 100% of maximum C-start displacement and stiffness. We CT-scanned specimens to measure cross-sectional area, second moment of inertia and visualize the packing point.



Results

Armor plates interlocked at 50%-75% of the full C-start bending showing body stiffness increases before they reach peak escape curvature (1.C). Species with more armoring require more work (2.5x-1.75x more) to bend to 100% curvature (1.D). For all species, stiffness increased after the packing point, from 2.5x stiffer behind the head to almost 5x stiffer at the tail.

Discussion

The substantial rise in stiffness after plate interlocking suggests that agonid armor acts as an energy-storage system, remaining flexible and compliant during small deflections but rapidly stiffening under larger deflections. The majority (80-95%) of the total work required to reach 100% displacement occurs after the packing point, indicating that most potential energy is stored only after reaching high curvature, allowing for rapid energy return during the final stage of the C-start.

Understanding the roles of the active and passive components within the digital flexors of the equine forelimb

Ms Olivia Kenny, Dr Kasara Toth, Mr Joshua Mang, Dr Nigel Shrive, Dr. John E.A. Bertram, Dr Holly Sparks

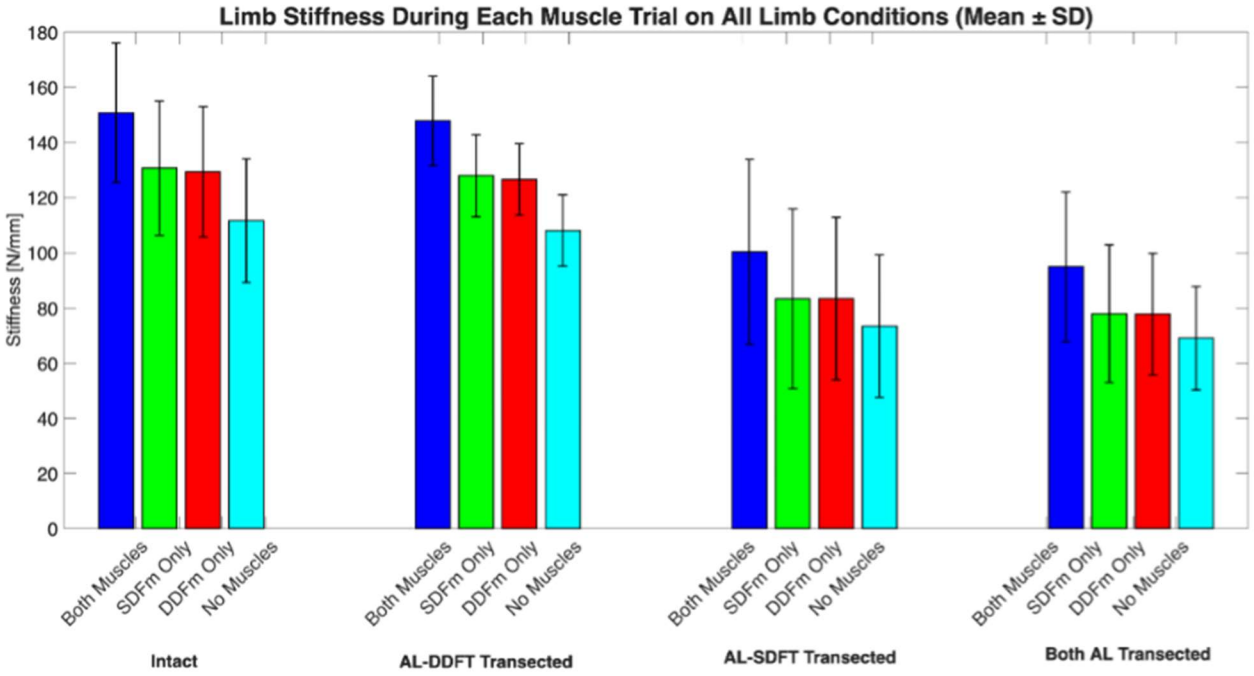
University of Calgary, Calgary, Alberta, Canada

Introduction

Equine musculoskeletal overuse injuries are unfortunately common. Studying the injury mechanics and risk factors benefits horses and advances our understanding of comparable human conditions. The distal forelimb has two flexor muscle-tendon-ligament units (MTLUs) containing the superficial and deep muscles (SDFm and DDFm), tendons (SDFT and DDFT) and accessory ligaments (AL-SDFT and AL-DDFT). These MTLUs differ structurally and the SDFT is preferentially injured in racehorses [1, 2]. Identifying how active (muscles) and passive (tendons and ligaments) components function is critical, especially as fatigue increases injury susceptibility during exercise. This study aims to determine the roles and load distribution in the equine forelimb digital flexor system during mid-stance.

Methods

A novel testing frame was developed to test cadaveric forelimbs. Cyclic loads of 1000-3000N were applied vertically to the limb and 250-500N applied to each muscle to simulate active muscle engagement. Fetlock joint angle, SDFT strain, force and displacement data were measured. Four muscle engagement trials were completed (1) no muscle engagement (2) SDFm only (3) DDFm only (4) SDFm and DDFm engaged simultaneously. These trials were completed on three limb conditions (a) the intact limb [N=10] (b) single accessory ligament transected: AL-SDFT [N=5], AL-DDFT [N=5] (c) both accessory ligaments transected [N=10].



Results

Limb stiffness was calculated as force divided by displacement and group means/standard deviations are shown in Figure 1. SDFT strain and fetlock drop were greatest with no muscle engagement and lowest with both muscles engaged. Preliminary analysis indicates no statistical differences in SDFT strain or fetlock drop between individual muscle-engagement conditions.

Discussion

AL-SDFT transection reduced limb stiffness more than AL-DDFT transection, suggesting it provides greater passive support at mid-stance. Individual muscle engagement produced similar limb stiffness, SDFT strain and fetlock drop. SDFm engagement did not directly increase the SDFT strain possibly through the alteration of joint conformations and tendon moment arm reduction. This indicates the SDFT functions ambiguously, acting partly as a ligament during specific loading conditions. This information is critical in understanding the role and load distribution of the forelimb components during mid-stance.

Subject-Specific CFD Characterisation of Craniospinal CSF Flow in Cavalier King Charles Spaniels with Chiari-Like Malformation and Syringomyelia

Mr Ryan Jones MEng[1], Prof. Clare Rusbridge BVMS PhD DECVN FRCVS[1,2], Dr Srdjan Cirovic PhD[1]

[1]University of Surrey, Guildford, Surrey, United Kingdom. [2]Wear Referrals Veterinary Specialist & Emergency Hospital, Bradbury, Stockton-on-Tees, United Kingdom

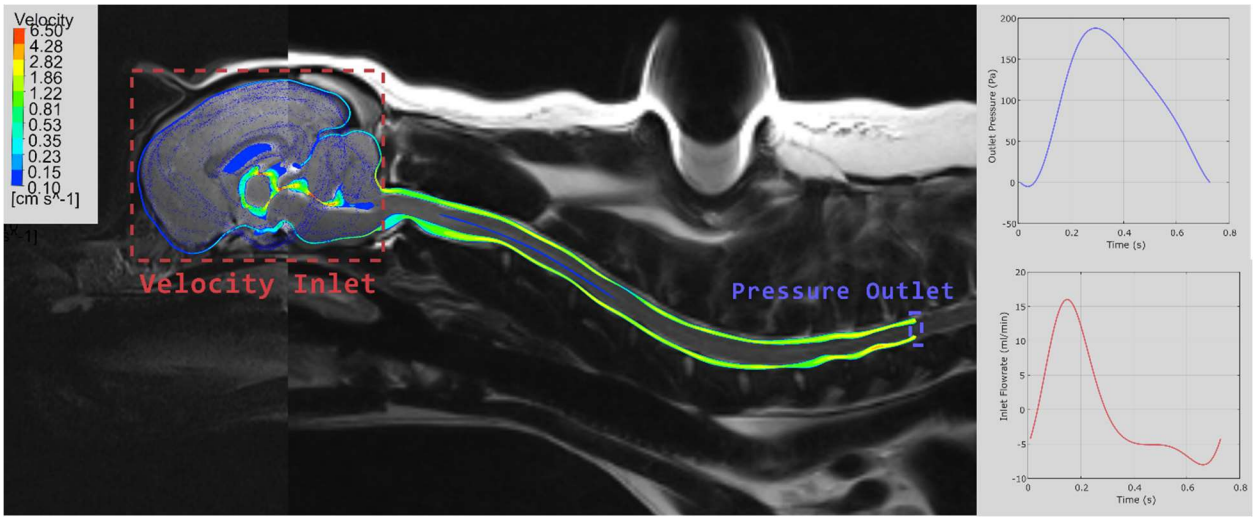
Introduction

Cavalier King Charles Spaniels (CKCS) spontaneously develop Chiari-like malformation (CM) and syringomyelia (SM), conditions associated with craniospinal overcrowding and disrupted cerebrospinal fluid (CSF) dynamics. Because these disorders closely parallel human CM and SM, CKCS represent a valuable comparative model for investigating their origin and treatment. This study performed subject-specific simulations of CSF flow in healthy, CM, and CM+SM CKCS and to identify flow parameters that statistically discriminate among these groups.

Methods

Thirty subject-specific CFD models of the ventricular system, cranial and spinal subarachnoid space (SAS), and central canal (CC, truncated at T3/4) were constructed from clinical MRI. The cranial SAS was modelled as a uniformly wide (0.5 mm) and the spinal SAS was created by lofting surfaces between manually defined inner and outer curves. A pulsatile velocity boundary condition was applied to ventricular and cranial SAS surfaces representing arterial-driven CSF motion; a pressure boundary condition at the caudal spinal end was implemented via a lumped dural compliance. Ten models were generated for each group (healthy, CM, CM+SM), from which velocities, pressures, impedances, and flow volumes were calculated. Principle component analysis (PCA) was then applied to identify group-specific flow patterns.

Results



All model exhibited laminar CSF flow (Reynolds numbers <150 and Womersley numbers <5). Significant group differences were observed in craniospinal impedance; In syringomyelia cases, the integrated impedance between C2-3 was elevated in the SAS (~6 Pa/ml) but reduced in the CC (~1455 Pa/ml) compared with healthy and CM-only dogs (~1 Pa/ml in the SAS and ~2600 Pa/ml in the CC). PCA of slice-wise flow features (relative peak and mean velocities, flow rates, pressure gradients, and regional impedance) revealed distinct clustering. Several SM models exhibited focal CSF acceleration in regions where

the syrinx diameter increased abruptly. Syrinx-affected dogs also demonstrated large instantaneous pressure differences (>40 Pa) between the SAS and CC.

Discussion

These findings demonstrate that impedance and pressure patterns are altered in SM in ways consistent with proposed mechanisms of syrinx formation. Moreover, PCA reveals subtle flow abnormalities that support refined flow-based classification of CM and SM, and may offer useful parameters for postoperative assessment.

Inverse Dynamics Analysis of a Dolphin Musculoskeletal Model During Swimming

Professor Shunichi Kobayashi Ph.D.[1], Graduate Student Taisuke Nakamura[1], Graduate Student Aoi Take[1], Professor Yutaro Motoori Ph.D.[2]

[1]Shinshu University, Ueda, Nagano, Japan. [2]The University of Osaka, Toyonaka, Osaka, Japan

Introduction

Dolphins exhibit excellent swimming performance, and the thrust generated by their tail flukes has attracted considerable attention. To develop underwater propulsion systems using fluke-inspired fins, it is necessary to understand dolphin swimming and the associated whole body motion and loading. Musculoskeletal modeling with inverse dynamics provides a noninvasive method for estimating internal forces. In this study, we built an anatomically based dolphin musculoskeletal model and used inverse dynamics with fluid forces on the tail flukes to clarify the muscle forces and tendon tensions in the caudal peduncle during swimming.

Methods

Based on anatomical data for dolphins [1], we constructed a musculoskeletal model focusing on the region from the caudal peduncle to the tail flukes of the dolphin. The model included dorsal axial tendons I and II dorsally, the ventral axial tendon ventrally, and 18 caudal vertebrae, ventral chevron bones, and ligaments (Figure 1). Inverse dynamics analysis was performed in AnyBody using the prescribed motion, mass properties, and externally applied fluid forces to compute the muscle forces (tendon tensions). The fluid forces were obtained from a numerical simulation [2] of a swimming dolphin using an immersed boundary–lattice Boltzmann method and applied from the body surface to each vertebra.

Results

The muscle length changes corresponding to the vertebrae-connected tendons tended to increase toward the leading edge of the tail fluke, and tendon tension was generated even during stretching. In dorsal axial tendon I, tension occurred during the upstroke, with particularly large forces on the trunk. In contrast, in the ventral axial tendon, tension was generated during the downstroke, with large values in the tendon attached to the trunk-side of the chevron bones.

Discussion

The tendon tension fluctuated with the hydrodynamic forces on the tail flukes, showing large peaks at the upstroke–downstroke transition. In both the dorsal and ventral axial tendons, tension increased from the caudal peduncle toward the trunk. However, the model accuracy remains limited, and tendon attachment locations require further refinement.

Computational Modeling of YAP Phosphorylation Within Integrin Adhesions

Dr. Hamidreza Jafarinia[1], Dr. Lidan Shi[2], Dr. Haguy Wolfenson[2], dr. Aurélie Carlier[1]

[1]Maastricht University, Maastricht, Limburg, Netherlands. [2]Technion, Haifa, Haifa, Israel

Dr. Hamidreza Jafarinia

Dr. Lidan Shi

Dr. Haguy Wolfenson

Introduction

Mechanical and biochemical cues intricately activate YAP, which is pivotal for the cellular responses to these stimuli. Recent findings reveal an unexplored role of YAP in influencing the apoptotic process. It has been shown that on soft matrices YAP is recruited to small adhesions, phosphorylated at Y357, and translocated into the nucleus triggering apoptosis [1]. Interestingly, YAP Y357 phosphorylation is significantly reduced in larger mature focal adhesions on stiff matrices. Building upon these novel insights, we aimed to use stochastic modelling to delve deeper into the complex dynamics of YAP phosphorylation within integrin adhesions.

Methods

The dynamics of YAP phosphorylation within integrin adhesions is simulated using a spatially stochastic Gillespie algorithm. In each simulation step, YAP undergoes diffusion or reaction events, including binding, unbinding, phosphorylation, dephosphorylation (Figure 1). We also model adhesion formation and disassembly at varying intervals within the cell. Simulations are conducted in MATLAB version 2022.

Results

Our findings emphasize several key points: firstly, increasing the cytosolic diffusion rate of YAP correlates with higher levels of phosphorylated YAP (pYAP), secondly, increasing the number of binding sites and distributing them across the membrane surface, mimicking smaller adhesions, leads to higher pYAP levels, particularly at lower diffusion rates. Moreover, we show that the binding and release rate of YAP to adhesions as well as adhesion lifetimes significantly influence the size-effect of adhesion-induced YAP phosphorylation.

Discussion

The findings highlight the complex and dynamic interplay between adhesion lifetime, the rate of pYAP unbinding from adhesions, and dephosphorylation rates, collectively shaping overall pYAP levels. In summary, our work advances the understanding of YAP mechanotransduction and opens avenues for experimental validation.

Relation Between Perfumes Intensity and Mechanical Tension Index Influenced by Age and Gender

Ms Emilie Khattignavong[1,2], Mrs Sophie Raviot-Derrien[2], Mr Hassan Zahouani[1]

[1]Ecole Centrale de Lyon, Ecully, Auvergne Rhône Alpes, France. [2]COTY R&D, Versoix, Geneva, Switzerland

Introduction

Perfume is a mixture of odorants and solvents whose physicochemical properties such as volatility, molecular weight, and vapor pressure can vary widely. Understanding how these properties influence the fragrance evaporation and how perfume interacts with skin surface is essential for controlling its release over time.

At the same time, intercellular lipids (ICL) in the stratum corneum (SC), the skin's outermost layer, are essential for skin barrier function and controlling the penetration of external substances. This barrier function is strongly linked to the ICL [1]. At the SC surface, the molecular organization and composition of these lipids can be altered by external factors such as cosmetic products like perfume. From a mechanical point of view, human skin is subjected to an initial tension exerted by the superficial connective tissue: the fascia. The developed model allows for the study of three parameters in the spectral domain: wavelength, spatial frequencies, and anisometry along the x and y axes. Based on a static equilibrium model of internal forces, the model quantifies three tension index.

Methods

Confocal Raman microscopy (CRM) is a technique capable of analyzing the skin structure and composition. A protocol was developed to investigate the molecular mechanisms involved in the interactions between fragrances and human skin *in vivo* using CRM. Hydration, lipid content, and lipid organization were measured on untreated skin and on skin treated with fragrance at T0h and T6h. Mechanical parameters, including skin tension index, were also assessed, and an olfactory study was conducted to establish relationships between these parameters in a panel of 20 volunteers.

Results

The results show that the fragrance leads to a decrease in hydration and disrupts lipid organization over time. Strong correlations were also identified between skin tension index and the perceived fragrance intensity at T0h, particularly among older and male participants.

Discussion

These observations suggest that the application of perfumes may increase the permeability of the SC [2]. Furthermore, the skin tension index appears to be a key parameter to consider in the perceived fragrance intensity.

Exploring Collagen Mechanics and Protein Interactions Across Hierarchical Scales: Insights from Fluorescence Microscopy and AFM Imaging

PhD Candidate Janine Srocka, PhD Candidate Koushik Bar, Professor Nancy R. Forde

Simon Fraser University, Burnaby, BC, Canada

Introduction

Extracellular matrix (ECM) mechanics play a crucial role in cellular physiology, and maintaining ECM homeostasis is essential for proper cellular development and tissue function. Cells sense and respond to mechanical stimuli, but the role of force-induced structural changes in ECM scaffolding proteins, such as collagen, in mechanical signal transduction remains poorly understood. Collagen exists in a range of hierarchical assemblies, from individual molecules to fibrils and fascicles. Given this complexity, it is essential to assess collagen's mechanical behaviour across these different scales to fully understand how structural transitions impact force transmission and protein–protein interactions.

Methods

In this study, we explored collagen's mechanical properties and how they influence its interactions with binding partners. To investigate collagen's behaviour across different scales, we utilized both fluorescence microscopy and atomic force microscopy (AFM). A fluorescence-based stretching assay was employed to screen for proteins whose interactions with collagen are modulated by mechanical strain, offering insights into collagen's force response at the tissue scale. AFM imaging was used to visualize collagen at various hierarchical levels, from single molecules to fibrils, enabling the assessment of its mechanical properties and structural organization. Additionally, AFM imaging was employed to examine protein binding to collagen at the molecular level.

Results

In our experiments, we identified proteins whose interactions with collagen were either affected or unaffected by mechanical strain, as demonstrated by our fluorescence-based stretching assay. AFM imaging was used to observe single collagen molecules, both with and without bound proteins, providing initial structural insights into these molecular interactions.

Discussion

Our findings provide initial insights into different approaches for studying collagen across its hierarchical scales. While fluorescence-based assays and AFM imaging offer valuable perspectives on collagen's mechanical properties, these approaches present experimental challenges such as distinguishing specific from non-specific binding. These difficulties highlight the need for further optimization of experimental protocols. Moving forward, improving strain-specific assays and exploring collagen's behaviour at multiple scales will be crucial for advancing our understanding of ECM mechanics and collagen's role in mechanotransduction.

Spontaneous Clustering of LINC Complex Units Enhances Nuclear Force Transmission

PhD Student Nya Domkam, Professor Mohammad Mofrad PhD

University of California Berkeley, Berkeley, CA, United States

Introduction

The LINC (LInker of the Nucleus to the Cytoskeleton) complex plays a pivotal role in this process. Composed of SUN proteins in the inner nuclear membrane and KASH peptides in the outer nuclear membrane, the LINC complex forms a continuous mechanical bridge across the nuclear envelope. Through this bridge, forces from the cytoskeleton can directly influence nuclear architecture and function.

Although a single LINC complex unit (LCU) is structurally capable of withstanding some level of mechanical load, the magnitude of forces generated by aligned actin bundles in the actin cap likely exceeds the capacity of an individual LCU without unfolding.

In this study, we investigate whether LCUs spontaneously form stable higher-order assemblies under minimal-force conditions

Methods

We performed all-atom molecular dynamics simulations. The SUN2/KASH2 trimeric structure served as the basis for all models. Multiple candidate cluster arrangements were constructed using complementary approaches: protein–protein docking, AI-based structure prediction, and manually oriented configurations.

Results

Analysis of interaction energetics revealed two distinct stabilizing mechanisms across models. Many were stabilized by electrostatic complementarity and hydrogen-bond networks, with a locally increased density of hydrogen bonds at the interacting interfaces. While others were stabilized predominantly by hydrophobic packing, which overcame

repulsive interactions among neighboring charged residues and produced a tightly associated interface.

To quantify relative stability, we ranked all structures by total complexation free energy. The most favorable complexation energies—and the most favorable stepwise energy profiles—were observed in protein–protein docking models.

Discussion

The emergence of multiple stable clustering modes suggests that LINC complex organization at the nuclear envelope may be driven not only by externally applied forces but also by favorable thermodynamic interactions. Distinct stabilizing mechanisms — electrostatic/hydrogen-bond networks versus hydrophobic packing — likely represent alternative assembly pathways that the cell can exploit under different mechanical environments. These modes may differentially contribute to nuclear force buffering when cytoskeletal tensions increase.

Future work will directly test the contribution of hydrophobic interactions by mutational disruption of interface residues. Experimentally, in vitro oligomerization assays such as size-exclusion chromatography can validate clustering, while FRAP studies in cells can evaluate cluster stability by comparing protein mobility between mutants and wild type.

Basic Study Using Ex-Vivo Pig Ear Skin for Connective Tissue Softening via Fractional Laser

Basic Study Using Ex-Vivo Pig Ear Skin for Connective Tissue Softening via Fractional Laser Ren Sato Doctoral Student, Basic Study Using Ex-Vivo Pig Ear Skin for Connective Tissue Softening via Fractional Laser Ippei Yagi Assistant Professor, Basic Study Using Ex-Vivo Pig Ear Skin for Connective Tissue Softening via Fractional Laser Satoshi Uchida Professor

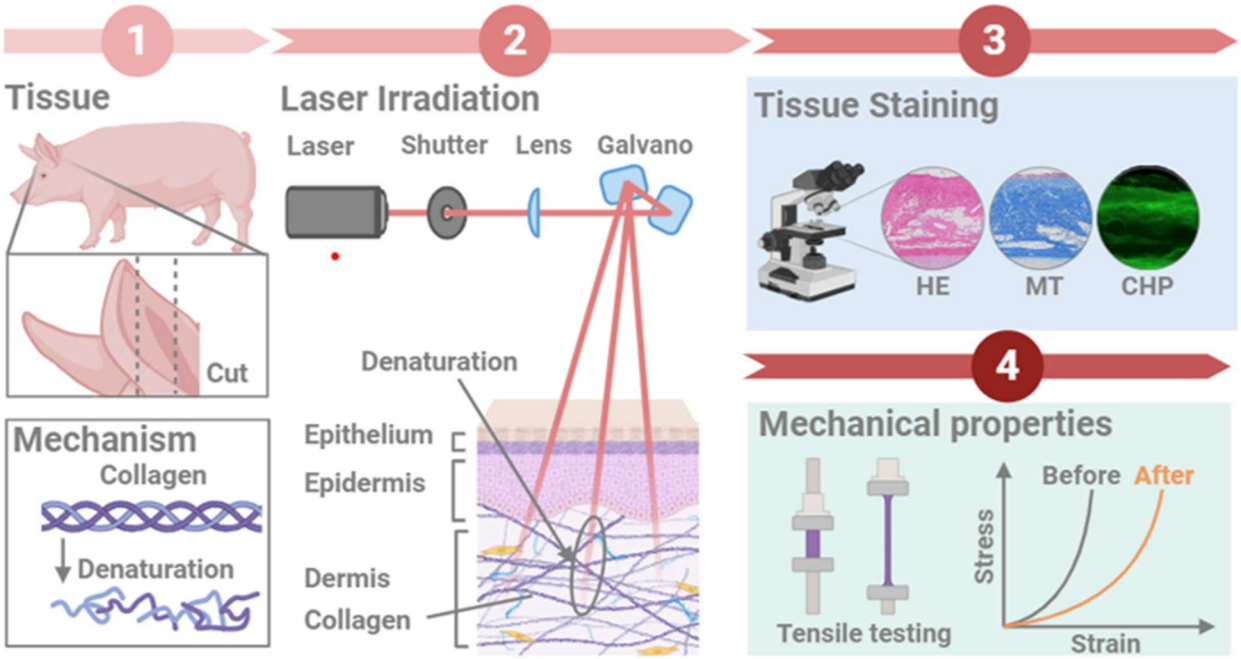
Tokyo Metropolitan University, Hino, Tokyo, Japan

Introduction

Fibrosis causes organ dysfunction through excessive collagen accumulation and tissue stiffening. Current pharmacological treatments, such as pirfenidone, only delay disease progression and cannot reverse established rigidity or side effects. This study investigates a novel application of Fractional Laser (FL) therapy—typically used for skin tightening—to instead *soften* fibrotic tissue via controlled thermal denaturation. The hypothesis is that heating collagen above 63°C transforms it into gelatin, thereby reducing tissue stiffness.

Methods

To verify this mechanism, researchers conducted *ex-vivo* experiments using porcine ear dermis. A 1064 nm fiber laser was applied to tissue samples at four irradiation densities (150, 300, 450, and 600 dots/mm^2). The effects were evaluated using Collagen Hybridizing Peptide (CHP) staining to visualize denaturation and uniaxial tensile testing to measure changes in Young's Modulus.



Results

Histological analysis confirmed that the laser successfully induced deep thermal denaturation. Mechanical testing revealed a significant, density-dependent response. While the lowest density (150 dots/mm^2) caused slight stiffening due to dehydration, higher densities resulted in marked softening. Specifically, irradiation at 600 dots/mm^2 reduced the tissue’s Young's Modulus to 39% of the pre-treatment value. These results indicate that at sufficient densities, the structural breakdown of collagen dominates over dehydration effects.

Discussion

This study provides fundamental evidence that FL irradiation can be tuned to reduce tissue stiffness, offering a potential alternative to drug therapy for fibrosis. However, a key limitation is the use of an ex-vivo model, which excludes biological wound healing responses. Future in-vivo studies are necessary to determine if the thermal damage triggers inflammatory re-fibrosis or if the softening effect is sustainable during the healing process.

Preliminary Quantification of Hindlimb Joint Biomechanics in a Large Animal Model of Hypophosphatasia Using a Novel Inverse Dynamics Model

Dr. Aaron Henry PhD[1], Dr. Dana Gaddy PhD[1], Dr. Larry Suva PhD[1], Dr. Andrew Robbins PhD[2]

[1]Texas A&M University, College Station, Texas, United States. [2]University of Texas at Tyler, Tyler, Texas, United States

Introduction

Hypophosphatasia (HPP) is a rare genetic disorder impacting bone mineralization and development. Biomechanical investigations have focused on orthopedic symptoms, but joint biomechanics during gait have yet to be quantified in any HPP population. Large animal models provide a vital platform to understand disease progression, thus this study evaluated HPP impacts on hindlimb gait biomechanics in a sheep model.

Methods

Sixteen skeletally mature Rambouillet sheep (wildtype [WT] and HPP) were utilized, with kinematic and kinetic data collected using a Vicon Motion Capture System and AMTI force plates integrated into a custom runway. Joint centers and body segment inertial properties (BSIPs) were calculated using predictive models based on computed tomography data [1,2], while a novel inverse dynamics model calculated hindlimb joint kinetics. Primary endpoints included ground reaction forces, joint angles, intersegmental forces, and moments of the hip, stifle, hock, and metatarsophalangeal joints. A two-way Type II ANOVA test compared extrema values of all kinematic and kinetic endpoints between WT and HPP groups.

Results

Endpoints were generally similar, with exceptions primarily in the stifle joint. Significant differences were seen in joint flexion extrema of the hip, stifle, and hock. HPP sheep had significantly smaller peak stifle posterior intersegmental force. Regarding moments, HPP sheep had higher peak stifle flexion moment at early stance, reduced peak stifle extension just before swing, and a larger peak abduction moment at the stifle in early stance. No significant differences were seen in joint range of motion or non-sagittal plane joint angle extrema.

Discussion

This study provides the first quantitative analysis of joint biomechanics during gait of any HPP population. Results do not suggest substantial differences between HPP and WT hindlimb gait, though significant differences occurred primarily in the sagittal plane, particularly at the stifle joint. However, the limited sample size resulted in relatively low statistical power; inclusion of additional animals or improvement of the inverse dynamics model could identify more subtle differences.

Images (Optional)

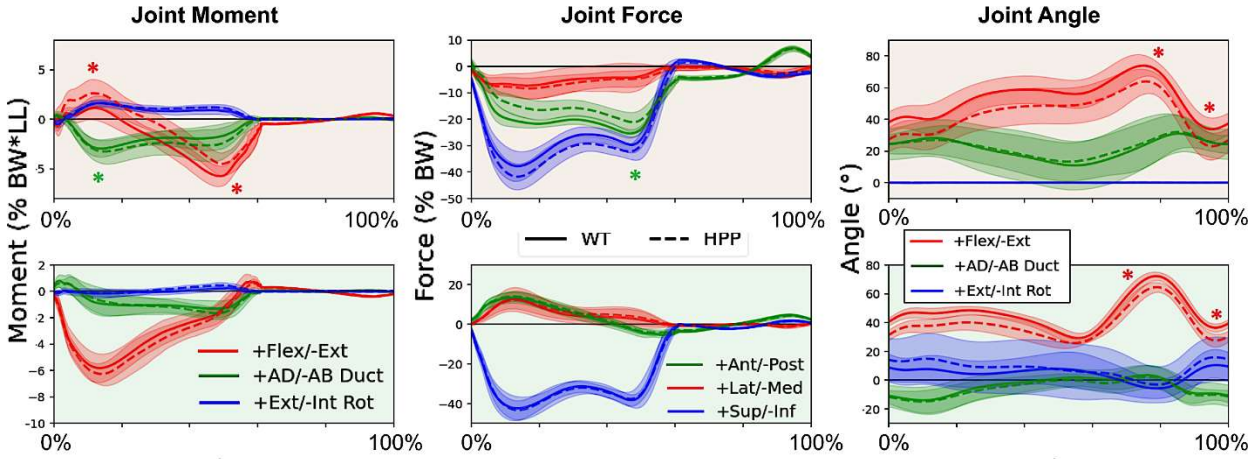

Figure 1: Intersegmental angles, forces, and moments for the stifle (top row) and the hock (bottom row) joints. (*) Indicates statistical significance ($p<.05$) for the local extreme of the matching color. X-axis is percentage of gait cycle.

Towards Better Understanding of Trimester Specific Gait Kinematics During Pregnancy

Ms. Alyson Colpitts MASc, Ms. Heather Li Yam Nam, Dr. Martine McGregor PhD, Dr. Elise Laende PhD

University of Waterloo, Waterloo, ON, Canada

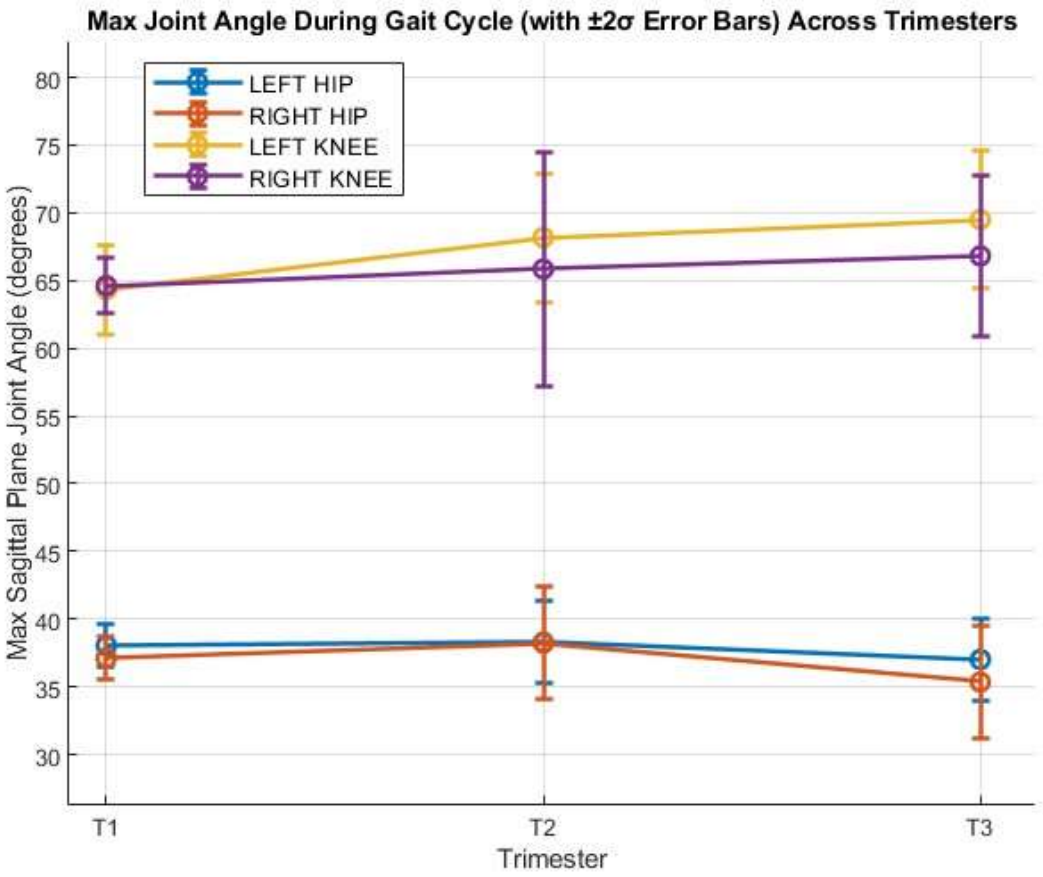
Introduction

Current understanding of biomechanical changes during pregnancy and post-partum is limited. A 2025 meta-analysis on pregnant and postpartum gait kinematics, which included only 32 viable papers, found indications that pregnant women experience increased pelvic tilt, knee flexion, and lateral foot progression angle, with decreased hip extension and ankle plantarflexion [1]. The objective of our study was to investigate kinematic changes over pregnancy and the feasibility of capturing data these changes using accessible markerless motion capture.

Methods

Data were collected using 8 synchronized Sony video cameras and processed with markerless motion capture software (Theia3D, Kingston, ON). Exercises included walking, fast walking, balance, and lifting and carrying tasks. Subjects who were pregnant were recruited to participate in 6 sessions, one at the end of each trimester of pregnancy (12, 24, and 36 weeks) and three post-partum (12-, 24-, and 36-weeks post-partum). Pose data were processed using Visual3D and subsequently MATLAB to generate 3D joint kinematics and calculate average maximum values of joint motion in the sagittal plane.

Results



Complete kinematic data for overground walking were available for two participants over their pregnancies. Similar to existing literature, participants had decreased maximum hip sagittal plane angle between trimester 1 (37.6+/-0.9 degrees) and trimester 3 (36.2+/-2.0 degrees) and increased maximum knee flexion angle from trimester 1 (64.5+/-1.4 degrees) to trimester 3 (68.2+/-3.1 degrees; Figure 1).

Discussion

Findings from this data support current understanding of gait changes throughout pregnancy. Recruitment and analysis are ongoing with 4 additional participants currently enrolled. Variability increase from first to third trimester, as indicated by standard deviation, will be further examined. This work demonstrated initial feasibility of using a novel markerless motion capture approach to track kinematics in a pregnant population,

enabling high throughput and minimizing participant burden which will support ongoing research in this understudied area.

How Muscle–Tendon Inertia Influences Neuromuscular Coordination in Cycling

Dr Ameur Latreche[1], Dr Stephanie Ross[2], Dr Taylor Dick[3], Dr James Wakeling[1]

[1]Simon Fraser University, Burnaby, BC, Canada. [2]University, Calgary, AB, Canada. [3]The University of Queensland, Brisbane, Qld, Australia

Introduction

Muscle–tendon unit (MTU) inertia is usually neglected in musculoskeletal simulations, despite its potential to affect the muscle forces and hence the coordination patterns. The purpose of this study was to assess whether coordination patterns between muscles, predicted from a musculoskeletal simulation of cycling, differ as intramuscular mass of lower limb muscles was systematically varied. We combined a mass-enhanced Hill-type muscle model, embedded into musculoskeletal simulations of pedalling, and classified the predicted activations with principal component analysis (PCA) and mixed-effects statistics.

Methods

Cycling kinematics and crank load data were used from 12 subjects. We implemented a multi-body mass-enhanced Hill-type muscle model into a muscle redundancy solver [1] linked to OpenSim [2] for 43 muscles of the lower extremity. The muscle masses were scaled from 0.01 to 125 times the mass of the nominal human-sized muscles. We simulated pedalling at a range of speeds (80, 120, 140 r.p.m.). Predicted muscle activation patterns in 43 lower limb muscles were interpolated to 100-points per pedal cycle (3 cycles analysed per trial), pooled across muscles and classified by PCA.

Results

Cadence emerged as the dominant factor that affected the PC scores. The mass-scale also produced a robust significant, non-trivial modulation of several principal components, especially PC4. For PC4, the mass-scale had a significant main effect ($F = 248$, $p < 0.0001$) such that larger muscle masses were associated with greater peak amplitudes and a systematic shift in the timing of the PC4 waveform compared with lower mass-scales.

Discussion

These findings demonstrate that muscle mass is a functionally relevant parameter that influences the organisation of neuromuscular coordination during cycling. Incorporating mass-enhanced muscle models into simulation pipelines may therefore be critical for

evaluating predictions of muscle activation and energetics, particularly for studies that consider how muscle coordination varies across animal size.

How Do Anatomically Defined and Kinematically Optimized Coordinate Systems Differ in Knees With Osteoarthritis?

Ms Amiya Gupta BS, Dr. Lesley Lizalek PhD, Dr. Joshua Roth PhD

University of Wisconsin-Madison, Madison, WI, United States

Ms Amiya Gupta

Dr. Lesley Lizalek

Introduction

Conceptually, local coordinate systems that define the widely utilized joint coordinate system reported by Grood and Suntay should be defined based on key anatomy linked to biomechanics (e.g., articular surface of the femur); however, practically, there are a variety of approaches used for defining the local coordinate systems of the knee including palpable landmarks (e.g., femoral epicondyles), segmented articular surfaces (e.g., cylindrical or spherical axis), and kinematically optimized based on passive kinematics, which may need to changes when studying knees with osteoarthritis. Thus, our objectives in this study were to: (1) quantify differences between the coordinate systems defined using the aforementioned approaches in cadaveric knees with varying severities of osteoarthritis, and (2) determine whether these differences correlated with degree of osteoarthritis severity.

Methods

We procured 9 knees with a range of osteoarthritis severities. Using bone models created from computed tomography scans, we defined local coordinate systems based on (1) palpable bony landmarks, (2) the cylindrical axis, and (3) the spherical axis of the femur. Using a robotic testing system, we moved each knee through passive flexion and internal-external rotation ranges of motion in the coordinate system based on the spherical axis of the femur. These kinematics were input into an established coordinate system optimization algorithm to determine the coordinate system that minimized off-axis kinematics during both passive flexion and internal-external rotation trajectories.

Results

We found the femoral coordinate system based on the cylindrical axis was most similar to that based on the spherical axis (Figure 1, RMSE of difference in axis-angle = 2.7°). We also found that the differences in the optimized coordinate system were weakly correlated with osteophyte volume ($R^2 = 0.24$), but these were more strongly correlated than differences in the other two anatomically defined coordinate systems (palpable: $R^2 = 0.12$ and cylindrical: $R^2 = 0.21$).

Discussion

Our key findings were that (1) optimized coordinate systems have large differences from coordinate systems defined based on the articular surfaces, and (2) these differences became slightly larger for knees with more severe OA, which suggests that care must be taken when defining the coordinate system for knees with more and less severe OA.

Images (Optional)

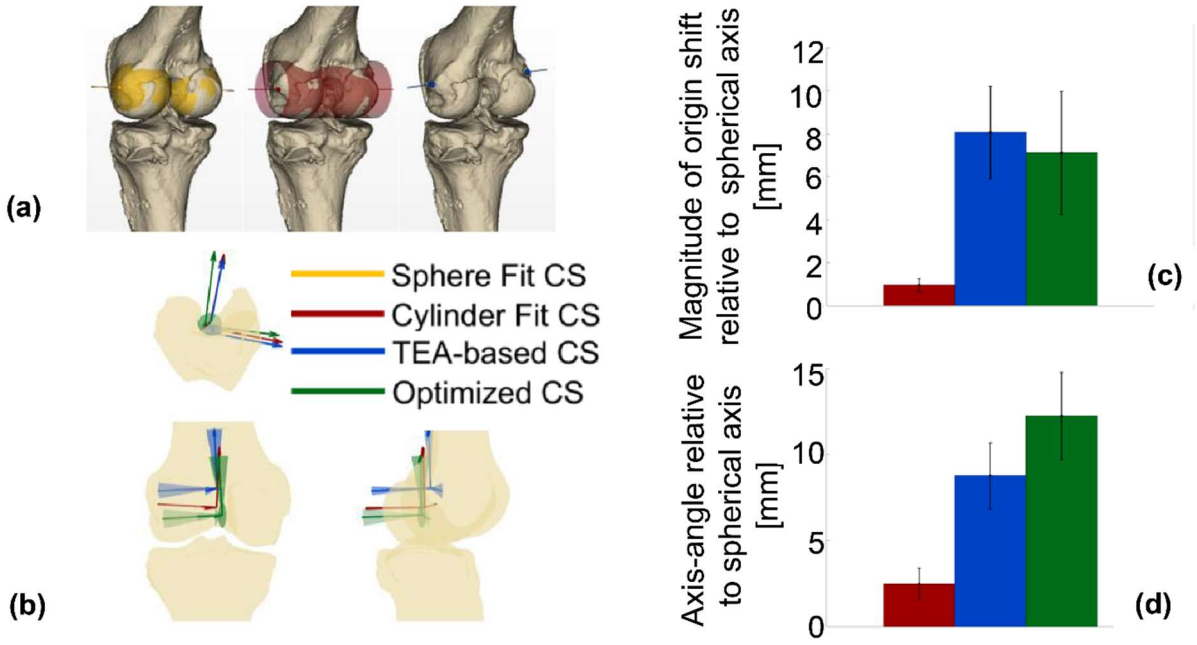

Figure 1. (a) Images show the three anatomically defined coordinate systems. (b) Plots show how the coordinate systems differ within the 9 knees. Arrows represent the mean axes and the shaded funnels represent the standard deviations of the differences between axes. (c) and (d) show these same differences between axes. Linking Ankle and Hindfoot Morphology with Kinematics in Asymptomatic Flatfoot

Mr. Andrew Peterson MS[1], Mr. Tradd Rector[1], Ms. Elizabeth Bowman[1], Dr. Kassidy Knutson PhD[1], Dr. Karen Kruger PhD[2,3], Dr. Amy Lenz PhD[1]

[1]University of Utah, Salt Lake City, Utah, United States. [2]Marquette University, Milwaukee, Wisconsin, United States. [3]Shriners Children's, Chicago, Illinois, United States

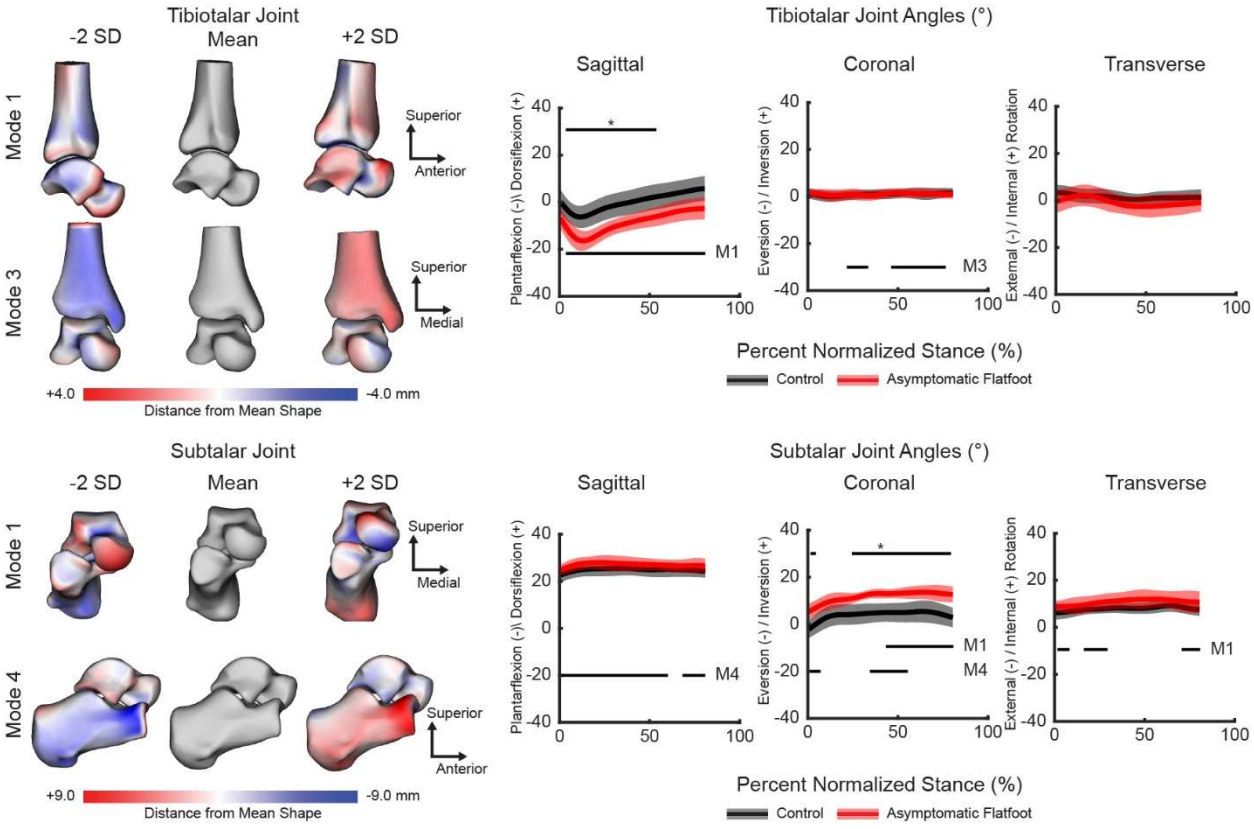
Introduction

Ankle and hindfoot morphology are presumed to influence tibiotalar and subtalar mechanics, yet quantitative studies linking 3D bone shape to dynamic motion remain limited.

Methods

Weightbearing CT scans and biplane fluoroscopy kinematics were collected for asymptomatic flatfoot (AFF, n=10) and control (CNO, n = 13) participants during walking. Two statistical shape models were generated: the tibia-talus complex and the talus-calcaneus complex. Shape scores from principal component analysis (PCA) modes of variation were correlated with stance-normalized joint kinematics using one-dimensional regression (SPM1D, α=0.05).

Results



For the tibiotalar joint, the AFF group was significantly more plantarflexed in early-to-mid stance and had greater transverse-plane range of motion (ROM). Two shape modes significantly correlated with kinematics (Figure 1). PCA Mode 1 showed a plantarflexed joint related to increased plantarflexion throughout stance. PCA Mode 3 showed a flatter talar dome, broader morphology, and external-rotation related to increased inversion during mid-to-late stance. For the subtalar joint, the AFF group was significantly more inverted throughout stance and had greater transverse-plane ROM. Two shape modes significantly correlated with kinematics (Figure 1). PCA Mode 1 showed valgus alignment related to increased inversion during mid-to-late stance and internal rotation during early and late stance. PCA Mode 4 showed steep posterior facet and rounder talar dome related to greater dorsiflexion across stance and inversion during early-to-mid stance.

Discussion

Alignment-related modes (tibiotalar mode 1, subtalar mode 1) primarily influence baseline posture, whereas the curvature and facet-related modes (tibiotalar mode 3, subtalar mode 4) affect joint compliance and motion magnitude. Although group mean shape scores did

not differ, morphology predicted stance-phase kinematics, indicating continuous structure-function coupling rather than discrete group effects. Rounder, steeper articulations were associated with more inverted, compliant mechanics observed in the AFF group, while higher calcaneal pitch and neutral alignment reflected the stiffer control pattern. Subtle shape and alignment differences modulate how the bones move and interact. In some planes, AFF individuals appear to adapt functionally, maintaining near-normal kinematics despite morphological variation, while in others, distinct shape axes determine which portions of stance diverge. Such compensatory coupling between structure and motion may underlie why certain morphologies remain asymptomatic while others progress to deformity.

Racial Differences in Knee Kinematic Outcomes in Response to Injury Prediction and Return to Activity Assessment Tasks: A Pilot Study

Ms. Anita Borhani, Dr. Kristie Liu, Dr. Timothy Burkhart

University of Toronto, Toronto, Ontario, Canada

Introduction

Race is rarely considered in biomechanical research despite documented racial differences in musculoskeletal injuries, perioperative outcomes, knee morphology, and movement mechanics [4, 5]. Hill et al. reported differences in gait, running, and landing mechanics between African Americans (AA) and Caucasian Americans (CA) [1, 2], yet no studies have examined whether similar differences exist in functional tasks used for injury-risk and return-to-activity assessment. Therefore, BIPOC groups may be under-represented in normative biomechanical benchmarks. This study aims to quantify three-dimensional knee kinematic differences between Black Canadians (BC) and White Canadians (WC).

Methods

Twenty-three healthy adults aged 18–35 (10 BC, 13 WC) performed a 90° cutting task and step up/down while markerless motion capture and ground reaction force data were collected. Three-dimensional right knee angles were extracted at movement initiation, and 200 milliseconds after in cutting and at ascent-phase peak vertical ground reaction force in step up/down, to calculate knee range of motion (RoM). Independent t-tests and Cohen's d effect sizes were used to quantify between-group differences ($\alpha = 0.05$).

Results

Knee flexion/extension RoM was significantly greater in BCs (44.39 ± 7.91) than WCs (38.33 ± 8.18, $p = .04$, $d = .75$) during step up/down. No other significant differences were found, although cutting abduction/adduction RoM showed a moderate effect size (BC: 5.34 ± 2.83, WC: 3.87 ± 1.52, $p = .08$, $d = .68$).

Discussion

BCs showed greater sagittal-plane knee RoM during step up/down, suggesting enhanced muscular shock absorption relative to passive structures [3]. Although most comparisons were non-significant, the moderate frontal-plane effect size during cutting aligns with Hill et al.'s finding that AA females exhibited greater frontal-plane knee RoM during landing than

CA females [2]. This suggests that meaningful race-related kinematic differences may exist but remain undetected in small samples. Future work should include larger, sex-stratified cohorts, and neuromuscular and morphological measures to inform more representative functional benchmarks for BIPOC groups.

Images (Optional)

Table 1. Three-dimensional knee RoM (mean ± SD) in the first 200 milliseconds of cutting and between heel-off and the first peak in vertical ground reaction force during the ascent phase of step up/down for Black Canadian (BC) and White Canadian (WC) participants.

		Mean ± SD		Group Comparison	
		BC	WC	p-value	Cohen's d
90° Cut	Flexion/Extension (°)	37.77 ± 8.04	40.16 ± 7.23	.23	-.32
	Abduction/Adduction (°)	5.34 ± 2.83	3.87 ± 1.52	.08	.68
	Internal/External Rotation (°)	7.42 ± 2.51	7.63 ± 2.92	.43	-.07
Step Up/Down	Flexion/Extension (°)	44.39 ± 7.91	38.33 ± 8.18	.04*	.75
	Abduction/Adduction (°)	7.94 ± 4.63	7.84 ± 3.64	.84	.02

Determination of the Subtalar Joint Axis: A Comparison of Methods

M.Sc. Anja Seeger, Prof. Dr. Wilfried Alt

Institute of Sport and Movement Science, University of Stuttgart, Stuttgart, Baden-Württemberg, Germany

Introduction

The orientation of the subtalar axis (STA) might be associated with injury mechanisms of the ankle and knee joints [1]. Therefore, a valid axis determination (deviation, inclination) is necessary. Previously described methods rely either on motion capturing of eversion/inversion movements or on analysing articular surfaces using imaging procedures. There is little literature addressing a direct comparison of these approaches. In this study, we present first results comparing function-based and structure-based STA determination methods using MR.

Methods

Three MRIs of the right foot of 13 participants were obtained: in 15° eversion, 20° inversion, and neutral foot position. Calcaneus and talus were segmented and exported as 3D-files. The structure-based STA was calculated by fitting spheres to the talar articular surfaces following Parr [2] and Montefiori [3] (fig. 1). For determining the function-based STA, an iterative closest point algorithm was used to register the bones in eversion and inversion orientation to neutral orientation. The points on the calcaneus with the least motion between eversion and inversion were identified (fig. 1). Using PCA, a best-fit straight line (the STA) through these points was estimated. Deviation and inclination were calculated with reference to an anatomical coordinate system after Manter [4], based on the neutral MRI. Spearman correlation was applied to deviation and inclination for the following comparisons: function-based vs. Parr, function-based vs. Montefiori, and Parr vs. Montefiori.

Results

Correlation was strong for deviation in all comparisons (function-based - Parr: 0.85; function-based - Montefiori: 0.75; Parr - Montefiori: 0.9). For inclination, correlation was weak between the function-based and both structure-based methods (function-based - Parr: 0.18; function-based - Montefiori: 0.36) but strong between the two structure-based methods (Parr - Montefiori: 0.65).

Discussion

The results for deviation were similar across all methods. However, for inclination, the comparison between function- and structure-based methods showed a clear difference. This abstract includes preliminary results. Data analysis is ongoing and will provide further insight, including additional participants and a comparison to STA determination based on Conconi [5].

Patellar Instability Anatomy Affects Patellofemoral Walking Kinematics: A Subject-Specific Musculoskeletal Modeling Study

Ms. Annette Chang[1], Dr. Anthony Gatti[2], Dr. Shital Parikh[3], Dr. Scott Delp[2], Dr. Seth Sherman[2], Dr. Marissa Sinopoli[1]

[1]Harvey Mudd College, Claremont, CA, United States. [2]Stanford University, Stanford, CA, United States. [3]Cincinnati Children's Hospital Medical Center, Cincinnati, OH, United States

Introduction

Patellar instability can cause pain and osteoarthritis. It is associated with atypical knee anatomy, including patellar tilt, patella alta, trochlear dysplasia, and external rotation of the tibia relative to the femur [1]. Understanding how anatomy influences biomechanics may inform surgical intervention to reduce instability. The goal of this study is to estimate how simulated patellofemoral walking biomechanics differ between knees with and without patellar instability. We hypothesized that knees with patellar instability and atypical patellofemoral anatomy would exhibit elevated measures of dynamic instability, including lateral tilt, lateral shift, and lateral trochlear constraint forces.

Methods

We retrospectively analyzed magnetic resonance images of 8 knees with patellar instability (10-18 years, 4F/4M) and 8 control knees (12-17 years, 4F/4M). We generated subject-specific 3D bone and cartilage meshes from scan segmentations and integrated them into a generic musculoskeletal model [2]. We personalized model parameters, including ligament slack lengths and muscle wrapping surfaces, based on subject-specific anatomy. Next, we ran the COMAK routine in OpenSim with generic gait data [2,3] to compute 12-degree-of-freedom knee kinematics, cartilage pressures, and muscle activations. We extracted three measures of dynamic instability: patellar tilt, patellar shift, and lateral trochlear constraint force. We used statistical parametric mapping to compare the biomechanics between the two groups.

Results

Mean patellar tilt was significantly greater ($p \leq 0.021$) in knees with patellar instability through the first half of stance and from late stance to early swing (0-33% and 50-63% of the gait cycle; Figure A). Knees with patellar instability demonstrated nonsignificant trends toward elevated patellar shift and lateral trochlear constraint force throughout the gait cycle (Figures B, C).

Discussion

These findings demonstrate that knee morphology associated with patellar instability produces elevated patellar tilt, a key measure of dynamic instability, across most of stance. This work establishes a foundation for future research to investigate specific anatomical morphologies that contribute to increased dynamic patellar tilt and to simulate personalized surgical treatments for patients with patellar instability.

Images (Optional)

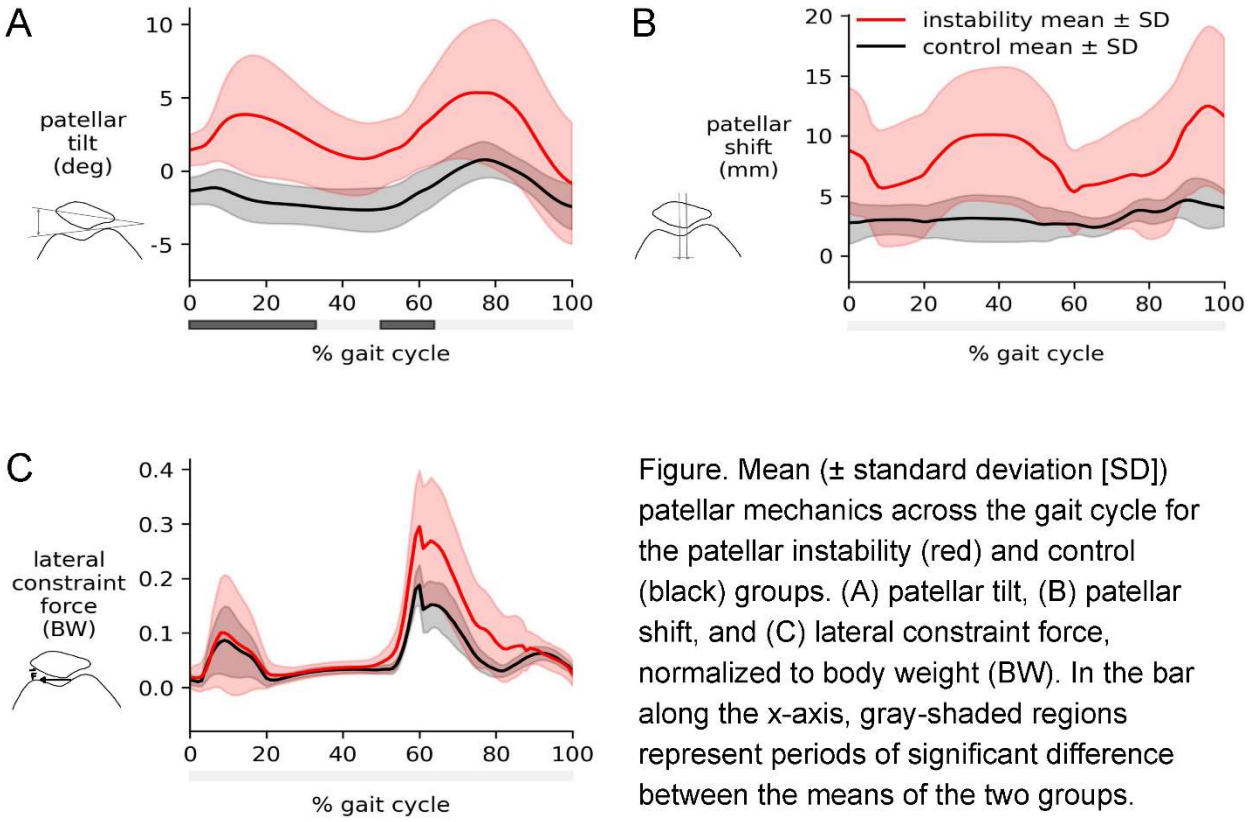

Figure. Mean (± standard deviation [SD]) patellar mechanics across the gait cycle for the patellar instability (red) and control (black) groups. (A) patellar tilt, (B) patellar shift, and (C) lateral constraint force, normalized to body weight (BW). In the bar along the x-axis, gray-shaded regions represent periods of significant difference between the means of the two groups.

Optimizing IMU Configurations for Upper-Limb Kinematics via Regression Neural Network

Mr. Arthur Fabre[1,2], Dr. Wolbert van den Hoorn[1,2], Dr. Laith Alzubaidi[2,3], Prof. Peter Pivonka[2,3], Prof Graham Kerr[1,2]

[1]School of Exercise and Nutrition Sciences, Queensland University of Technology, Brisbane, Queensland, Australia. [2]Australian Research Council Training Centre in Joint Biomechanics, Queensland University of Techonology, Brisbane, Queensland, Australia. [3]School of Mechanical, Medical & Process Engineering, Queensland University of Technology, Brisbane, Queensland, Australia

Introduction

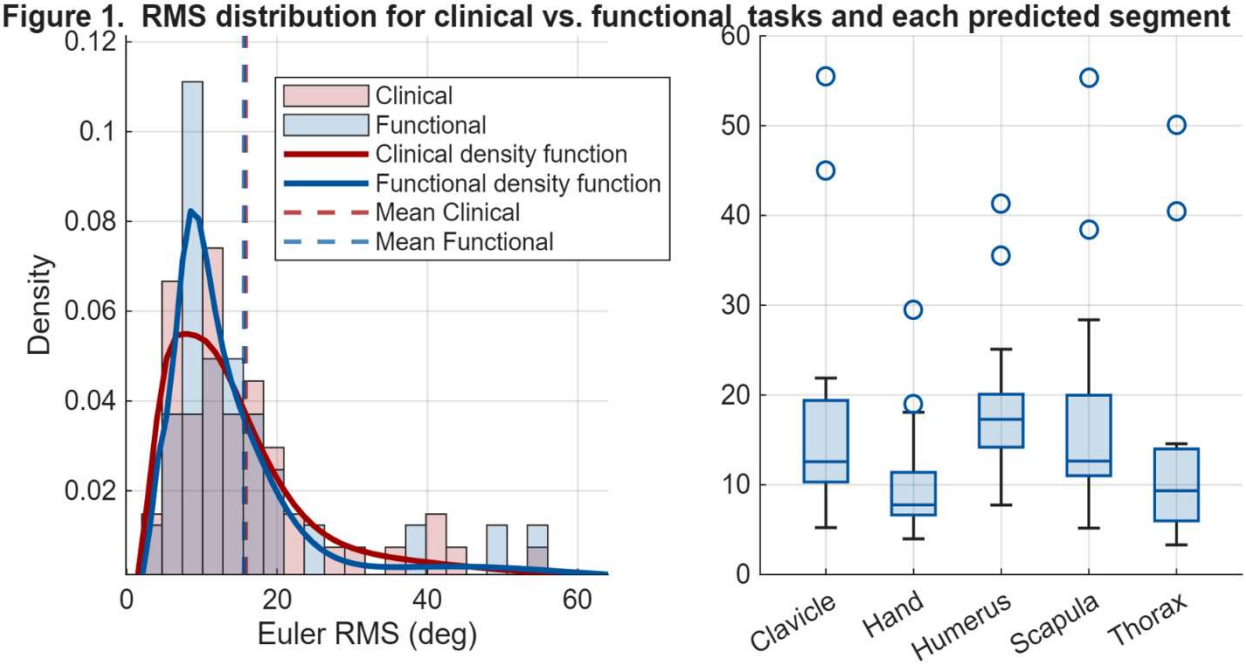
Inertial-measurement-units (IMUs) enable portable three-dimensional assessment of upper-limb joint orientation. Current multi-sensors configurations are burdensome and impractical for clinical or remote monitoring [1]. Reduced configurations would improve compliance, ecological validity and their adoption in multiple settings [2]. This study explored the accuracy of a regression-neural-network (RNN) in the prediction of IMU-derived upper limb and shoulder segment orientations from a single wrist sensor.

Methods

An RNN was developed to predict the orientation of the thorax, clavicle, scapula, upper arm and hand segments using the wrist. The network included two hidden layers (128 and 64 neurons) with rectified linear unit activation, L2 norm regularization and standardized predictors. Twenty participants performed clinical (e.g. internal/external rotation, humerothoracic flexion, abduction) and functional tasks (e.g. box transfer to a shelf, walking, running) while IMUs recorded segment kinematics. The predictors included segment quaternions and angular velocities of the wrist; the response was the quaternion orientation of the remaining body segments. Data were normalized, randomized, and split by participant. Model performance was assessed using root mean square of the decomposed error quaternion (RMS) and coefficient of determination (R^2) of the predicted quaternion.

Results

Using the wrist as the sole predictor yielded the highest accuracy for estimating hand orientation (RMS: 8°, see Figure 1, R^2: 0.83). Predictions for the humerus were moderately accurate (RMS: 17°, R^2: 0.42), while scapula and thorax showed similar errors and lower agreement (RMS: 14° and 9°; R^2: 0.22 and 0.20, respectively). Clavicle predictions were



poorest, with RMS of 13° and near-zero R^2 (0.03). Overall, prediction accuracy decreased with increasing anatomical distance from the wrist, confirming its strong predictive value for distal segments and limited utility for proximal ones.

Discussion

This work demonstrates the potential for optimizing IMU configurations to simplify upper-limb motion assessment while improving wearability and remote monitoring. Future research should explore physics-informed neural networks [3] and multi-predictor strategies to enhance accuracy and generalizability across tasks, as these models can embed biomechanical constraints into learning and improve temporal coherence in the prediction of IMU-derived body segment orientation.

Hidden Segmental Asymmetries in Lumbar Spine Motion: Implications for Spinal Pathologies and Clinical Assessment

Dr. Asghar Rezaei, Mr. Alexander Hooke, Dr. Babak Dashtdar, Mrs. Areonna Schreiber, Dr. Abdelrahman Hamouda, Dr. Kai-Nan An, Dr. Benjamin Elder, Dr. Kenton Kaufman, Dr. Lichun Lu

Mayo Clinic, Rochester, MN, United States

Introduction

The lumbar spine's multiplanar motion is vital for daily function, but segmental asymmetries may contribute to spinal pathologies such as low back pain and deformity. While global symmetry is often assumed, hidden segmental differences in torque and range of motion (ROM) may underlie uneven vertebral loading and disease progression. This study aims to quantify segmental kinematics and asymmetry in human lumbar spines, advancing understanding of spinal biomechanics and informing clinical strategies.

Methods

Six cadaveric lumbar spines were imaged and prepared for biomechanical testing. Fiducial markers enabled precise 3D tracking of vertebral motion using optical metrology. Specimens were mounted to a 6-degree-of-freedom robotic system, which applied controlled flexion-extension, lateral bending, and axial rotation. Motions were initiated from neutral and progressed to maximum ROM under quasi-static loading. Segmental torque and ROM asymmetries were calculated as normalized differences between right and left sides. Imaging findings were correlated with biomechanical data to explore associations between pathologies and asymmetry.

Results

Segmental ROM asymmetry exceeded 40% and torque asymmetry surpassed 15% in several vertebrae, even when global outputs appeared symmetrical. Asymmetry patterns varied within and between spines. Imaging revealed degeneration and deformities that partially explained subject-specific asymmetries, but no universal pattern was found. Some subjects showed compensatory adaptations between segments, suggesting complex biomechanical interplay.

Discussion

Segmental asymmetries in torque and ROM are prevalent in the lumbar spine and may contribute to uneven loading and progression of spinal disorders. The study's novel

approach highlights limitations of global assessments and underscores the need for segment-level analysis. Findings support individualized, pathology-specific interventions and suggest further research with larger cohorts is needed. Overall, segmental biomechanical analysis advances understanding of lumbar spine function and informs clinical practice.

The Functional Strength Landscape of the Human Foot-Ankle Complex

Dr. Aubrey Gray[1], Dr. Ross Smith[2], Dr. Kota Takahashi[3], Dr. Jason Franz[4,5]

[1]University of Massachusetts Amherst, Amherst, MA, United States. [2]University of Memphis, Jackson, TN, United States. [3]University of Utah, Salt Lake City, UT, United States. [4]University of North Carolina at Chapel Hill, Chapel Hill, NC, United States. [5]North Carolina State University, Raleigh, NC, United States

Introduction

The human foot and ankle are governed by form-function interactions involving active muscle force, passive series elastic structures, and joint articulations. Prior work has suggested that the sophisticated network of intrinsic and extrinsic force-generating and force-transmitting structures may yield a "strength landscape" of maximum force-generating potential for the plantar intrinsic muscles (PIM) and plantar flexors (PF). However, no study to date has characterized the functional strength landscape of the foot-ankle complex across ankle and metatarsal phalangeal (MTP) joint postures in context of walking kinematics and timing of muscle excitations. We hypothesized that MTP extension would offset declines in the force-generating potential of the foot-ankle complex (i.e., PF + PIM) with ankle plantarflexion – coinciding with late stance kinematics and peak calf and intrinsic foot muscle excitations during walking.

Methods

22 younger adults (26±5 years, 15F/7M, 74.3±13.7kg, 1.7±0.1m) participated. Participants completed PF and PIM maximum voluntary isometric contractions (MVICs) on a Biodex dynamometer (PF) and a foot dynamometer (PIM) across combinations of ankle and MTP joint postures. Specifically, at 3 ankle joint angles (20˚ dorsiflexion, 0˚ neutral, and 20˚ plantarflexion) we tested 3 MTP joint angles (0˚, 30˚ and 60˚ MTP extension) and vice versa, for a total of 9 MVIC conditions. Participants also walked at 1.4 m/s while we recorded joint kinematics and excitations of the soleus, medial gastrocnemius, and flexor digitorum brevis.

Results

An interaction (p=0.001) revealed that ankle angle (p=0.018) more than MTP angle (p=0.062) affected PF strength (Fig. 1A). The interaction also revealed that MTP extension decreased PF strength when in ankle dorsiflexion but increased PF strength when in ankle plantarflexion. Conversely, although not supported by a significant interaction (p=0.256),

we found that MTP angle ($p<0.001$) but not ankle angle ($p=0.558$) affected PIM strength (Fig. 1B). Coincident joint kinematics and muscle excitations supported the hypothesis.

Discussion

These findings demonstrate that the interaction between ankle and toe postures plays a critical role in preserving force-generating potential of the foot-ankle complex through push-off in walking. Potential explanations are that MTP extension enables favorable force-length conditions and/or removes series elastic tissue slack for biarticular extrinsic foot muscles contributing to push-off.

Evaluation and Comparison of Muscle Forces Estimates from a Musculoskeletal Model with EMG during Obstacle Crossing in Soldiers

Mr Aurélien Schuster[1,2], Dr Charles Pontonnier[2], Pr Georges Dumont[2]

[1]Centre de Recherches des écoles de Saint-Cyr Coëtquidan, Guer, Britanny, France. [2]Univ Rennes, Inria, CNRS, IRISA, M2S, Rennes, Britanny, France

Introduction

The increase in load carried in military contexts contributes to onset of musculoskeletal disorders such as low back pain. Musculoskeletal analysis, particularly muscle forces estimation, can help quantify these problems and understand the injuries mechanisms. Most studies on muscle activity focus on walking or running, whereas studying other operational tasks such as obstacle crossing could improve model validation [1]. This study examines lower back muscle forces estimates during obstacle crossing using electromyography as a reference.

Methods

Five soldiers performed five obstacle-crossing trials using the same technique. Participants provided informed consent and the protocol was approved by the National Ethics Committee (CPP n°2024-A02736-41). Forty-eight reflective markers were placed on anatomical landmarks following ISB recommendations. Surface EMG were placed on each side of the iliocostalis, longissimus, and multifidus muscles, according to SENIAM guidelines. Reaction forces were measured using ground force plates and sensors on the obstacle. Using a full-body musculoskeletal model with an articulated thoracolumbar spine [2], inverse dynamics and static optimization calculations with CusToM [3], the lower trunk joint torques (L5/S1) were extracted, and muscle forces were estimated and compared to EMG via cross-correlation for each acquisition.

Results

Marker tracking errors showed a mean RMS of 1.61 ± 0.28 cm. The highest mean dynamic residuals reached 4.24 ± 1.02%peakRF for vertical forces and 2.08 ± 0.34%peakRF·hCOM for moments in the transverse plane. The means (±SD) of normalized muscle forces and EMGs are shown in Figure 1(a), with takeoff and landing indicated (Figure 1(b)).

Discussion

Strong correlation coefficients (r > 0.7) indicate good agreement between estimated muscle forces and EMG regarding activation timing. Peak forces were found in longissimus and multifidus before lift-off matching with peak extension torques. Similarly, peak lateral flexion torques between lift-off and landing matched higher iliocostalis muscle forces and EMG. Despite tracking errors consistent with the literature, the dynamics residuals call for caution in interpreting these results. Moreover, large standard deviations in EMG and muscle forces suggest important inter-individual strategies that warrant further investigation.

The Effects of Cues to Run Softly and Quietly vs. Changing to a Forefoot Strike Pattern on Kinetics and Kinematics in Healthy Individuals

Dr. Caleb Johnson, Mr. Cole Dempsey, Mr. Lucas Sarantos, Mr. David Zeppetelli

U.S. Army Research Institute of Environmental Medicine, Natick, MA, United States

Introduction

Cues to run softly/quietly (SOF) have been shown to be a viable gait modification for reducing external forces during running, even compared to shifting to a forefoot strike pattern (FFS). However, no studies have compared changes in joint kinetics/kinematics between these two modifications.

Methods

33 participants completed testing, including running with habitual gait (HAB), as well as with the SOF and FFS modifications, on an instrumented treadmill while optical motion capture was used to capture three-dimensional kinematics. Variables of interest included: a) frontal/sagittal plane peak hip/knee/ankle moments, as well as sagittal knee stiffness, b) frontal/sagittal plane joint angles and sagittal foot angles at initial contact (foot strike angle). One-way repeated measures ANOVAs (1x3) were used to compare variables between gait conditions.

Results

Full results are reported in the Table. Due to the large number of statistically significant differences found, we chose to focus on “key differences” based on those having at least a moderate effect size (Cohen’s $d \geq 0.5$). The SOF condition showed increased hip extension (vs. FFS) and flexion (vs. HAB/FFS) moments, and reduced knee stiffness (vs. HAB/FFS) and ankle plantarflexion moments (vs. FFS). The FFS condition also showed increased knee flexion and ankle plantarflexion moments compared to HAB. For kinematics, the SOF condition showed higher peak knee flexion angles (vs. HAB/FFS) and excursion (vs. HAB), foot strike angles (vs. HAB/FFS), peak/initial contact ankle dorsiflexion angles (vs. FFS), and peak eversion angles (vs. FFS), as well as lower initial contact ankle inversion angles (vs. FFS). The FFS condition also showed lower initial contact ankle dorsiflexion angles and foot strike angles (i.e., plantarflexion), and increased initial contact inversion angles, compared to HAB.

Discussion

These results provide support for the SOF modification as an alternative to FFS for reducing biomechanical loading during running, especially in reducing knee/ankle forces. However, the increases in hip joint forces lead to some caution for its use in those susceptible to hip injuries and warrant further investigation.

Stride Characteristics in an Accelerative Figure-Eight Maneuver During Competitive Chuckwagon Racing

Ms. Camille Eamon MSc, BSc[1], Mr. Matthijs van den Broek BSc[1,2], Dr. Karelhia Garcia Alamo DVM, MSc[1], Ms. Charlotte de Bruyne MSc, BSc[1], Ms. Brittany Davis MSc, BSc[1], Ms. Maggie Fallscheer[1], Ms. Sara Frostad[1], Ms. Sara Skotarek Loch MSc, BSc[1], Dr. Edmond Pajor PhD, MSc, BSc[1], Dr. Renate Weller DVM, PhD, MSc[1], Dr. Zoe Yau Shan Chan PhD, MPhil, BE[1], Dr. Thilo Pfau Dr.-Ing, Dipl.-Ing[1]

[1]University of Calgary, Calgary, Alberta, Canada. [2]Delft University of Technology, Delft, South Holland, Netherlands

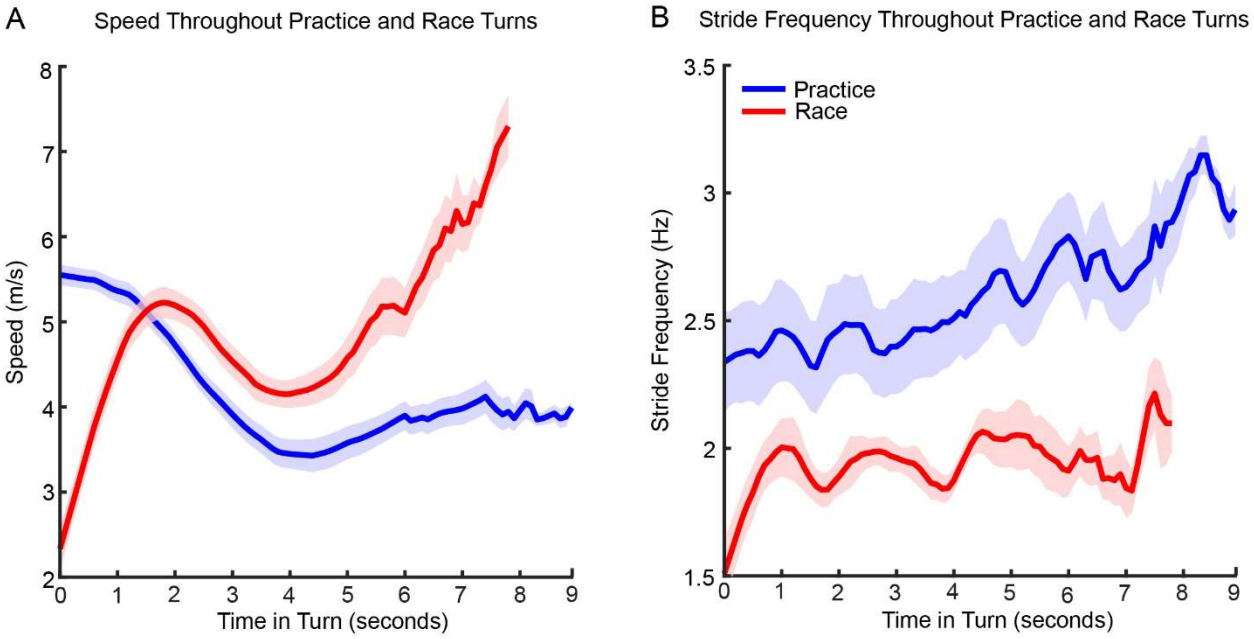
Introduction

In Chuckwagon racing, teams of four Thoroughbred racehorses pull a wagon on dirt racetracks. Each horse has a position as left or right leader (LL, RL) or wheeler (LW, RW). Races begin with a figure-eight maneuver around two barrels, which is not seen in other disciplines. Previous work has used stride characteristics to predict racehorse injury risk [1], but limited work has been done in Chuckwagon racing. Using wearable sensors, we previously showed that one Chuckwagon racehorse who sustained a catastrophic fracture while racing as a RW had highly asymmetrical movement in the days leading to the injury. Here we quantified this horse's stride characteristics in the figure-eight and compared them to other RWs and RLs.

Methods

Over ten race days, 8 RLs and 9 RWs (1 injured) wore Global Navigation Satellite Systems combined with Inertial Measurement Units (GNSS-IMUs) sampling at 25Hz on their harnesses at the midline of the back in the cranial/mid thoracic area. GNSS speed and position data were recorded during practice figure-eights (minutes before race start) and race figure-eights. Stride cycles were identified from speed plots to calculate stride frequency (SF). Linear mixed models compared SF between practice and race figure-eights with speed as a covariate and horse as a random factor ($p<0.05$).

Results



Thirty-six figure-eights (18 practice, 18 race) were analyzed. Four maneuvers were obtained for the injured horse: practice and race four days pre-injury, and on the day of injury. Mean speed was 4.23m/s in practice and 4.70m/s in race for all horses (Figure 1A). Uninjured horses showed higher SF in practice (2.60Hz) than race (1.98Hz; $p<0.001$; Figure 1B). The

injured horse had higher SFs than others four days pre-injury (practice 3.06Hz, race 1.92Hz) and on the day of injury (practice 3.18Hz, race 1.90Hz).

Discussion

SF was higher in practice figure-eights, with the injured horse exhibiting higher practice SFs than other horses. More data is needed to characterize normal stride characteristics during this unique maneuver and identify horses at an increased injury risk. GNSS-IMU devices offer a practical tool for non-disruptive monitoring to support proactive injury management.

Effect of Race Progression on Speed and Stride Parameters in Chuckwagon Racehorses

Dr. Thilo Pfau Dr.-Ing, Dipl.-Ing[1], Ms. Camille Eamon MSc, BSc[1], Mr. Matthijs van den Broek BSc[1,2], Ms. Charlotte de Bruyne MSc, BSc[1], Ms. Brittany Davis MSc, BSc[1], Ms. Maggie Fallscheer[1], Ms. Sara Frostad[1], Dr. Karelhia Garcia Alamo DVM, MSc[1], Ms. Sara Skotarek Loch MSc, BSc[1], Dr. Renate Weller DVM, PhD, MSc[1], Dr. Edmond Pajor PhD, MSc, BSc[1], Dr. Zoe Yau Shan Chan PhD, MPhil, BE[1]

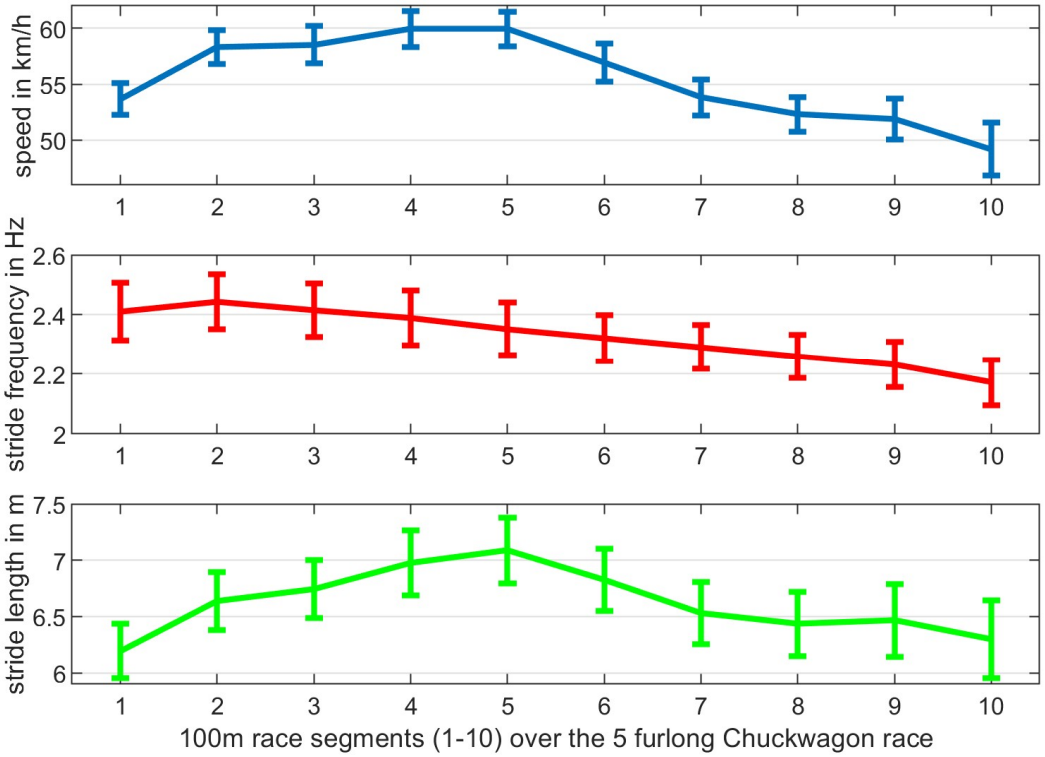
[1]University of Calgary, Calgary, Alberta, Canada. [2]Delft University of Technology, Delft, South Holland, Netherlands

Introduction

Chuckwagon racing is a competitive horseracing event where teams of four Thoroughbreds pull a 600kg wagon around a dirt racetrack. There is a lack of fundamental knowledge about associations between speed, stride parameters and Chuckwagon race characteristics and this limits the development of predictive injury models similar to models emerging for other disciplines.

Methods

59 Chuckwagon horses competing at the 2025 Calgary Stampede Rangeland Derby were equipped with global navigation satellite system (GNSS) loggers attached to their harnesses. Average speed, stride frequency (SF) and stride length (SL) were calculated for 100m race segments using validated algorithms. Linear mixed models (random factor: horse, fixed factor: race segment) were implemented for speed, SL and SF. Additional models for SL and SF included speed as fixed covariate and track geometry information ($1^{st}/2^{nd}$ curve, $1^{st}/2^{nd}$ straight) as fixed factor. Significance was set to $p<0.05$ with Bonferroni correction for multiple comparisons.



Results

Speed increased from the start and plateaued around 60 km/h towards the end of the first straight (segments 4 to 5, Fig 1A), then decreased continually. SF (Fig 1B) increased rapidly peaking in segment 2 (2.43Hz) then dropping. SL peaked later (segment 5, Fig 1C, 7.11m) before dropping in alignment with speed. Significant effects of race segment were found for all three variables (all $p<0.001$). Models including speed as covariate (mean speed of 55.5 km/h) showed a significant interaction between speed and geometry. SF was approximately 0.1Hz higher (and SL 0.3m lower) in the 1^{st} compared to the 2^{nd} curve and compared to both straights (all pairwise $p<0.001$).

Discussion

This study presents in-race speed and stride parameters for competitive Chuckwagon horseracing using a validated GNSS-logger. Speed and SL reach peak values at the end of the first straight. Consequently, the track should be monitored in this region where peak vertical ground reaction forces occur in the limbs. Changes in SL between track segments exceed the changes observed previously in the runup to injury emphasizing the need for detailed discipline-specific stride parameter models.

Two Ultrasonographic Methods of Evaluating Acromio-Humeral Distance: Intra- and Inter-rater Reliability in Young, Healthy Participants

Dr. Christa Nelson PT, DPT, PhD, Dr. Lance Grunert PT, DPT, Dr. Eleni Papastratakos PT, DPT, Dr. Nate Rusk PT, DPT, Dr. Ana Maria Acosta PhD

Northwestern University Feinberg School of Medicine, Department of Physical Therapy and Human Movement Sciences, Chicago, IL, United States

Introduction

Shoulder subluxation is a debilitating condition that can significantly affect shoulder mobility and participation in daily activities. Clinically, subluxation is measured through finger breadth palpation or tape measurements, but this lacks precision and reliability. Advanced imaging methods such as MRI, CT or radiographs can quantify subluxation but are costly or expose patients to radiation. Ultrasound (US) provides an accessible alternative and has been used to evaluate humeral position in shoulder impingement, glenohumeral instability, and post-stroke, but it often requires advanced training. Two ultrasonographic measures have been described: the acromio-humeral distance (AHD) and the acromio-greater tuberosity distance (AGT), but reliability information is limited and only reported using expert ultrasonographers. No known studies have examined reliability of these measures when performed by novice raters. The purpose of this study was to evaluate intra- and inter-rater reliability of AHD and AGT measurements obtained by novice ultrasonographers.

Methods

Thirteen adults with no prior shoulder pathology (7 female, 6 male; age = 24.5 ± 2.3 years) participated. Using 2-D ultrasound (Aixplorer Multiwave), two randomly selected (out of three possible) novice ultrasonographers acquired three images per shoulder for both AHD and AGT (24 total images / participant). Images were imported into Fiji ImageJ software, where two random raters measured AHD and AGT in each image. Intra- and inter-rater reliability were calculated using ICCs with 95% confidence intervals.

Results

AHD measurements demonstrated excellent single rater reliability with ICC (95% CI) = 0.96 (0.94, 0.97) and excellent inter-rater reliability with ICC (95% CI) = 0.98 (0.97, 0.99). Results for AGT measurement demonstrated excellent single rater reliability with ICC (95%CI) =

0.98 (0.96, 0.98) and excellent inter-rater reliability with an ICC (95% CI) = 0.99 (0.98, 0.99). Intra-rater reliability for AHD was excellent with test-retest reliability ICC (95% CI) = 0.90 (0.87, 0.93), and good for AGT ICC (95% CI) = 0.86 (0.81, 0.89).

Discussion

US proved to be a repeatable, reliable method to evaluate AHD and AGT distance with good-excellent intra- and inter-rater reliability across 3 novice ultrasonographers. AHD was the most reliable between the two measures. Future work is indicated to evaluate these measures in different shoulder positions and clinical populations.

Uneven and Loose Surfaces Challenge the Ankle Joint Complex by Increasing Frontal Plane Angles and Moments During Walking

Dr Clare Milner PhD, Mr Dylan Mulligan MS

Drexel University, Philadelphia, PA, United States

Introduction

Laboratory-based studies of gait typically measure biomechanics during walking over level ground. However, walking in the outdoor environment often includes uneven or loose surfaces that likely alter gait biomechanics. These surfaces may increase the risk of injury such as ankle sprains by increasing frontal plane movement in the ankle joint complex. The purpose of this study was to compare frontal plane ankle biomechanics during walking over level, uneven, and loose surfaces. We hypothesized that frontal plane range of motion and moments would be largest on the loose surface, then the uneven surface, and smallest during level walking.

Methods

As part of an ongoing study, 5 young healthy adults provided written informed consent to participate (4 female, 1 male, age 23.4 (0.5) years, height 1.70 (0.05) m, weight 74.4 (13.8) kg). All procedures were approved by the Institutional Review Board. Motion capture (200Hz) and force plate (1000Hz) data were collected as participants walked over level ground, a fixed uneven surface, and a loose rocks surface in sneakers. Each surface was instrumented with a force platform. Gait data were processed in Visual3D and MATLAB and frontal plane angles and internal moments extracted for three steps per condition per participant. Effect size was used to evaluate differences among conditions.

Results

Both uneven and loose surfaces had a large effect for increased frontal plane range of motion and peak inversion moment during walking (Table 1). Peak eversion moment was decreased with a moderate effect on the uneven surface, but moderately increased on the loose surface. Generally, the loose surface had greater effects compared to the uneven surface.

Discussion

Walking surface profile affects frontal plane ankle range of motion and peak internal inversion moment in young healthy adults. Effects varied according to surface type and were greater during walking on a loose surface than a fixed uneven surface, and both were

greater than during level surface walking. Investigators should consider including multiple surface types likely to be encountered in everyday life in gait assessments to better reflect the changing demand on the ankle joint complex.

Images (Optional)

Table 1: Mean and standard deviation of frontal plane angle range of motion and peak moments during walking on different surfaces.

	Range of Motion (degrees)	Peak Inversion Moment (Nm/kg)	Peak Eversion Moment (Nm/kg)
Level ground	13.5 (4.2)	0.14 (0.05)	-0.10 (0.07)
Uneven surface	18.5 (3.2)	0.21 (0.10)	-0.05 (0.06)
Loose surface	22.2 (10.3)	0.24 (0.14)	-0.20 (0.27)
Effect Size uneven vs level	1.35	0.93	-0.77
Effect Size loose vs level	1.29	1.05	0.59
Effect Size loose vs uneven	0.55	0.25	0.91

Sex-Dependent Effects of Footwear Longitudinal Bending Stiffness on Metatarsal Strains During Running

Dr. Colin Firminger PhD[1], Dr. Sarah Manske PhD[2], Dr. W. Brent Edwards PhD[1], Dr. Michael Asmussen PhD[3]

[1]Human Performance Lab, University of Calgary, Calgary, AB, Canada. [2]University of Calgary, Calgary, AB, Canada. [3]Vancouver Island University, Nanaimo, BC, Canada

Introduction

Second and third metatarsal stress fractures are highly prevalent overuse injuries amongst runners, with females facing nearly twice the stress fracture risk as men [1]. Stress fracture development is associated with repetitive bone strain, and shoes with increased longitudinal bending stiffness (LBS) may represent an intervention to reduce metatarsal strain during running [2]. Therefore, the purpose of this research was to examine the effect of shoe LBS on metatarsal strains in female and male runners.

Methods

Sixteen athletes (8 female) ran at 3.3 m/s on an instrumented treadmill wearing a high-LBS (0.54 Nm) and low-LBS (0.28 Nm) Nike Alphafly 3 while plantar pressure and motion capture data were recorded. The high-LBS shoe was unmodified, while the low-LBS shoe had six medial-lateral cuts in the forefoot through the embedded carbon fibre plate. Musculoskeletal models of the second and third metatarsophalangeal joints were used to estimate metatarsal loading during stance [3], and weight-bearing computed tomography (WBCT) scans with concurrent motion capture were taken at different running-specific metatarsophalangeal angles to establish relationships between WBCT-measured and motion capture-estimated metatarsal orientations. Subject-specific finite element models were then created using bone geometry from the WBCT scans and solved from 30-80% of stance, with peak strain being tabulated for statistical analysis.

Results

Female runners illustrated significantly lower peak strain in the high-LBS shoe for the second ($p=0.024$) and third ($p=0.050$) metatarsals, while no significant change was observed for males ($p\geq0.262$; see Figure 1). Decreased peak second metatarsal strains in the female runners were associated with significant reductions metatarsal load ($p=0.027$) in the high-LBS condition, while metatarsal orientation remained consistent ($p=0.222$).

Discussion

This study is the first to systematically evaluate the effect of shoe LBS on metatarsal strains, illustrating significant reductions in strain for the second and third metatarsals in the high-LBS shoe amongst female runners. In terms of metatarsal stress fracture risk, this research elucidates potential benefits of using high-LBS shoes in a population of female runners.

Images (Optional)

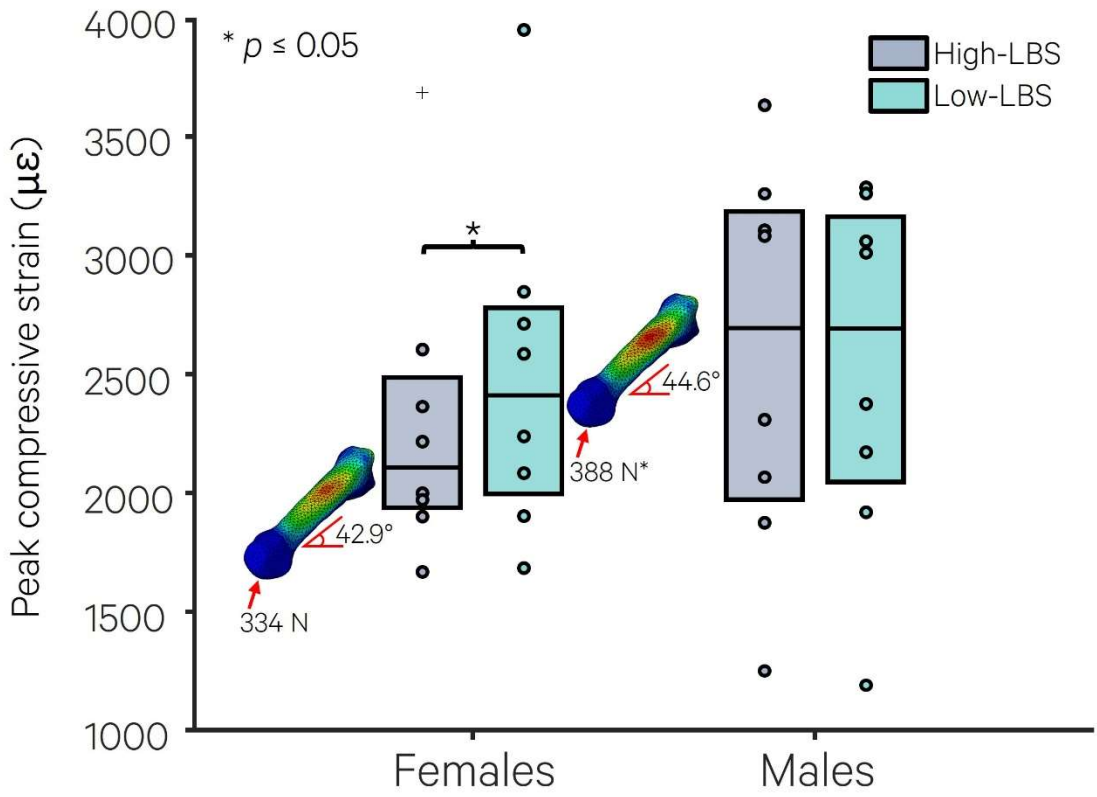

Figure 1: Second metatarsal peak compressive strains for females (n=8) and males (n=8). Finite element modelled strains are shown for a representative female subject with group-averaged metatarsal head force and orientation overlaid.

Biarticular Muscle Control for a Multi-joint In Vitro Physiological Lower-limb Simulator: A Phantom Study

Mr. R. Yogeshwar Rao, Mr. Shridhar Iyer, Mr. Eshan Kshatriya, Dr. Darshan S. Shah PhD

BiOME Lab, Indian Institute of Technology Bombay, Mumbai, Maharashtra, India

Mr. R. Yogeshwar Rao

Introduction

In vitro physiological knee simulators replicate joint kinematics and kinetics and are widely used to evaluate knee biomechanics before and after surgery [1]. Most simulators control knee flexion and apply quadriceps/hamstring loads to achieve a target vertical ground reaction force, but they typically actuate a single quadriceps tendon despite physiological activation arising from both the uniarticular vastii and the biarticular rectus femoris. This actuator mismatch reduces simulator fidelity for tasks requiring coordinated multi-muscle activation. Therefore the aim of the study was to evaluated a hybrid biarticular controller on a multi-actuator lower-limb simulator.

Methods

A two degree-of-freedom scaled sagittal-plane lower-limb model was fabricated with the linkage geometry and mass distribution chosen to femur and tibia proportions [3] (Fig. 1). Dynamic muscle forces were simulated by linear actuators (TiMotion, Taiwan) connected via steel cables to replicate lines of action of uniarticular (vasti, iliopsoas) and biarticular (hamstrings, rectus femoris) muscles. Inline S-beam load cells (Rudra sensors, India) measured muscle forces, while optical encoders (Potel, India) measured hip and knee flexion angles. A novel hybrid controller architecture consisting of position feedback controllers for the hip and knee joint angles, along with force feedback controllers for each muscle enforcing muscle-specific bounds corresponding to muscle capacity. Four input scenarios based on combinations of the following three setpoints for the hip and the knee flexion – fixed (constant), flexion-extension (FE; 0°-40°-0°), extension-flexion (EF; 40°-0°-40°) – were performed in triplicate. Mean of the root mean square errors across trials and their standard deviations were used to evaluate controller accuracy and repeatability, respectively.

Results

Repeatability improved by 74% for biarticular motions, as compared to uniarticular motions (Fig. 1). Accuracy decreased by 52% for out-of-phase biarticular motion, as compared to in-phase motion.

Discussion

The study demonstrated an accurate and repeatable biarticular controller for a multi-joint simulator, although certain motion combinations exhibited higher tracking errors that highlight actuator redundancy and biarticular coupling. These issues can be mitigated by adding biarticular load-sharing blocks with a redundancy-handling capability to the controller. Future work will validate the hybrid biarticular controller on a human-scaled physiological knee simulator with native cadaveric specimens.

Ankle Kinetics in Persons with Achilles Tendinopathy During Unipedal Repetitive Vertical Hopping

Dr. David Ortiz-Weissberg PhD[1,2], Dr. Kornelia Kulig PhD, PT, FAPTA[1]

[1]University of Southern California, Los Angeles, CA, United States. [2]University of San Diego, San Diego, CA, United States

Dr. David Ortiz-Weissberg

Introduction

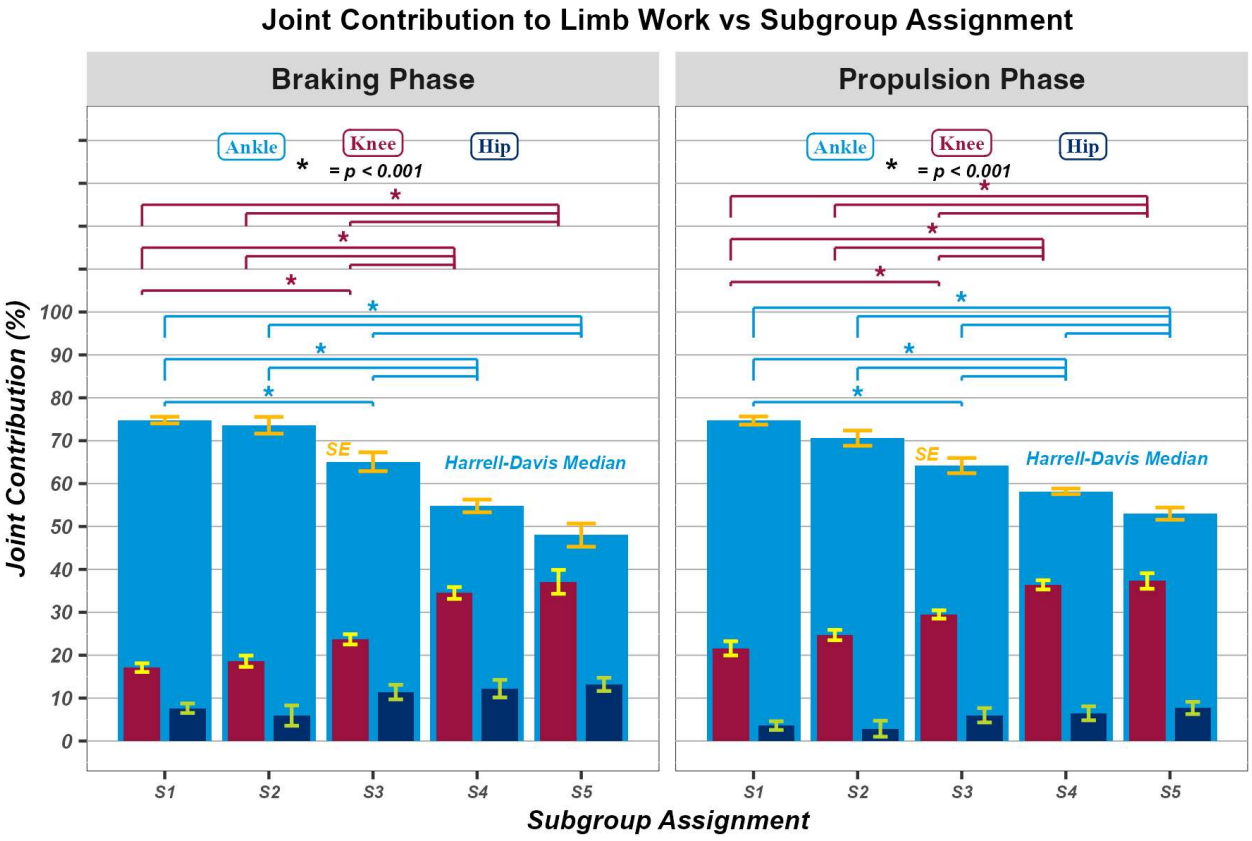
The Achilles tendon is the largest tendon in the body and aids in propulsion during numerous tasks. Given that the Achilles is the primary plantar flexor tendon, Achilles tendinopathy may have negative consequences for movement. Investigating ankle joint kinetics is crucial for understanding how Achilles tendinopathy impacts ankle function and movement. Repetitive vertical hopping is the only multi-joint task where the joint energetics are consistently greatest at the ankle across task speeds and phases, making it the optimal task for examining ankle kinetics.

This study aimed to examine how Achilles tendinopathy impacts ankle kinetics during unipedal vertical hopping. We hypothesized that the involved limb would exhibit reduced ankle contributions to limb-level energy relative to unaffected limbs.

Methods

We recruited 27 persons with and 27 without a history of Achilles tendon pain or morphologic alterations. Participants were tasked with unipedal repetitive vertical hopping at 2.33 Hz on both limbs. The joint contribution to limb energy was the ratio of NJM work to the sum of joint work. Robust paired difference tests were used to compare the ankle contribution to limb energy between the involved limb and a matched healthy control limb. To account for the high variance, k-means clustering of all available limbs was performed (clustering variable: average power). The ankle and knee contributions were compared between clusters using robust confidence intervals.

Results



At the whole-group level, there were no significant between-group differences in ankle contributions to limb-level energy absorption and generation. The k-means clustering

identified five subgroups. Subgroups 4 and 5 displayed significantly lower ankle and greater knee contributions (both absorption and generation) than the other subgroups (Figure 1). 28 of the 37 limbs with a history of Achilles tendinopathy were assigned to Subgroups 4 and 5.

Discussion

This is the first study to characterize joint kinetics in persons with Achilles tendinopathy using a task that is dynamic and ankle-driven and thus challenges the ankle. The subgroups confirms that persons with Achilles tendinopathy frequently display impaired ankle kinetics and compensatory increases in knee kinetics. However, this is not universally true: some symptomatic limbs were placed in subgroups with high ankle kinetic magnitudes.

Combinations of Three-Dimensional Tibiofemoral Geometries in Young Female Athletes Are Related to Increased Anterior Cruciate Ligament Force Estimated from Computational Models

Mr. David Shamritsky MEng[1], Ms. Isabella Gomez Hjerthen BS[1], Dr. Mitchell Wheatley PhD[1], Dr. Andrew Pechstein PhD[1], Mr. Julius Kim BS[1], Dr. Danyal Nawabi MD[1], Dr. Thomas Wickiewicz MD[1], Dr. Andrew Pearle MD[1], Dr. Bruce Beynnon PhD[2], Dr. Carl Imhauser PhD[1]

[1]Hospital for Special Surgery, New York, NY, United States. [2]University of Vermont, Burlington, VT, United States

Introduction

Features of tibiofemoral bony geometry are associated with young female athletes' risk of sustaining noncontact anterior cruciate ligament (ACL) rupture. However, the relationship between bony geometry and ACL loading in this high-risk population remains unclear. Our objective was to identify three-dimensional variations in female tibiofemoral bony geometry that are related to estimates of ACL force using physics-based computational modeling.

Methods

Three-dimensional (3D) renderings of tibiofemoral bone, cartilage, and menisci were generated from magnetic resonance imaging of 60 female athletes with a noncontact ACL tear and 60 matched uninjured athletes (mean age: 17±2 years). Computational models were constructed by mapping the cruciate, collateral, and capsular ligaments onto the 3D renderings and applying standardized properties to these ligaments. The tibia was then flexed to 15° and loaded with 100 N compression, 8 Nm valgus moment, and 30 N anterior force to simulate the clinical pivot shift exam. ACL force at peak applied load was estimated for each subject. Statistical shape modeling was used to quantify variations in bony geometry. All 120 geometries were cropped to isolate the distal femoral condyles and the tibial plateau. Then, a mesh correspondence and alignment algorithm was applied. Finally, principal component analysis identified the ten principal components (PCs) with largest contributions to total geometric variation. These ten PCs were related to ACL force using stepwise multiple regression (α=0.05). The increase in ACL force corresponding to a 2-standard deviation (SD) change in each significant PC was reported to describe their relative impact on ACL force.

Results

ACL force averaged 124±33 N across all 120 female subjects. PCs with the fourth and seventh largest contributions (PC4: 5.4% and PC7: 2.8% of total variation, respectively) were correlated with ACL force ($p<0.001$). 2-SD changes in PC4 and PC7 corresponded to 21 N and 22 N increases in ACL force, respectively.

Discussion

By integrating clinical imaging data with physics-based computational models and statistical shape modeling, we reveal that ACL loading in young, high-risk female athletes is related to unique combinations of bony geometries. Mechanistic evaluation of how bony anatomy modulates knee mechanics will allow for anatomy-based injury screening, prevention protocols, and surgical treatments.

Estimating Scapular Kinematics During Tasks With Independent Scapular Motion Using Individualized Regression Models

Ms. Denise Balogh MSc, Dr. Angelica Lang PhD

University of Saskatchewan, Saskatoon, Saskatchewan, Canada

Introduction

Individualized linear regression (ILR) models have been proposed as an alternative to both generalized scapular regression models and the double calibrated acromial marker cluster (AMC) for the estimation of scapular kinematics [1,2]. This study examines how the number of ILR model predictor variables and training poses affects the prediction of scapular kinematics.

Methods

Reflective markers were placed on 13 healthy participants according to ISB standards to capture bilateral shoulder kinematics [3]. Participants positioned each arm in 11 static 'training' poses, and anatomical landmarks of the scapula were palpated. Scapular Euler angles, humeral helical angles, and acromial process (AP) displacements were calculated. Humeral helical angles from either 11 or 6 poses, with or without AP displacements, were used as predictor variables for the development of 4 different ILR models for each participant: Model 11, Model 6, Model 11+AP, and Model 6+AP. The ability of the ILR models to predict scapular kinematics during 7 new 'test' poses, as compared to scapular kinematics obtained from palpation and from direct tracking with the AMC, was examined. The root mean square error (RMSE) between scapular angles extracted from the AMC and ILR models and the palpated scapular orientations was calculated. Three-way repeated measures ANOVAs (method*test pose*scapular axis; a=.05) were additionally computed on the scapular angles.

Results

Mean RMSEs were below 14º for all methods except for Model 6+AA, in which large RMSEs occurred (Table 1). Model 11 consistently produced the lowest ILR model RMSEs for many of the 'test' poses, emphasizing the benefit of developing the models from a greater number of 'training' poses. However, including the AP displacements as predictor variables may not benefit the models. Significant 3-way ANOVA interactions ($p<0.05$) indicated that for certain 'test' poses and axes combinations, differences in estimates of scapular orientation were present across methods.

Discussion

The predictor variables to an ILR model impact the accuracy of static scapular kinematic estimations. Additional analysis will expand to the prediction of dynamic scapular kinematics, with the full study sample (N=20).

Images (Optional)

Table 1. Mean (standard deviation) RMSEs (palpation – AMC/ILR model) for each scapular axis across all 7 'test' poses. All values are in degrees.

	AMC	Model 11	Model 6	Model 11+AA	Model 6+AA
Internal Rot.	6.84 (1.72)	8.90 (2.55)	11.90 (1.93)	9.94 (2.17)	36.44 (17.56)
Upward Rot.	7.42 (1.93)	8.92 (2.49)	13.56 (1.73)	9.20 (2.30)	53.91 (25.56)
Tilt	10.48 (10.18)	5.25 (0.68)	8.28 (1.51)	7.77 (2.09)	44.42 (21.86)

Hyaluronic Acid Formulations Modulate the Efficacy of Lubricin in Lubricating Articular Cartilage

Graduate Student Spencer Witt B.S.[1], Undergraduate Student Dylan Shen[1], Professor Heidi Reesink PhD, DVM[2], Professor Matthew Paszek PhD[2], Professor Lawrence Bonassar PhD[1]

[1]Cornell University, Ithaca, New York, United States. [2]University of California Davis, Davis, California, United States

Introduction

Articular cartilage maintains low friction due to synergistic interactions between lubricin and hyaluronic acid (HA) within synovial fluid. Much work has been done characterizing the friction of a variety of HA and lubricin forms. The objective of this study is to characterize the interactions of eLub, a recently synthesized recombinant lubricin based on the equine PRG4 gene, with various formulations of HA using the Stribeck framework (Fig 1A).

Methods

A 20 mg/mL eLub stock was diluted with PBS and HA to yield 0.16 and 1.6 mg/mL eLub and 5 mg/mL HA. Friction was measured on a biaxial load-cell tribometer. Cartilage plugs (6 mm diameter) were punched from neonatal bovine femoral condyles, trimmed to 2 mm thick, and glued to pivots. Samples were compressed to 30% strain against glass in the lubricant bath, allowed to relax for 1 h, then slid reciprocally at 0.1–10 mm/s. The friction coefficient was computed as the shear-to-normal load ratio.

Results

In the absence of eLub, all four types of HA exhibited changes in the friction coefficient consistent with a classical elastoviscous Stribeck model (Fig. 1B). All formulations of HA lower friction when combined with 0.16 mg/ml eLub (Fig. 1C). At 1.6 mg/ml, the viscous friction was higher than boundary friction and the increase varied across different formulations of HA. (Fig. 1B, 1C).

Discussion

Without eLub, HA lowered friction compared to PBS consistent with previous work. Friction at 0.16 mg/ml eLub with HA exhibits synergy, as the viscous friction of the combined solution is lower than either eLub or HA alone. Unexpectedly, at high concentrations of eLub, the friction coefficient of the combined solution is higher than eLub alone, with

varying response based on the formulation of HA. Additionally, the effects of different HA formulations can be seen at lower eLub concentrations, with different HAs exhibiting varying reductions in friction coefficient. In sum, this study demonstrated novel interactions between a recombinant lubricin and commercially available HAs in cartilage lubrication, revealing unexpected frictional behaviors that could influence the design and optimization of therapeutic lubricants.

Images (Optional)

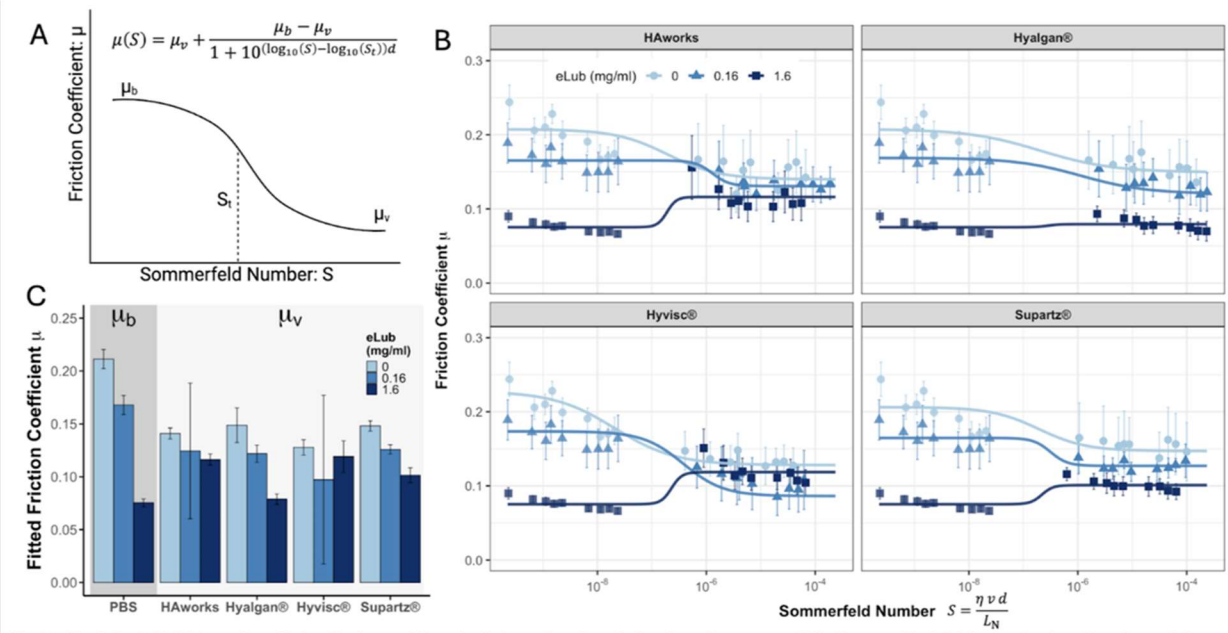

Fig. 1A: The Stribeck Model for cartilage friction. The Sommerfeld number is the product of speed, viscosity, and contact area divided by normal load. Friction is a function of boundary and viscous friction, the Sommerfeld number, and the Sommerfeld transition number. **Fig. 1B:** Friction of four formulations of HA combined with eLub, with Stribeck curves. Darker shades represent increasing eLub concentrations. Values on the left of each box represent boundary friction at different speeds, while the values on the right represent viscous friction values. **Fig. 1C:** Comparison of the boundary (PBS) and viscous (HA) friction values at various eLub concentrations.

How Do Menstrual Cycles Affect Active and Passive Modulators of Joint Level Stiffness? A Literature Review

Dr Anne Silverman PhD[1,2], Dr. Katherine Knaus PhD[1], Dr. Eline van der Kruk PhD[2]

[1]Colorado School of Mines, Golden, CO, United States. [2]Delft University of Technology, Delft, South Holland, Netherlands

Introduction

Maintaining effective torsional joint stiffness is critical to avoid injury. Active (muscles) and passive (e.g., ligaments) structures modulate torsional stiffness during movement, but their relative contributions remain unclear. High stiffness allows for rapid rates of force development, and low stiffness often results in greater tissue strains; extreme stiffnesses are likely to result in injury. Injury prevalence often differs between men and women, such as in anterior cruciate ligament (ACL) injuries and ankle sprains(e.g. [1,2]). One hypothesis explaining differential injury prevalence is changing connective tissue mechanical properties due to changing hormone levels over the menstrual cycle. Altered neuromuscular control may also change and/or compensate for changing passive mechanical properties. The purpose of this review was to investigate menstrual cycle effects on active and passive modulators of joint-level stiffness.

Methods

The following search terms were applied in Scopus to title/abstract/key words: ("menstrual cycle" OR menstruation) AND (joint) AND (strength OR stiffness OR laxity OR biomechanics) and were subject to multiple exclusion criteria (Table).

Results

The search returned 204 articles. 137 articles were removed due to the exclusion criteria (Table), leaving 55 remaining articles. 30 of these articles evaluated knee joint laxity, commonly used in studies related to ACL injury. 14 articles evaluated muscle level stiffness, and/or excitation. 19 articles presented joint level torque/angle measures during isometric (5), isokinetic (8), and/or dynamic (10) conditions, with 18/19 incorporating active contributions. 35 articles found a significant effect on outcome parameters with the phases of the menstrual cycle, most often indicating that joint laxity and muscle strength (measured by joint torque) increase during the ovulation phase. 12 studies incorporated male participants for comparison.

Discussion

The effects of the menstrual cycle on joint level stiffness and the modulators of this joint stiffness remain unclear. These results highlight the difficulty in evaluating the interacting changes in different tissues that contribute to joint level stiffness. Additionalmeasurements, especially of active muscle contributions to joint level stiffness, are needed to evaluate menstrual cycle effects on joint level biomechanics.

Inertial Tracking of Skeletal Kinematics Matches the Accuracy of Marker-Based Tracking: A Biplane Radiography Comparison

Mr. Vu Phan[1], Mr. Tom Gale[2], Dr. William Anderst[2], Dr. Eni Halilaj[1]

[1]Carnegie Mellon University, Pittsburgh, PA, United States. [2]University of Pittsburgh, Pittsburgh, PA, United States

Introduction

Despite years of advancements and growing interest, inertial tracking is still considered inferior to marker-based analysis. Based on this premise, new inertial tracking methods, from structured filtering to data-driven algorithms that use marker-based motion tracking as the ground truth, have been proposed. Our study assesses the foundational assumption that marker-based motion tracking is more accurate than inertial tracking, with the goal of informing future progress in computational frameworks for inertial data analysis.

Methods

With IRB approval and informed consent, 15 healthy athletes (8 males and 7 females; age: 20.07 ± 1.24 years; height: 173.07 ± 9.99 cm; weight: 71.88 ± 10.86 kg) performed four physical exercises while being recorded with three different systems: inertial motion tracking, marker-based motion tracking, and biplane radiography of the knee joint (as the reference ground truth for skeletal kinematics) (Fig. 1A). Marker-based kinematics were computed directly from marker trajectories using unconstrained kinematics. Inertial-based kinematics were computed using open-source filters. The primary outcome was the root-mean-square difference (RMSD) between a tracking system and the ground-truth skeletal kinematics. We used Wilcoxon signed-rank tests for comparisons.

Results

Both inertial and marker-based systems captured knee flexion/extension with a median RMSD of <4°, ab/adduction >5°, and internal/external rotation >7° (Fig. 1B). There was no significant difference between inertial and marker-based tracking, across degrees of freedom or tasks. In both approaches, internal/external rotation showed the poorest tracking accuracy. Open-source state estimation filters like Madgwick (MAD), Mahony (MAH), and the versatile quaternion-based filter (VQF) performed equally well and better than the extended Kalman (EKF) and data-driven (RIANN) filters (Fig. 1C).

Discussion

While further validation across demographics and broader activities are necessary to confirm the generalizability of our findings, these initial findings mark an exciting turning point in the field of human movement biomechanics. Wearables have been met with cautious optimism as a set of tools that will transform our field by enabling ecologically valid studies, but the evidence required to trust them as much as we have trusted marker-based motion tracking has been elusive. This is a first step toward building that trust.

Images (Optional)

[1]Center for Injury Biomechanics, Virginia Tech – Wake Forest University School of Medicine, Winston-Salem, NC, United States. [2]Orthopedic Surgery and Rehabilitation, Wake Forest University School of Medicine, Winston-Salem, NC, United States. [3]Sports Medicine, Wake Forest University School of Medicine, Winston-Salem, NC, United States. [4]Virginia College of Osteopathic Medicine and Virginia Tech University, Blacksburg, VA, United States

Introduction

High-velocity, low-amplitude osteopathic manipulative treatment (HVLA-OMT) is widely used by osteopathic physicians to manage low back pain (LBP), which affects 84% of adults and is a leading cause of disability [1]. Despite its clinical effectiveness, little is known about the internal biomechanics of HVLA-OMT. Previous studies have quantified forces applied by physicians and pre- and post-manipulation changes in facet joint gapping [2,3]. However, the mechanisms underlying HVLA-OMT remain unclear. This study aims to characterize lumbar biomechanical changes in silico using motion capture-driven computational modeling.

Methods

One participant underwent an HVLA-OMT delivered by an osteopathic physician (Fig.1a). Contact forces were recorded with load-cells mounted on the physician's forearms. 3D kinematics were captured at 120Hz using reflective markers on the participant, physician, treatment table, and load-cells. Marker trajectories were filtered using a 4^{th}-order Butterworth filter and used to drive the GHBMC 5th percentile female pedestrian human body model in LS-Dyna (Fig.1b)[4], incorporating table stiffness. Facet joint gap and intervertebral disc height changes were quantified during HVLA thrust.

Results

Manipulation started with a 50N preload, and the thrust peaked at 265N over 2.73s (impulse = 557N·s) (Fig.1c). On average, facet gapping showed a peak increase of 0.31±0.28mm (3.79min-22.96max%) over 2.80s, with moderate correlation to thrust rate

(R^2=0.59) (Fig.1d). Disc height showed a peak decrease of 0.73±0.29mm (8.26min-17.60max%) over 2.81s, showing strong correlation with thrust rate (R^2=0.96) (Fig. 1e).

Discussion

This study quantifies mechanical events of HVLA-OMT, including applied forces and internal lumbar responses such as facet gap and disc height changes. Preliminary findings demonstrate relationships between thrust forces and changes in facet gapping and disc height, with variable responses across lumbar levels. Data collection is ongoing in participants with LBP, and future analyses will examine additional biomechanical responses, including stress and strain in lumbar ligaments, muscles, and vertebral bodies, to better understand potential contributors to clinical outcomes.

Anteroposterior Translations of the Tibiofemoral Joint During the Forward-Lunge Activity

Mr Fengtao Zhang MEng, BEng[1], Professor Todd Stewart PhD, BSc[1], Dr Aiqin Liu PhD, MEng, BEng,[2]

[1]Institute of Medical and Biological Engineering, Leeds, West Yorkshire, United Kingdom. [2]Faculty of Biological Sciences, Leeds, West Yorkshire, United Kingdom

Introduction

Assessing anterior-posterior translations in the knee joint during rehabilitation and sports activities is vital for understanding the biomechanical interactions necessary for healing. Dual fluoroscopy and 3D CT/MRI[1] offer high imaging accuracy but are constrained by cost, limited accessibility, and small fields of view, while optical marker-based motion capture enables large-cohort dynamic analysis but lacks accuracy in anterior-posterior translation. This study aimed to develop a new OpenSim model to investigate whether anterior-posterior knee translation during forward lunge activities can be accurately estimated from 3D motion capture data.

Methods

Gait .c3d data was taken from seventeen healthy subjects (9 males, 8 females, age 20-70 years) completing a forward-lunge, and converted to OpenSim compatible .trc and .mot format. A modified OpenSim model, with six-degree-of-freedom enabled, was firstly scaled to each subject's anthropometrics.

A Euler rotation matrix was applied to obtain the anterior-posterior translation of tibia relative to femur in the global coordinate. The entire analysis pipeline, from model modification and scaling to the final application of the Euler rotation matrix for coordinate transformation, was executed using custom Python scripts interfacing with the OpenSim API.

Results

Compared to the static pose of CT/MRI/Fluro studies the forward-lunge began with the subjects moving, generating a small swing phase causing the knee to be flexed initially at 22.3°[1]. The average anterior-posterior translation (Figure 1) showed the tibia moved ~5mm posteriorly from –14.2mm(± 8.0) at flexion of 21.0° to –19.2mm (± 8.5) at flexion of 51.1°. Average tibial movement progressed anteriorly with ~13.2mm translation to –

6.0mm(± 7.8) between the flexion angle of 22.3° and 105.94°. These magnitudes were generally less than those published from past weight-bearing static pose trials.

Discussion

Marker-based motion capture with a modified OpenSim model and custom Python programming successfully enabled tibiofemoral anterior-posterior translation to be assessed during the forward-lunge. Average tibial anterior-posterior translation of 8.2mm (± 8.0) mm was observed. Future work will expand to a broader range of activities and incorporate rotation to investigate joint contact motion paths and shear towards defining movement characteristics for evaluation of cartilage substitution therapies.

Developmental Remodelling of the Articular Cartilage Matrisome

Miss Giulia Giuffredi

University College Dublin, Dublin, Dublin, Ireland

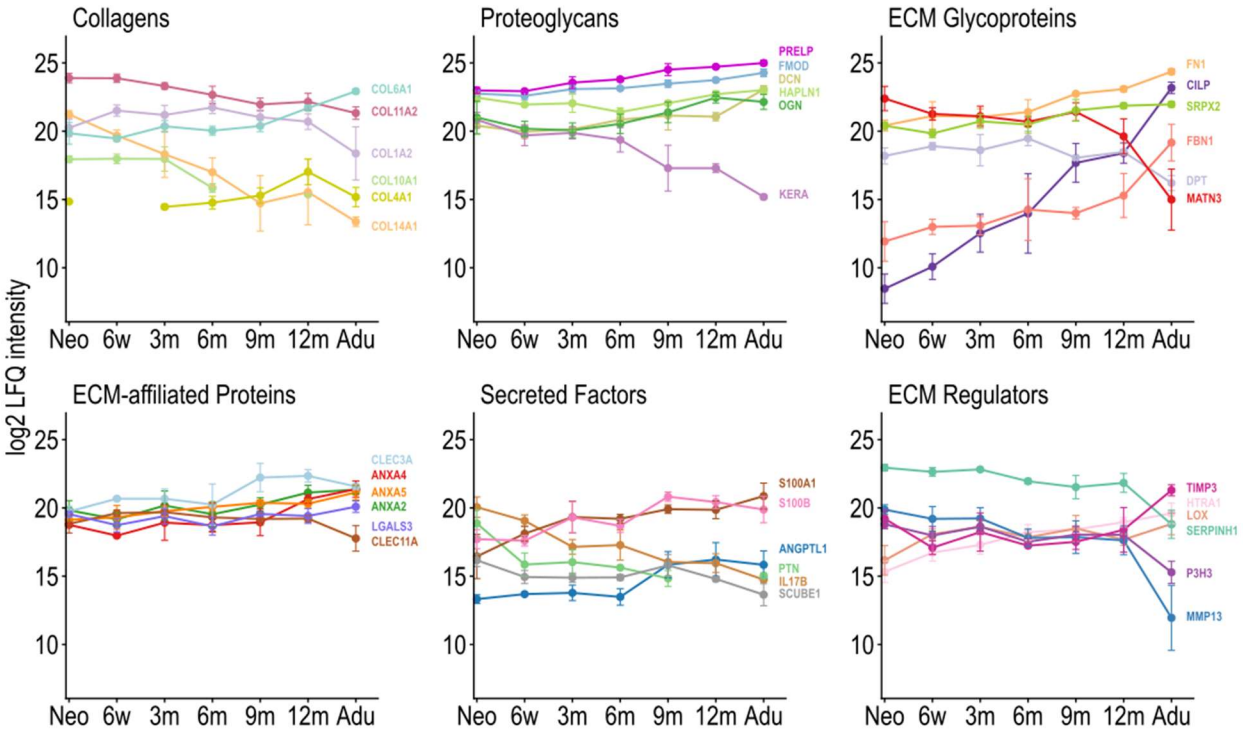
Introduction

Articular cartilage (AC) is a connective tissue whose extracellular matrix (ECM) is composed mainly of type II collagen and aggrecan, providing tensile strength and resistance to compression. Due to its avascular and sparsely cellular nature, AC has limited turnover and repair capacity, making it vulnerable to degeneration. Tissue remodelling during growth is essential for long-term joint function, yet the underlying protein-level adaptations remain poorly characterised. Here, label-free mass spectrometry was used to profile the ECM proteome of goat AC, a large-animal model relevant to human joint biology, to define tissue maturation at molecular level and generate a reference for developmental and disease-related research.

Methods

AC was collected at seven postnatal stages from neonatal to adult (n=3 per stage) under UCD ethical approval (AREC-21-22). Full-thickness distal first-phalanx samples (20 mg) were cryopulverised and extracted using a guanidine-HCl protocol to separate soluble and insoluble ECM fractions. Peptides were digested with trypsin and analysed by LC–MS/MS. Data were processed in MaxQuant using the Capra hircus proteome. Label-free quantification values were filtered, log-transformed and analysed in R. Proteins were classified with MatrisomeDB; differential abundance was assessed with limma and pathway enrichment performed with Reactome and Gene Ontology.

Results



A total of 799 proteins were identified, including 157 ECM components. Early stages were enriched in collagens and proteoglycans such as COL9A1, COL11A1 and ACAN, while regulators and structural proteins including COL6A1, FN1, CILP and HTRA1 increased with age. Enrichment analysis indicated reduced collagen biosynthesis after mid-juvenile stages and increased elastic-fibre formation, crosslinking and glycosaminoglycan metabolism, marking a shift from ECM synthesis to maintenance.

Discussion

AC maturation appears to involve functional reorganisation rather than replacement of ECM components. Early development emphasises fibril assembly and collagen

modification, whereas later stages strengthen existing networks through LOX-mediated crosslinking and expansion of the pericellular matrix. Pathways linked to collagen synthesis and ECM assembly decline with age, while those related to elastic-fibre formation and crosslinking become increasingly enriched. Several proteins that rise with age (HTRA1, CILP, SPP1, FN1) are also associated with osteoarthritis, suggesting shared mechanisms between matrix maturation and degeneration.

Influence of Treadmill Gradient on Multi-Segment Foot Kinematics and Gait Variability in Healthy Adults

Grant Schwiebert[1,2], Matthew Parrett M.Ed.[1], Mallory Rowan M.S.[1], Jessica Lewis PT, DPT[1], Dr. Sean Tabaie MD[1], Dr. Kirsten Kirsten PhD[1]

[1]Nationwide Children's Hospital, Columbus, Ohio, United States. [2]The Ohio State University, Columbus, Ohio, United States

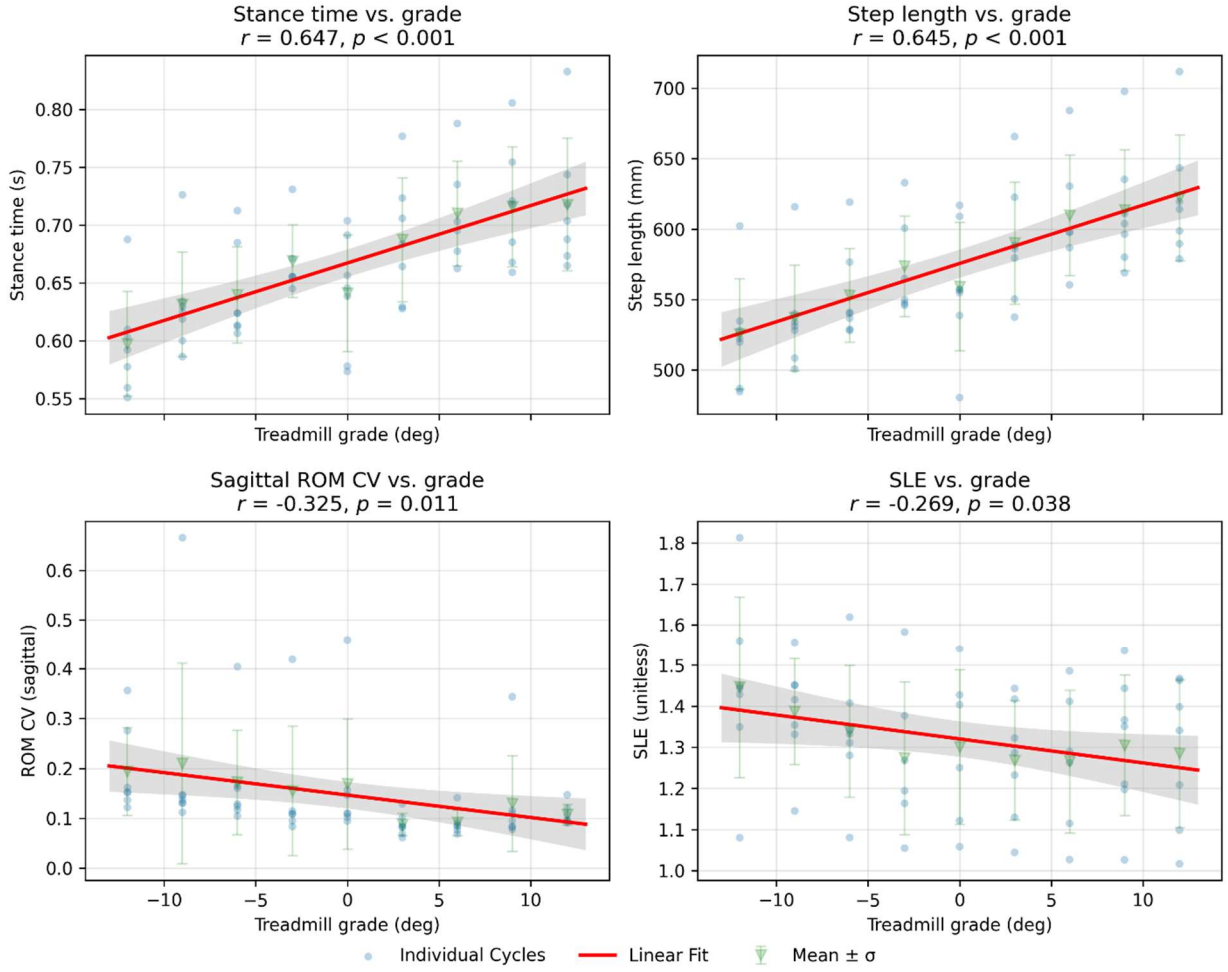
Introduction

Inclined and declined walking alters lower-limb mechanics, neuromuscular control, and stability demands. The influence of slope on regional foot kinematics, particularly hindfoot, midfoot, and medial/lateral forefoot coordination, remains poorly understood. Unlike single-segment models, multi-segment foot models (MSFMs) can detect changes in arch deformation and segment coordination. This study aimed to identify slope-dependent changes in segmental kinematics, spatiotemporal variability, and nonlinear dynamic stability, which is crucial for understanding functional demands in clinical populations and informing treatment strategies.

Methods

Seven healthy adults (6M, 24.1±3.9yrs, 77.0±9.8kg, 175.8±7.6cm) walked barefoot at 2.5 mph across nine grades (0°, ±3°, ±6°, ±9°, ±12°) for 90 seconds while 3D kinematics were collected using a novel MSFM. Intersegmental Euler angles of the tibia, hindfoot, midfoot and medial/lateral forefoot and hallux planar angles were computed across ≥69 gait cycles. Variability metrics (standard deviation (SD), coefficient of variation (CV), range of motion (ROM), ROM-CV), spatiotemporal metrics (stride time, stance/swing duration, cadence, step length/width), and short- and long-term Lyapunov exponents (SLE/LLE) were calculated per grade. Pearson correlation analysis evaluated the relationship between slope angle and segmental kinematics, variability, and stability.

Results



Spatiotemporal parameters displayed strong grade associations: stance-time (r=0.64), step-length (r=0.64), cadence (r=0.62), and stride-time (r=0.59). Joint-angle variability showed more modest grade effects, with sagittal ROM-CV demonstrating the strongest association (r=–0.325, p=0.011). Frontal-plane hindfoot–tibia and forefoot–tibia variability showed minimal sensitivity to grade, suggesting preserved mediolateral control. Dynamic

stability was invariant across grades: SLE showed only a small correlation (r=–0.269, p=0.038), and LLE showed no significant effect (r=–0.024, p=0.855).

Discussion

Despite spatiotemporal adaptations with changing slope, regional foot-segment kinematics and nonlinear stability metrics were largely preserved, indicating that healthy adults maintain robust intra-foot coordination under altered mechanical and neuromuscular demands. This robustness may reflect effective neuromechanical compensation mechanisms at the ankle and foot. Future work will expand sample size, incorporate pathological case studies, and integrate subject-specific foot morphology to refine interpretations of slope-dependent segmental mechanics, advancing applications in clinical gait analysis, fall-risk evaluation, and slope-based treatment strategies.

Introduction

Back-support exoskeletons (BSEs) are increasingly used to reduce occupational physical demands during repetitive lifting, yet little is known about how users adapt their movement strategies and how perceived exertion changes with repeated use. Prior studies vary widely in task type and exposure duration, and findings have been mixed, resulting in a limited fundamental understanding of how users adapt and whether adapted behaviors are retained after a prolonged break.

Methods

Twenty-seven healthy adults were randomly assigned to a passive BSE, active BSE, or no-BSE control group (6 males, 3 females per group). Each participant completed one familiarization session and four experimental sessions. Sessions 1–3 included a pre-adaptation phase (~5 min), an adaptation phase (~15 min), and a post-adaptation phase (~5 min). Session 4 included only the adaptation phase (~15 min) to assess retention. Participants performed trials of repetitive symmetric lifting of a load equal to 15% of body mass at a fixed pace of 6 lifts/min. Lifting height, pace, and load were standardized to isolate adaptation effects rather than task-related variability. Primary outcomes were trunk, hip, and knee ROM; lower-back and leg RPE (Borg CR-10). Linear mixed-effects models evaluated Intervention, Session, and Trial effects ($\alpha = 0.05$).

Results

Intervention × Session interactions were significant for all joint ROMs. Both BSE groups exhibited greater trunk ROM than control (≈11–20°, ~23–40%). Trunk ROM decreased over time in the passive group but remained elevated in the active group (~20° greater in Sessions 2–3). Hip ROM decreased by ~15° (passive) and ~9° (active) across sessions versus <1° in control. Knee ROM in BSE users became 20–32° lower (~50%) than control by Sessions 3–4. Lower-back and leg RPEs declined by ~2 CR-10 points (≈70–75%) by Session 4, while the control group plateaued.

Discussion

Multi-session BSE use led to clear motor adaptation, characterized by increased trunk and reduced knee ROM and substantial reductions in perceived exertion. Passive BSE users showed progressive stabilization of trunk ROM, whereas active BSE users maintained larger trunk ROMs. These findings highlight the importance of structured, multi-session familiarization when integrating BSEs into practice.

How Do Sulcus Angle and TT-TG Distance Drive Patellofemoral Contact Mechanics?A Finite Element Analysis Investigation

Ms. Carolina S. Haboba Nebel MS[1], Mr. Thomas Turinske BS[2], Mr. Edouard J. Augustin BS[1], Mr. Kofi K. Acheampong BS[1], Mr. Jay Amin[1], Mr. Cade Smelley BS[1], Mr. Divesh Sachdev[1], Dr. Adam B. Yanke MD[1], Dr. Hannah J. Lundberg PhD[1]

[1]Rush University Medical Center, Chicago, IL, United States. [2]Rosalind Franklin University of Medicine and Science, North Chicago, IL, United States

Introduction

We developed a series of patient-specific models using a semi-automated finite element analysis (FEA) computational framework to investigate how individual phenotypes influence patellofemoral contact mechanics across knee flexion. We hypothesized that subjects with a sulcus angle greater than 145 degrees and a TT-TG greater than 15 mm will have more concentrated contact pressure in the lateral condyle with higher peaks and smaller contact area, as well as abnormal patellar range of motion.

Methods

One control patient and five patellofemoral instability patients with knee 3D MRI scans from 2019-2023 were included. The patients had a variety of Dejour classifications, dysplasia, J-sign, TT-TG, and sulcus angles. Femur, tibia, and patella bones and femoral and patellar articular cartilage were segmented (Mimics, Materialize, NV). Bones were modeled as rigid bodies, cartilage as linear elastic (E = 14MPa, v = 0.45) [1], and patellar and quadricep tendons with hyperelastic material properties. Axial connectors actuate the quadricep tendon and represent the MPFL to stabilize the patella. Tibiofemoral contact was simulated with a 50N load. FEA models were built in Abaqus Explicit. Femoral contact pressure and area were compared to patient anatomical characteristics.

Results

The control patient (TT-TG: 7.6mm, sulcus angle: 139.3°, no instability) had a contact area range of 1.4-3.35 cm^2. Contact pressure peak (3.1 MPa) at 55°. Average contact pressure over the entire ROM was 2.8 MPa. Patellofemoral instability patients (TT-TG: 14.9-22.8 mm) had less contact area minimum average 0.8 (0.68-1.4 cm^2) – maximum average 1.9 (1.4-2.7 cm^2), a lateral patella at 0° of flexion, abnormal patellar tracking, and higher and lateral

peak contact pressures (4.3-5.6 MPa). Greater sulcus angle (>145°) was associated with early peak contact pressure (8-24° of flexion), compared to the peaks at 33-39°of flexion for models with sulcus angles in the standard range (134-139°).

Discussion

The previously validated computational framework shows meaningful results, visualizing how individual phenotypes influence the mechanics of the joint. TT-TG greater than 15mm led to higher contact pressure during the flexion range, and sulcus angles greater than 145° led to lateralized contact pressure, with early higher peaks and smaller contact areas.

Images (Optional)

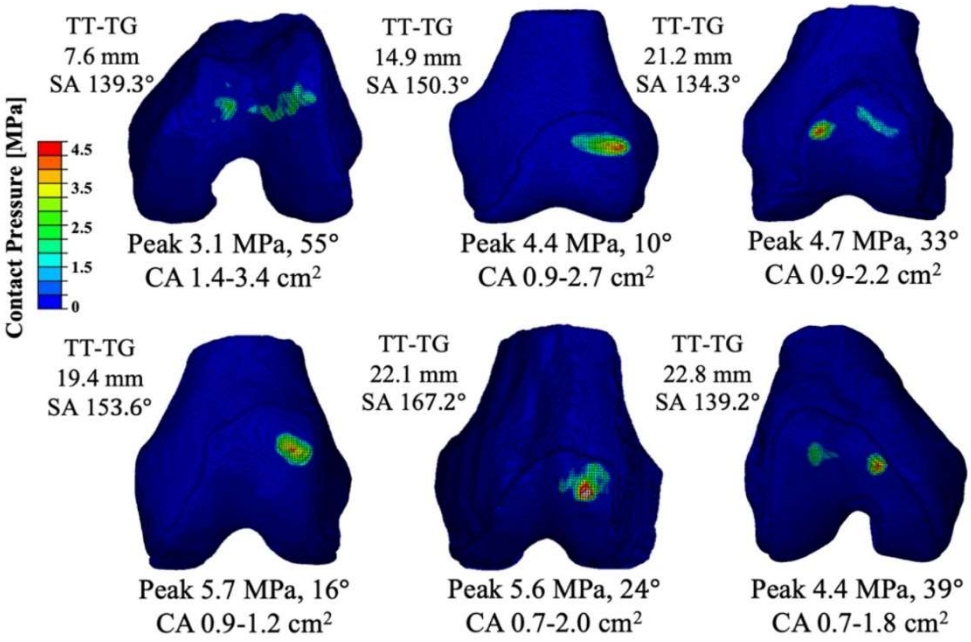

Figure 1 – Finite Element Analysis results (peak of contact pressure, flexion angle at which the peak occurs, contact area (CA)) and patient anatomical characteristics (TT-TG, Sulcus Angle (SA)). Results are shown for the flexion angle with greatest contact pressure for each model

Validation of Theia 3D Markerless Motion Capture for Quantifying Upper Extremity Kinematics

Miss Hayley Janes BHSc, Mr. Michael Watterworth PhD Candidate, Miss Gillian Slade MHSc Student, Dr. Nicholas La Delfa PhD

Ontario Tech University, Oshawa, Ontario, Canada

Introduction

Marker-based motion capture (MoCap) systems are widely regarded as the gold-standard for quantifying human kinematics. Markerless motion capture (MoCap) offers a promising alternative that addresses several limitations of common marker-based kinematics approaches. Despite its potential, research validating markerless MoCap for upper extremity kinematics remains limited. This study aims to evaluate the validity of novel markerless MoCap technology for estimating shoulder, elbow and wrist joint angles by comparing markerless (Theia3D) outputs with those from a marker-based system.

Methods

Kinematic data from 13 (5M,7F) participants were captured simultaneously with 10 Vicon and 8 Sony HD cameras. Each participant completed three identical sessions, which consisted of a series of range of motion (ROM) trials and several dynamic functional movements. Vicon Nexus and Theia3D were used to process and calculate upper extremity joint angles for the shoulder (3 degrees of freedom), elbow (2) and wrist (2) in Visual3D. Two rotation sequences were used: XZY for shoulder flexion movements and ZXY for all other trials. RMSD and concordance correlation coefficients (CCC) were calculated between the Vicon and Theia time-series data, and ICC(3,1) was used to assess the consistency of ROM values across the three sessions.

Results

Results from nine right-arm ROM conditions are reported. Figure 1 shows the mean joint angles over time with RMSD and CCC values presented within each panel. The highest agreement between systems occurred in shoulder internal/external rotation (0.985), while the lowest correlation occurred for elbow pronation/supination (0.073). Theia showed higher ICC values for elbow flexion/extension (0.771) and shoulder plane of elevation (0.822) compared to Vicon (0.488 and 0.639, respectively), whereas Vicon produced higher ICCs for all remaining movements.

Discussion

These results show that Theia3D demonstrates strong agreement with traditional marker-based MoCap for several shoulder movements, although substantial differences remain for shoulder flexion movements (18.5°, 17.0°, 21.8°). Elbow and wrist motions also show lower agreement, indicating further refinement of markerless tracking for these joints is warranted. Advancing and validating Theia3D for shoulder, elbow, and wrist motions will be an important step in enabling markerless motion capture to play a larger role in upper extremity focused research.

Diurnal variation in neuromuscular function in males and females

Ms. Isla R. G. MacPherson[1,2], Dr. Alexander M. Zero[1], Mr. Charlie Kanuka[2], Dr. Chris McNeil[2], Dr. Charles L. Rice[3], Dr. Brian H. Dalton[2], Dr. Geoffrey A. Power[1]

[1]University of Guelph, Guelph, Ontario, Canada. [2]University of British Columbia, Kelowna, British Columbia, Canada. [3]University of Western Ontario, London, Ontario, Canada

Introduction

Peripheral circadian clocks located within skeletal muscle may influence contractile function, as strength (i.e., maximum voluntary isometric contraction torque; MVC) is greater, and rate of torque development (RTD) is faster throughout the day [1, 3, 4], but with little data available for females [4]. It is currently unknown whether peak isotonic power is influenced by circadian rhythm and if RTD may contribute to the potential fluctuations in power throughout the day in females and males.

Methods

Healthy, recreationally active adults (n=16, 7 females, aged 25±3y) with regular sleep schedules participated. Testing occurred in the morning 1-h after waking (i.e., AM) and 12-h from this timepoint (i.e., PM). Voluntary and electrically evoked (i.e., percutaneous muscle stimulation) contractile function of the knee extensors was assessed on a dynamometer. Isometric measures at a knee angle of 80º included MVC torque, peak RTD, and evoked twitches. Peak power was determined from a range of isotonic loads (unloaded-60% MVC) throughout an 80-140º knee joint range of motion.

Results

Body temperature increased in both females and males (~0.5-1%; $P<0.05$) throughout the day. Although males were stronger (peak MVC and twitch torque), faster (RTD), and more powerful (isotonic power) as compared with females, (all $P<0.05$), twitch torque, voluntary peak RTD, and peak power were unaffected by time-of-day (all $P>0.05$). For MVC torque there was a trend towards an interaction of time × sex ($P=0.055$), such that males had a greater diurnal effect with ~10% higher MVC torque in the PM than AM. Voluntary activation decreased (~2%) for both sexes from AM to PM ($P<0.05$).

Discussion

To date, results indicate there was no diurnal-related difference in power production or RTD, which was similar between the sexes. Nonetheless, both sexes exhibited different time-of-day effects for MVC torque. From AM to PM, males showed a larger relative

increase in MVC torque, indicating greater diurnal variation in strength compared with females. However, these changes do not appear to be explained by voluntary activation or twitch contractile properties.

Longitudinal Changes in Anterior Tibial Laxity Following ACL Injury in MRL/MpJ and C57BL/6J Mice

Mr. Jackson Gabbard[1], Ms. Olivia Dyer[1], Dr. Blaine Christiansen Ph.D.[2], Dr. Stephanie Cone Ph.D.[1]

[1]University of Delaware, Newark, DE, United States. [2]University of California, Davis, Sacramento, CA, United States

Introduction

Post-traumatic osteoarthritis (PTOA) is a debilitating disease that occurs after traumatic joint injury (i.e. anterior cruciate ligament (ACL) rupture). Using miniature 6 degree-of-freedom (DOF) robotic testing, we investigated the effects of ACL injury on *in situ* knee joint function in wild-type C57BL/6J mice and "super-healer" MRL/MpJ mice, which have shown resistance to articular cartilage degradation following injury-induced damage [1]. We hypothesized that MRL mice will exhibit no significant difference in joint mechanics between injured and uninjured limbs, while wild-type mice will have increased joint laxity in injured knees.

Methods

Female C57BL/6J (n=18) and MRL (n=16) mice (34 weeks old) underwent unilateral non-invasive right-limb ACL rupture via tibial compression. Animals were euthanized at 0-, 2-, or 4-weeks post-injury, and bilateral hind limbs were harvested for 6-DOF robotic testing (Mecademic, simVITRO). Joints were fixed at 40° flexion and loaded with 1N anterior tibial drawer force. Force-translation curves were created and anterior tibial translation, in situ joint slack and joint stiffness were calculated as previously described [2]. Statistics included ANOVA analysis.

Results

No significant difference was found in anterior tibial translation, joint slack, or joint stiffness due to injury state, mouse strain, or timepoint (Figure 1), likely related to high degrees of between-animal variability (~30-40% of means). Average anterior tibial translation for the C57BL/6J mice was 0.59mm±0.25mm (uninjured) and 0.62mm±0.19mm (injured), while MRL mice was 0.39mm±0.17mm (uninjured) and 0.58mm±0.22mm (injured). Average joint slack for C57BL/6J mice was 0.61mm±0.34mm (uninjured) and 0.61mm±0.26mm (injured). Average joint stiffness for MRL mice was greater, though these

findings did not reach statistical significance - in uninjured joints 2.03N/mm±0.75N/mm compared to injured joints 1.53N/mm±0.77N/mm.

Discussion

Contrary to our hypothesis, no significant differences were found between MRL and C57BL/6J joint function after ACL rupture. Future studies will assess specific mechanical and biological differences between mouse strains to better understand alternative mechanisms explaining the osteoarthritis resistance in MRL mice.

Flyband® ExoBoots™ Provide Superior Support, Comfort, and Performance During Dynamic Movements and Assessments Compared to Conventional Boots and Bracing

Ms. Jania Williams MS[1], Ms. Gabrielle Moser BS[1], Dr. Farah Fallahtafi[1], Dr. Corbin Rasumussen[2], Mr. Keith Eriks[3], Dr. Nataliya Rokhmanova[3], Mr. Mark Roser[3], Dr. Sarah A. Myers[1,4]

[1]University of Nebraska at Omaha, Omaha, Nebraska, United States. [2]Creighton University, Omaha, Nebraska, United States. [3]Results Groups LLc, Glastonbury, Connecticut, United States. [4]Omaha Veterans Affairs Medical Center, Omaha, Nebraska, United States

Introduction

Lateral ankle sprains are the most common musculoskeletal overuse injury in soldiers, likely due to training and deployments taking place on uneven terrain. Bracing is the current standard of care, but it is inadequate in rehabilitating soldiers from ankle injury. This study evaluated the impact of Flyband® ExoBoots™(FB) on ankle joint performance during dynamic movements. Conventional boots and bracing were compared to FB with carbon fiber ankle cartridges. We hypothesized that FB would allow easier movement in the anterior–posterior direction and increase comfort, while providing comparable support in the mediolateral (ML) direction.

Methods

Healthy adults (19-45 yrs) completed six experimental conditions that included a boot, conventional or FB, and standard low, mid, or high bracing for conventional boots and carbon fiber support for FB on their right ankle (Figure 1A). To evaluate dynamic movement and agility, participants performed a 55-step stair run and a three-cone shuttle drill (Figure 1B), in which completion times were recorded for each task. Peak ankle inversion and dorsiflexion angles were calculated from marker trajectories during two-foot landings on a 16° cross-sloping surface from a 24-inch. plyo box. User comfort was assessed using a Technology Acceptance Model (TAM) visual analog scale, ranging from ‘strongly disagree’ (0 points) to ‘strongly agree’ (15 points). A 2 x 3 repeated-measures ANOVA ($\alpha = 0.05$) tested the effects of boot type and bracing level on each outcome measure.

Results

Stair run and shuttle drill completion times were lower in FB compared to conventional boots ($p=0.010$, $p=0.013$; Figure1C). Peak inversion angle was greater in the low bracing

conditions compared to mid and high conditions for both boots (p=.038; Figure 1D). FB comfort ratings were higher than conventional boots, indicating increased comfort during dynamic tasks (p=0.024).

Discussion

The FB showed superior performance to the conventional boot, with faster completion times and greater sagittal mobility, indicating improved ML support and comfort. The interchangeable carbon fiber cartridges also provide comparable ankle ROM in the sagittal plane while restricting greater ROM in the frontal plane compared to conventional bracing. Future research will evaluate the effect of boots and bracing on service members with previous ankle sprains.

Images (Optional)

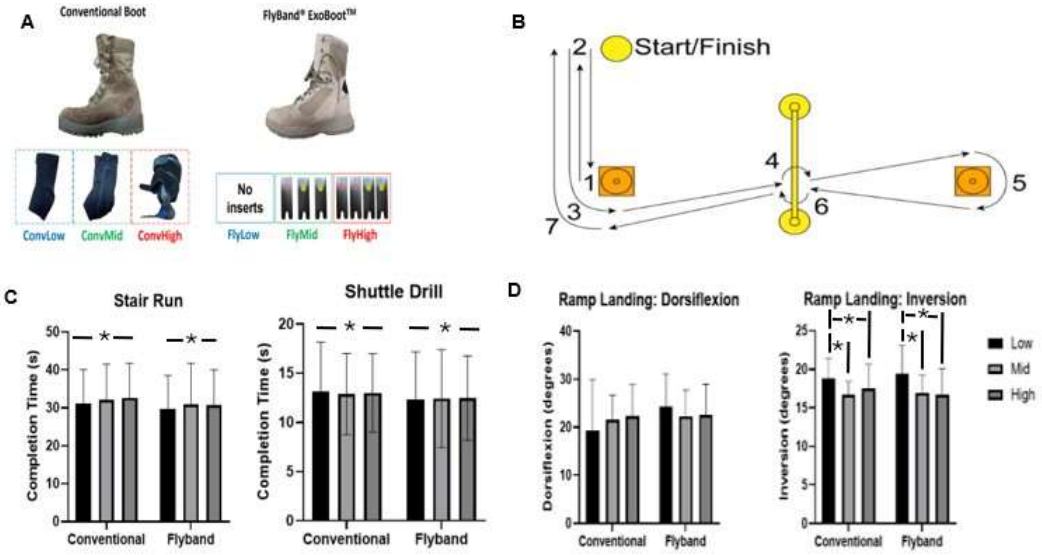

Figure 1. (A) Dynamic assessments were completed in six unique boot-brace combinations. (B) An indoor L-shaped obstacle course was completed by participants for agility assessment. (C) A significant main effect of boot was observed for stair runs and shuttle drill. (D) A significant main effect for bracing was observed between low-mid and low-high bracing conditions for inversion landing.

Using a Combined I*n-Vivo* and I*n-Vitro* Approach to Assess Changes in Spine Mechanical Properties With Prolonged Sitting

Ms. Jessa M. Davidson MSc, Dr. Jack P. Callaghan PhD

University of Waterloo, Waterloo, Ontario, Canada

Introduction

Low back pain responses in sitting may be linked to viscoelastic adaptations in spine tissues, which are mediated by the adopted lumbar spine postures as well as frequency and amplitude of micromovements [1]. Using both *in-vivo* and *in-vitro* testing, the current analysis assessed changes in spine mechanical properties in response to prolonged sitting.

Methods

Twenty participants completed one week of seated office work. During workdays, sitting time was quantified by a thigh-worn activity monitor and seated lumbar spine flexion-extension was quantified from the relative inclination of tri-axial accelerometers on the low back. Further, lumbar passive flexion stiffness was measured at morning and evening laboratory sessions.

A mechanical testing system was utilized to apply exposures, derived from *in-vivo* data, to forty-two porcine cervical (C34, C56) functional spinal units (FSUs). Following a 15-min 300N preload and definition of the neutral zone (NZ), FSUs were loaded at 10% of their predicted ultimate compressive tolerance for six hours. FSUs were loaded in static neutral, static flexion (300% NZ), or in flexion with low (25% NZ; 60s) and high (50% NZ; 30s) amplitude and frequency shifting micromovements. NZ testing was then performed again.

Results

Daily prolonged sitting resulted in increased lumbar passive stiffness. Small decreases in angular breakpoints occurred on Monday evening and Tuesday morning (4.6% and 6.8 %PassiveFlex), then angles progressively increased to within 1.7% to 2.3 %PassiveFlex of baseline values by the following Monday morning ($p \geq 0.06$). The daily changes were correlated with sitting time ($R^2 = 0.21$ [95% CI: 0.00, 0.62]).

Main effects of *time* for the NZ flexion limit, length, and slope indicated that prolonged static loading increased joint stiffness ($p \leq 0.01$). Moreover, mean changes in the flexion

limit were smallest for static neutral (0.5°) and largest for static flexion (-2.7°; $p = 0.03$), with micromovements demonstrating a moderately protective effect (-1.6°).

Discussion

Both *in-vivo* and *in-vitro* analyses indicated that prolonged sitting resulted in increases in spine stiffness. These changes were likely attributable to time-dependent elastic adaptations in spine tissues (e.g., fluid re-distribution). Seated micromovement may attenuate these viscoelastic adaptations, potentially mitigating the risk of low back pain.

Compensatory Movement Patterns With Symptom Presentation in Carpometacarpal Osteoarthritis

Ms. Jessica Molina, Ms. Alexis Benoit MS, Dr. Thomas Wright MD, Dr. Jennifer Nichols PhD

University of Florida, Gainesville, Florida, United States

Introduction

Carpometacarpal osteoarthritis (CMC OA) is debilitating due to pain, functional limitations, and decreased quality of life. Current treatments fail to address all aspects of CMC OA, often offering pain relief at the expense of function. To understand the multifaceted impact of CMC OA, this work aims to evaluate biomechanics and pain in tandem. Specifically, we assess to what extent radiographic and symptom severity affects motion.

Methods

Based on x-rays and the Australian/Canadian Osteoarthritis Hand Index pain subscale, 11 participants (age:66±9 years, 64% female) were categorized based on radiographic and symptom severity as Healthy (n=3), Early-Stage Pain (n=3), or Late-Stage Pain (n=5). Four range of motion (ROM) tasks [radial and palmar abduction/adduction; opposition to the base and tip of pinky] were evaluated using marker-based motion capture. ROM at the thumb [CMC flexion/abduction, metacarpophalangeal (MP) flexion, interphalangeal (IP) flexion] and pinky [5^{th} MP flexion, 5^{th} proximal interphalangeal (PIP) flexion, 5^{th} distal interphalangeal (DIP) flexion] were compared between groups using effect sizes (Cohen's d).

Results

Early-Stage Pain individuals showed consistent overcompensation along the thumb's kinematic chain for all tasks (Fig.1). For example, when comparing Early-Stage Pain and Healthy participants, large effect sizes ($d>0.8$) were consistently observed in thumb MP flexion (palmar abduction/adduction $d=0.85$, radial abduction/adduction $d=2.04$, opposition tip of pinky $d=0.90$), with the Early-Stage Pain group having greater ROM. In contrast, Late-Stage Pain individuals tended to exhibit phalangeal joint compensatory movements for all tasks (Fig.1). Notably, compared to the Early-Stage Pain group, the Late-Stage Pain group showed a dramatic increase in 5^{th} MP flexion (opposition base of pinky $d=2.59$).

Discussion

ROM was altered at different joints across cohorts, indicating that comprehensive analysis of ROM during functional tasks can delineate CMC OA disease severity. Notably, individuals with radiographic evidence of late-stage disease and pain compensated with increased flexion of their fifth digit during opposition tasks, while those with early-stage disease and pain relied upon increased motion within distal joints of the thumb. These results highlight the importance of considering how the combined effects of radiographic and symptom severity can be leveraged to further differentiate patient groupings for personalized care.

Measurement of Real-World Changes in Pain and Gait in Adults with Knee Osteoarthritis

Mr. Julien Mihy[1], Ms. Mayumi Wagatsuma[1], Mr. Spencer Miller[2], Dr. Elisa Arch[1], Dr. Katie Butera[1], Dr. Stephen Cain[2], Dr. Jocelyn Hafer[1]

[1]University of Delaware, Newark, DE, United States. [2]West Virginia University, Morgantown, WV, United States

Introduction

Adults with knee osteoarthritis (KOA) often experience pain with movement, which may influence daily activities like walking. It is vital to understand the effect of pain on walking as gait mechanics are associated with KOA initiation and progression. To date associations between pain and gait have only been assessed in controlled, laboratory settings. Thus, there is a critical gap in evidence regarding whether established relationships between gait and KOA disease progression retain their ecological validity in real-world settings. Accordingly, the purpose of this study was to evaluate the relationship between pain and gait during real-world walking in adults with symptomatic KOA.

Methods

Sixteen participants wore 4 inertial measurement units (IMUs) on their more symptomatic thigh and shank and on each foot during three days in the real-world. Peak pain during walking (0-10) was collected via text messages 5 times per day, every 2 hours. When receiving a text, participants were instructed to complete a ~3 minute walk and report their pain during that walk. We identified bouts of walking, foot trajectories, and gait events from raw IMU data. Bouts of walking closest to the time stamped text survey responses were analyzed. Segment angular velocities were integrated about functional mediolateral axes to estimate sagittal joint excursions. Gait mechanics were averaged across all strides within bouts of interest. A random coefficients model was run to determine the relationship between pain and gait parameters (i.e., gait speed, stride length, and knee and ankle ranges of motion (ROM)).

Results

Higher pain was associated with lower knee ROM ($p=0.03$, Figure), where a 1-unit increase in pain was associated with 2.7° less knee ROM on average. Pain was not associated with any other gait parameters (all $p>0.66$).

Discussion

This was the first study to assess concomitant pain and gait mechanics in a real-world environment. Our findings suggest that a 2-unit increase in pain – a common fluctuation in real-world pain in our data – could induce meaningful (i.e., ≥5°) changes in knee ROM. Therefore, individuals may be experiencing meaningful changes in gait mechanics regularly which could influence the rate of disease progression.

Images (Optional)

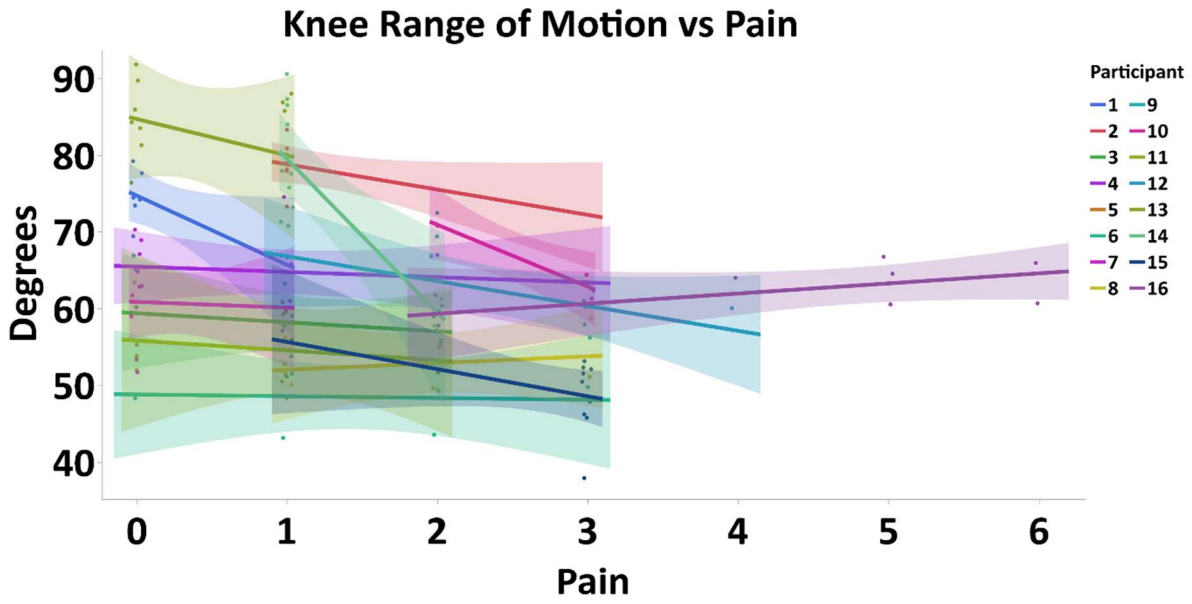

Figure Relationship between pain and knee range of motion (ROM) for all participants during three days of daily life. Lines represent the relation between knee ROM and pain for individual participants with each dot representing the pain and concurrent knee ROM at a text response timepoint. Shaded regions show the confidence intervals for each line of best fit.

Quantification of Frailty via the Lens of Feasible Output shows That Ankle Plantar Flexors Are Most Crucial to Stair Ascent

Mr Eric Kwei[1], Mr John Kim[1], Ms Sanskriti Gurappa[1], Mr Yamato Irie[1], Mr Zijie Zhu[1], Dr Francisco Valero-Cuevas[1,2]

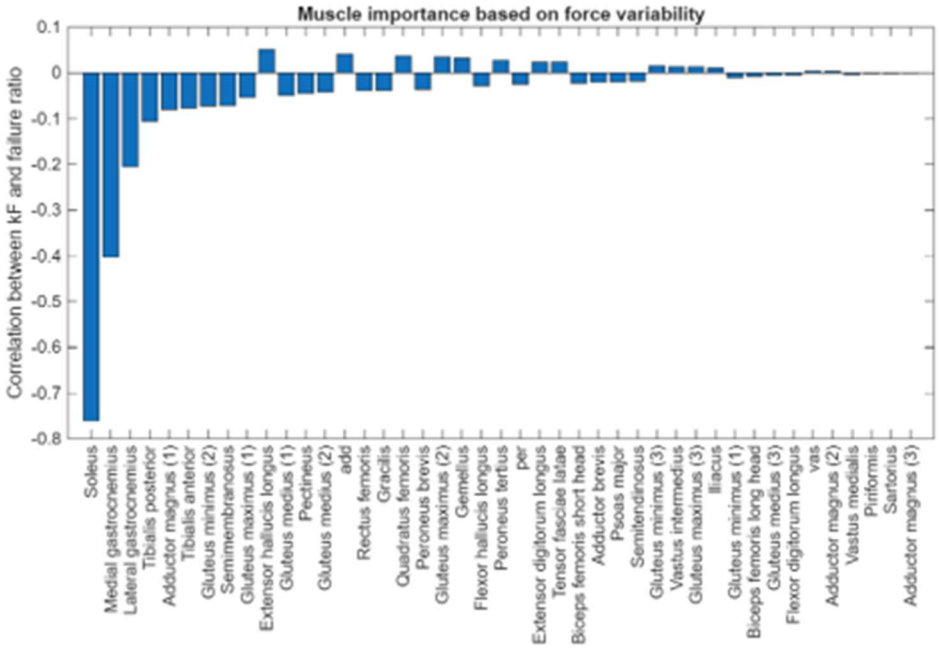
[1]University of Southern California, Los Angeles, California, United States. [2]Biokinesiology & PT, Los Angeles, California, United States

Introduction

Clinical measures of frailty focus on decline in physiology and mobility, but often lack neuromechanical specificity. We use a computational approach to quantify the relationship between muscle strength and the mechanical demands of stair ascent as it is an early indicator of functional decline in older adults, and may serve as a sensitive early detector of frailty. We use Feasibility Theory1 to evaluate the impact of muscle weakening on the ability to meet the vertical ground-reaction forces (GRFs) required throughout the cycle of stair ascent.

Methods

We applied published kinematic data[2] during stair ascent to a normative adult OpenSim lower-limb musculoskeletal model to predict the feasible force set (FFS) polytope at the leading foot during the ascent cycle as a function of optimal muscle fiber length, moment arms, pennation angles, tendon slack lengths, and maximum isometric force. Considering stepping as quasi-static, we computed moment-arms, Jacobians, and the maximum muscle force to calculate the FFS of the leg[3] during the step climbing cycle. This allowed us to quantify "frailty" as the distance of the GRF needed throughout in the cycle to the edge of the FFS: if the FFS shrinks below the necessary GRF at any point in the cycle, then stair climbing becomes infeasible.



Results

The shape and size of the FFS polytope changes across the ascent cycle, and Monte Carlo simulations weakening individual muscles show some muscles are particularly critical. Even modest (10–20%) strength reductions in the plantar flexor from normative values disproportionately shrink the feasible set's vertical component below the required GRF during certain phases of the ascent, resulting in failure, and suggesting limited robustness to plantar flexor muscle weakening.

Discussion

Defining frailty as a loss of feasible mechanical output allows comparison to task demands. This can help identify specific muscles and gait phases most vulnerable to sarcopenia in healthy aging or disease. This framework offers quantifiable thresholds for frailty to inform targeted strengthening interventions for older adults.

Sensitivity Analysis of Soccer Kicking Motion on Eccentric Muscle Mechanics Using Markerless Motion-Capture, Sensorized Insoles and Neuromusculoskeletal Simulation

Ms. Juliette Wyatt, Mr. Javier Batista, Dr. Nick Fey

University of Texas at Austin, Austin, Texas, United States

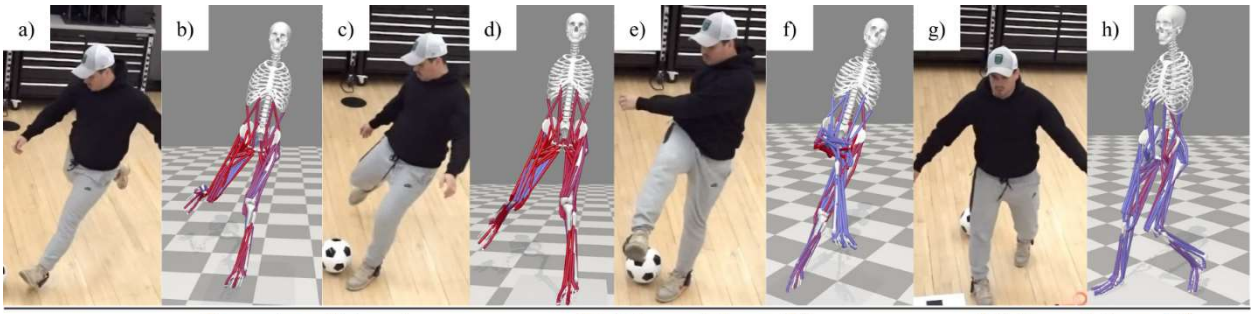
Ms. Juliette Wyatt

Introduction

Soccer, as one of the most popular sports worldwide, accounts for 228,000 sports injuries per year and 28% are hip related. Taking up 5-6% of all adult sports injuries, hip injuries significantly impact athletes in their performance. Due to the high occurrence of hip injuries in soccer players, it is vital to explore in-game causes. Utilizing state-of-the-art dynamic analysis, a range of angles were identified for soccer instep kicking to provide a training framework that ensures accuracy and kick power while minimizing hip injury risk. We hypothesized kicking with decreased hip rotation, increased knee flexion, and decreased hip adduction would result in less eccentric loads on hip musculature, therefore lowering risk of injury.

Methods

In hip motion and injury, the adductors, psoas, and rectus femoris muscles drive body movement [1,3-4], and were isolated for analysis in the optimized model. Using markerless Motion Capture (MoCap), nominal kicking motion was tracked, utilizing pressure-sensing insoles to obtain ground reaction forces (GRF). The dataset defined the right (dominant) leg as the kicking leg and the left as planted. In OpenSim, several iterations of static optimization were performed, sweeping through kicking kinematics within known performance variability to establish an optimized model.



Results

The optimized values were as follows: hip adduction angle at 22°, hip rotation at 32°, and knee angle at 68°. In kicking leg models, peak forces occurred at the start of the swing phase, particularly in the adductor longus and the rectus femoris. Higher knee flexion slightly increased the psoas force but was ultimately beneficial as forces were distributed more evenly. By reducing hip adduction and rotation angles, the muscle forces were lowered, creating safe kicking mechanics. This reduction of swing leg adduction and rotation resulted in lower stance forces on the planted leg.

Discussion

This study defined the specific joint angle parameters optimal for injury prevention while maintaining kicking performance. Soccer professionals can utilize this information to train in effective, risk-reducing kicking form and prevent future hip injuries. The technical approach involving motion capture and neuromusculoskeletal modeling may not only prevent injuries but also create stronger, more technical players.

Estimating knee contact force in a subject with knee osteoarthritis using out-of-the lab measurement systems

MSc. Karin van Minnen[1,2], Dr. Miel Willems[1], MSc. Gloria Scanagatta[1], Dr. Bryce Killen[1], Prof. Ilse Jonkers[1]

[1]KU Leuven, Leuven, Flemish Region, Belgium. [2]Delft University of Technology, Delft, South Holland, Netherlands

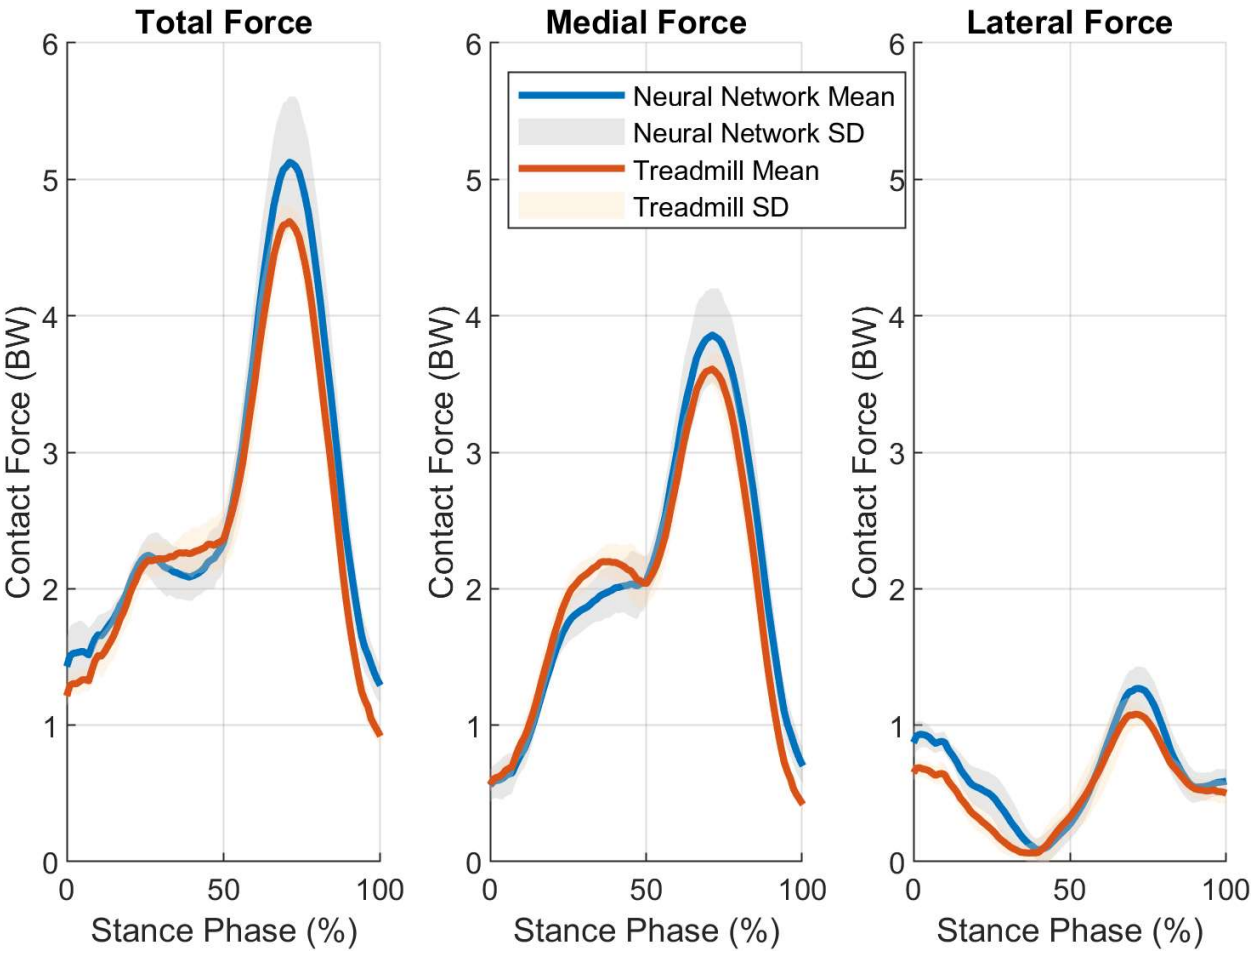
Introduction

Osteoarthritis (OA) is a chronic joint condition, with knee OA (KOA) the most prevalent form (1). Mechanical loading is a key factor in KOA and can be assessed using musculoskeletal (MSK) modelling. This study investigates whether out-of-the-lab measurement systems can serve as input for an MSK modelling framework to estimate knee joint load and support accessible screening.

Methods

Kinematic and kinetic data were collected for 40 seconds of treadmill walking in a male early KOA participant (62 y, BMI 28.4) using OpenCap (2), force plates, and pressure insoles (3). Insole ground reaction forces (GRFs) were decomposed into three components using an in-house neural network (NN). A jump synchronized kinematics and GRFs, and CoPs were aligned using heel and toe markers. A scaled Lenhart model (4) was used for inverse kinematics, inverse dynamics, and COMAK (5) with NN-estimated GRFs and treadmill GRFs (using insole CoP) to compute knee contact forces across eight stance phases.

Results



Maximum medial tibial contact force was 3.910 ± 0.345 BW for NN-predicted forces and 3.642 ± 0.105 BW for GRFs (treadmill), 7% lower. Lateral peaks were 1.299 ± 0.148 BW (NN) and 1.113 ± 0.102 BW (treadmill). The medial peak exceeded previously reported treadmill values (6), while the lateral peak for treadmill forces remained within the reported range.

Discussion

This study presents a workflow for estimating knee contact forces using out-of-the-lab systems. Previous work in our group identified a 3.16% threshold in the second peak to distinguish early KOA from non-OA. The current 7% difference exceeds this, suggesting the estimates are not yet clinically applicable. Future work will focus on optimizing insole-

based CoP and GRF alignment with video-based kinematics, leveraging Bayesian techniques to quantify the effects of positioning error. This is a critical step to maximize the use of out-of-the-lab systems for detecting clinically relevant differences in knee loading.

A CAD-Driven Jig Workflow for Specimen-Specific Joint Alignment Preservation

Ms. Kate Benfield, Mr. Cody Willson, Mr. Jack Holmes, Ms. Angelica Carhaus, Dr. Trevor Lujan

Boise State University, Boise, Idaho, United States

Introduction

Proper knee joint alignment is essential for accurately characterizing joint mechanics during in-vitro simulation. Standard workflows physically digitize bony landmarks to embed anatomical coordinate systems into the femur and tibia, with the bones then manually and permanently potted into the test system. However, this methodology is prone to operator error and becomes problematic when using robotic knee simulators since proper joint rotation requires the bone rotational axes to align with the simulator's mechanical axes. Here we developed a CAD-based jig workflow that allows the operator to virtually verify and correct joint alignment prior to potting.

Methods

An ovine knee joint was scanned using a Keyence 3D scanner to generate high-resolution 3D models of the femur and tibia **(Fig. 1A)**. 3D models were imported into SolidWorks, and anatomical coordinate systems were embedded using established bony landmarks [1]. Each bone was virtually oriented with the medial-lateral and anterior-posterior axes aligned with the global axes of custom jigs **(Fig. 1B)**, thus enabling the creation of specimen-specific cavities. These cavities fully constrain the position of each bone through a precise, form-fitting interface with the jig thus preserving alignment **(Fig. 1C)**. The bone-jig assemblies were then incorporated into a CAD model of the joint testing system to visually inspect alignment **(Fig. 1D)**. The process was repeated five times, and variability was quantified using landmark coordinate differences between trials and angular deviations from the SolidWorks global frame.

Results

Rotational variability across embeddings averaged 2.0° (ML), 1.0° (AP), and 1.3° (DP), while origin variability was 0.12 mm, 0.87 mm, and 0.69 mm along the x, y, and z axes, respectively. Inter-operator consistency was excellent for translations (ICC = 0.98) and rotations (ICC = 0.98). Qualitative assessment confirmed alignment between bones and test system rotational axes.

Discussion

This CAD-driven workflow provides a feasible method for defining and reproducing virtual joint alignment, allowing coordinate frames to be corrected and verified prior to physical joint potting. This work will be expanded using shape-fitting to define embedded bone axes and reduce alignment error, with future studies aimed at evaluating wear-and-tear in ovine knee joints using robotic simulation.

Images (Optional)

The Effects of a Barefoot Orthotic on Ankle Biomechanics

Dr. Kristie Liu, Ms. Dorsa Eshaghi, Dr. Timothy Burkhart

University of Toronto, Toronto, ON, Canada

Introduction

Plantar fasciitis and flat feet are estimated to affect 10% and 25% of the population, respectively. Foot orthotics are commonly used to address these conditions by correcting the foot alignment; however, they are currently designed to be worn in shoes. A novel foot orthotic, HeelSnaps®, has been developed to be worn barefoot. The objective of this study was to quantify the effect of the HeelSnaps® on ankle biomechanics.

Methods

15 healthy adults (6 male, 9 female) completed walking, change of direction (cutting), and squat tasks, barefoot and while wearing HeelSnaps®. Kinematic data were collected using an 8-camera markerless motion capture system (Qualisys Miqus; Qualisys, Gothenburg Sweden). Ground reaction force (GRF) data were collected using two force plates (BP600900; AMTI, Watertown, MA, USA).

Kinematic data were processed using Theia3D software (Theia Markerless Inc., Canada), where data were constrained to three degrees-of-freedom at the hips, knees, and ankles and filtered with a generalized cross-validatory spline smoothing and differentiation filter with an 8Hz cutoff frequency.

The walking and cutting tasks were analyzed during contact with the force place, while the squat was evaluated for the entire movement cycle. Ankle kinematics and GRFs were time normalized to 101 data points. One-dimensional paired t-test statistical parametric mapping was conducted to compare the barefoot and HeelSnaps® conditions ($\alpha=0.05$). The mean difference and standard deviation of statistically significant regions were calculated.

Results

See Table 1 for full results. During gait, significantly reduced dorsiflexion and increased plantarflexion were observed while wearing HeelSnaps®, with short durations of significantly reduced right ankle adduction and increased right ankle internal rotation.

Significant effects for cutting were limited to right-side cuts, with reduced left ankle dorsiflexion and vertical GRF. During the squat, ankle dorsiflexion was reduced bilaterally.

Table 1. Regions of statistical significance between the HeelSnaps® and barefoot conditions at the ankle and in ground reaction forces.

Discussion

Ankle dorsiflexion was reduced while wearing the HeelSnaps®; however, it is unclear whether these small differences improve foot alignment. Future work should evaluate whether foot mechanics are significantly altered in individuals diagnosed with plantar fasciitis and/or flat feet.

Classification of Lower-Extremity Alignment Sub-types in Children with Genu Varum Using Factor and Cluster Analysis

Presenter Kyungeon Kim M

Yonsei University, Seoul, Seoul, Korea, Republic of

Introduction

Lower-extremity alignment in children results from the combined influence of pelvic position, femoral and tibial rotation, knee alignment, and foot–ankle posture. Disruptions in this kinetic chain—particularly the structural deviations observed in genu varum (GV)—can alter load distribution and compensation patterns, increasing long-term risk for musculoskeletal dysfunction. However, existing research has relied largely on isolated alignment measures, leaving the **latent multidimensional structure** of GV-related alignment patterns poorly defined. Therefore, this study aimed to identify underlying alignment factors and classify distinct structural subtypes in children with GV through a combined factor and cluster analytic approach.

Methods

Clinical and biomechanical alignment variables—including Q-angle, tibiofemoral angle, and rearfoot angle in both weight-bearing conditions; pelvic alignment; femoral anteversion; leg-length discrepancy; navicular drop; tibial torsion; tibial varum; genu recurvatum; and forefoot angle—were collected from the dominant limb of 218 participants. Principal Component Analysis was conducted to identify the latent structure of lower-extremity alignment, yielding seven core factors. These factor scores were then used to classify alignment patterns within the GV. A hierarchical cluster analysis was first performed to determine the optimal cluster solution. Based on the dendrogram, K-means clustering was applied to assign participants to final clusters. One-way ANOVA was conducted to test factor score differences across clusters. Significant factors were further examined using Bonferroni post hoc tests. This procedure enabled the identification and validation of distinct GV alignment subtypes.

Results

Factor analysis identified seven distinct alignment factors capturing both structural and compensatory characteristics of the lower extremity. Based on these factor-derived patterns, three GV subtypes emerged. Cluster 1 exhibited marked pelvic asymmetry,

pronounced arch-collapse compensation, and strong pelvic–forefoot coupling. Cluster 2 was defined by increased tibial torsion accompanied by reduced pelvic tilt, representing a rotational compensation subtype. Cluster 3 showed elevated pelvic tilt and forefoot alignment with minimal pelvic asymmetry. Collectively, these clusters illustrate heterogeneous combinations of structural deviations and compensatory strategies among children with GV.

Discussion

The findings emphasize that GV encompasses multiple biomechanical pathways rather than a single structural deformity. The identification of subtypes based on factor-derived alignment profiles offers an important step toward individualized assessment and intervention.

Muscle Activity Patterns According to Chopstick-Holding Methods

Ms. Kyungmin Lee, Mr. Taehyung Kim, Prof. Gwanseob Shin

Ulsan National Institute of Science and Technology, Ulju-gun, Ulsan, Korea, Republic of

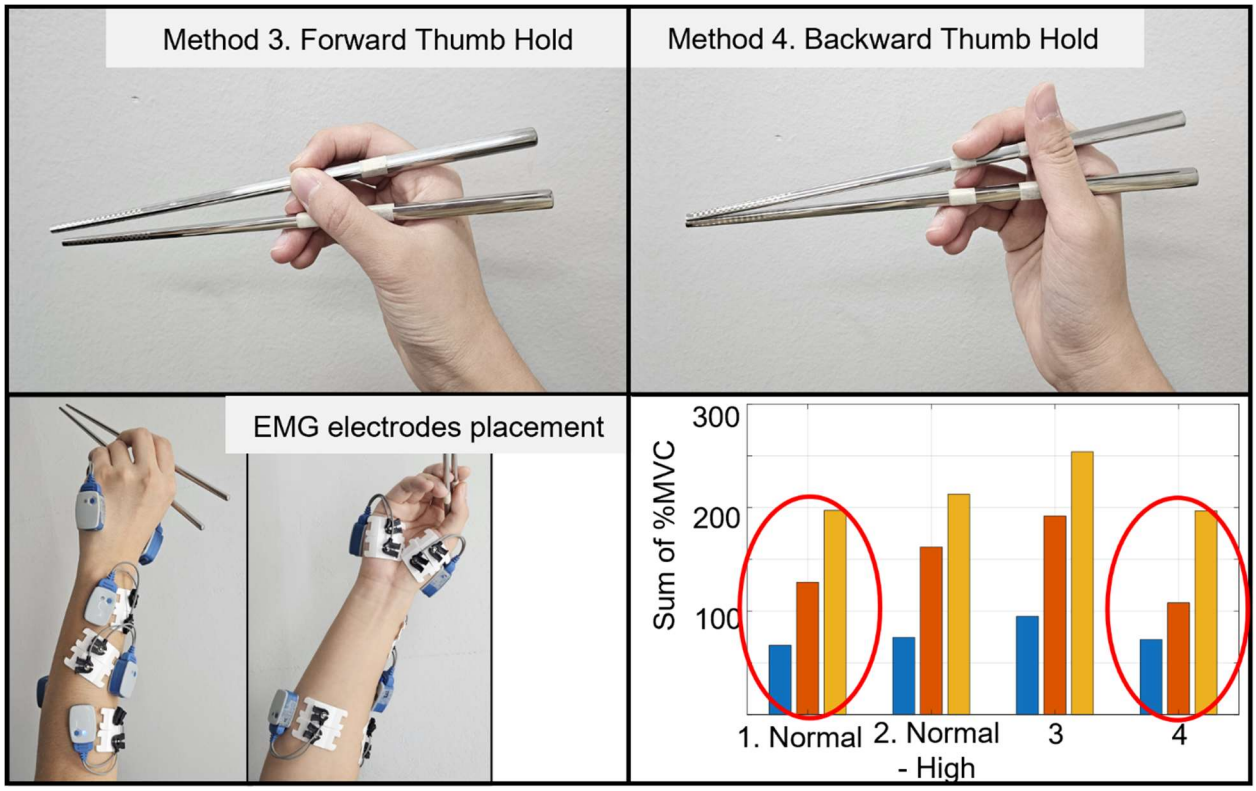
Introduction

Using chopsticks is a complex fine-motor skill that requires precise coordination of several hand and arm muscles. Chopsticks are widely used as an essential eating tool in East Asian cultures, and their use has recently spread worldwide. Despite this, the biomechanical characteristics according to different chopstick-holding postures and force levels have not been sufficiently examined. Especially, differences in holding styles may influence muscle activity and operation efficiency. The purpose of this study is to investigate the muscle activity patterns of hand and arm muscles under different chopstick-holding postures and force conditions.

Methods

Healthy participants in their twenties performed a task in which they maintained chopstick-holding postures under one uncontrolled preferred posture and three pre-determined controlled posture. And the task included three force conditions, and each condition was performed in a randomized order. During the task, electromyography (EMG) signals were collected from six hand and arm muscles to compare muscle activity according to the different posture and force condition. The EMG signals were normalized to maximum voluntary isomeric contraction (MVC) for analysis.

Results



Muscle activity was different depending on the chopstick-holding posture and force level. For most patients, EMG activity tended to increase in all muscles as the force level increased. Interestingly, among the newly introduced postures, backward thumb hold posture showed muscle activity that was similar to or more efficient that the participant's usual posture. In contrast, the other posture tended to show higher muscle activity compared to the usual posture.

Discussion

This study showed that chopstick-holding posture and force level influence muscle activity. Particularly interesting thing was that one of the newly introduced postures appeared to be as efficient as, or more efficient than, the participants' usual posture. These results suggest that there may be alternative methods of using chopsticks that are more efficient than the

traditional method commonly used. Therefore, the findings of this study emphasize the importance of holding techniques in chopstick use and provide new evidence that may be useful for future chopstick training, rehabilitation exercises, and ergonomic tool design.

Relationship Between Lower Extremity Joint Range of Motion and Center of Mass Vertical Displacement During Running

Ms Lailah Rosario, Ms. Megan Peach DPT, Dr. James Becker PhD

Montana State University, Bozeman, MT, United States

Introduction

Higher center of mass vertical displacement (comVD) in long-distance runners has been related to overuse injuries. While cycle metrics such as stride length and step frequency have been established as interventions to reduce comVD, it is unclear if manipulating lower extremity joint range of motion (ROM) has utility as an intervention to reduce comVD. This study aims to evaluate the relationship between lower extremity joint ROM and comVD during running.

Methods

Fifteen participants (7 F, 8 M; 23.25 ± 2.32 years, height 1.77 ± 0.08 m, mass 75.96 ± 12.99 kg, weekly activity 326.56 ± 158.48 minutes) ran five trials along a 15 m runway while whole body kinematics were recorded using markerless motion capture. A 13-segment biomechanical model was used to calculate center of mass, and sagittal hip, knee, and ankle angles. Total sagittal joint ROM and comVD was calculated during stance phase. A multiple linear regression model was used to determine relationships between hip, knee, and ankle ROM and comVD during running.

Results

A model including ROM for hip, knee, and ankle accounted for 41.4% of the variance in comVD ($F = 16.49$, $p = <.001$). Knee and ankle ROM, but not hip ROM, were significant predictors of comVD, with increasing ROM resulting in greater comVD.

Discussion

An increase of a single degree of sagittal knee or ankle ROM results in ~1 mm increase in comVD during running. Reducing knee or ankle ROM during running has potential as an intervention to reduce comVD. Future studies should examine interventions that target reductions in knee or ankle ROM as a means of decreasing comVD and identify any adverse biomechanical consequences that may result from decreasing ROM.

Images (Optional)

Table 1 Variable Statistics

	Mean ± SD	β	*p* value
ComVD (cm)	7.81 ± 1.67	0.03	-
Hip ROM (deg)	44.35 ± 5.41	-0.001	0.086
Knee ROM (deg)	33.53 ± 5.94	0.001	<.001
Ankle ROM (deg)	38.50 ± 6.37	0.001	.014

Estimating Joint Moments During Walking With a Markerless, Smartphone-Based Motion Capture System

BSc BEd Laura Rathmair[1], BSc MSc PhD Willi Koller[1], FH-Prof. Priv.-Doz. Dr. Brian Horsak Brian Horsak[2], Assoc. Prof.Mag. MSc PhD Hans Kainz[1]

[1]University of Vienna, Vienna, Vienna, Austria. [2]University of Applied Sciences St. Pölten, St. Pölten, Lower Austria, Austria

Introduction

OpenCap is a new, markerless motion capture system providing an easily accessible, low-cost alternative to marker-based motion capture. OpenCap estimates joint angles, ground reaction forces (GRF) and joint moments solely based on video recordings from at least two synchronized smartphones [1]. Several studies have examined OpenCap's accuracy regarding joint kinematics, whereas joint kinetics have only scarcely been examined. This study explored OpenCap's ability to estimate GRFs and joint moments during walking.

Methods

Walking trials of nine healthy, uninjured adults were recorded with a 12-camera marker-based system, and force plates simultaneously with OpenCap using four smartphones. Four different workflows were compared: 1) *OpenSimStandard*: standard marker-based approach in OpenSim with force plate GRF data, 2) *OpenCapOnly*: standard OpenCap configuration to estimate joint angles, GRFs and joint moments, 3) *OpenCapForcePlate*, standard OpenCap configuration using GRF data from force plates, and 4) *OpenSim+GRF*$_{est}$: combining marker-based kinematics with GRFs estimated as in OpenCap. For all workflows, average waveforms of joint angles, GRFs and joint moments were compared using Statistical Parametric Mapping (SPM) based paired t-tests [2].

Results

An overall root mean square error (RMSE) of 7.2 ± 3.4 degrees for joint angles between marker-based data and OpenCap was found. For both markerless and marker-based kinematics, GRFs were systematically overestimated by OpenCap. Peaks and zero-crossings of GRFs were more consistent with marker-based kinematics. SPM results revealed that *OpenCap+ForcePlate* was similar in waveforms to *OpenSimStandard*, while *OpenCapOnly* and *OpenSim+GRF*$_{est}$ differed significantly from *OpenSimStandard* for most of the stance phase.

Discussion

OpenCap+ForcePlate showed reasonable waveform similarity with *OpenSimStandard*, especially for joint moments in the sagittal plane. This workflow yielded both low RMSE and high coefficient of multiple correlations values, suggesting that the estimation of joint moments is primarily influenced by GRF quality rather than kinematic inputs. *OpenCapOnly* showed large deviations in GRFs and joint moments from *OpenSimStandard*, likely resulting from inaccurate GRF estimation due to imperfect markerless joint kinematics. Findings suggest that smartphone-based approaches can approximate the overall temporal patterns of gait kinetics, but caution is advised if accurate quantification joint moments is necessary.

Evaluating the Effect of Gait Modifications on Hip and Knee Joint Contact Forces in Children

BSc BEd Laura Rathmair[1], Dipl.-Ing. Clara Egner BSc[1], BSc Kevin Kitir[1], BSc MSc PhD Willi Koller[1], Assoc.-Prof. Mag. Hans Kainz MSc PhD[1], Dr. rer. nat. Nathalie Alexander[2], Ing. Dr. Andreas Kranzl[3], Dr. Peter Pivonka[4], Assoc. Prof. Claudio Pizzolato BSc MSc PhD[5]

[1]University of Vienna, Vienna, Vienna, Austria. [2]Ostschweizer Kinderspital, St. Gallen, Ostschweiz, Switzerland. [3]Orthopaedic Hospital Speising, Vienna, Vienna, Austria. [4]Queensland University of Technology, Brisbane, Queensland, Australia. [5]Griffith University, Brisbane, Queensland, Australia

Introduction

Gait modifications can alter joint loadings and influence the progression of degenerative diseases in adults [1]. In children with cerebral palsy, abnormal hip (HJCF) and knee joint contact forces (KJCF) have been linked to pathological growth plate stresses, which may contribute to pathological femoral development [2, 3]. However, it remains unclear whether gait modifications can change joint contact forces (JCF)- and thereby affect femoral growth- in children. This study aimed to evaluate how different gait modifications influence HJCF and KJCF in a paediatric population.

Methods

Three typically developing children underwent magnetic resonance imaging and three-dimensional gait analysis (Vicon, Oxford, UK) on a force plate instrumented treadmill (AMTI, Watertown, USA). Participants walked physiologically, and with varying degrees of in- and out-toeing, stance width, foot strike patterns and walking velocities. Personalized musculoskeletal models were created using the OpenSimCreator ModelWarper [4] which adapts bone geometries and muscle paths of a RajagopalLaiUhlrich2023 model to match the individual's anatomy obtained from imaging. Mean KJCF and HJCF of 5-7 trials per leg and condition were calculated for each participant using musculoskeletal simulations in OpenSim with static optimization. JCF were then compared across conditions

Results

So far, only modifications of the foot progression angle (FPA) have been analyzed. In all participants, the in-toeing modifications reduced peak KJCF during terminal stance at least on one leg, compared to normal walking. Effects of the gait modifications on the magnitude and orientation of HJCF varied among participants (Figure 1).

Discussion

To our knowledge, this is the first study to show that gait modifications can alter JCF in children. For participant TD03, asymmetries in KJCF may relate to differences in femoral anteversion (7° left, 13.3° right), highlighting how anatomy affects modification effects. Preliminary results showed that in-toeing can reduce peak KJCF during terminal stance. HJCF changes displayed substantial inter-individual variability with no consistent trend. These findings emphasize the need for personalized musculoskeletal models and individualized gait interventions to modulate joint loading in children.

In-vivo Tibiofemoral Kinematics of Healthy Knees during Daily Activities Using Biplanar Videoradiography

Miss Lauren Swain[1], Dr David Williams[1], Miss Janine Flohr[1], Mrs Jenny Williams[1], Prof Andrew Amis[2], Dr Richard van Arkel[2], Prof Cathy Holt[1]

[1]Cardiff University, Cardiff, Wales, United Kingdom. [2]Imperial College London, London, England, United Kingdom

Introduction

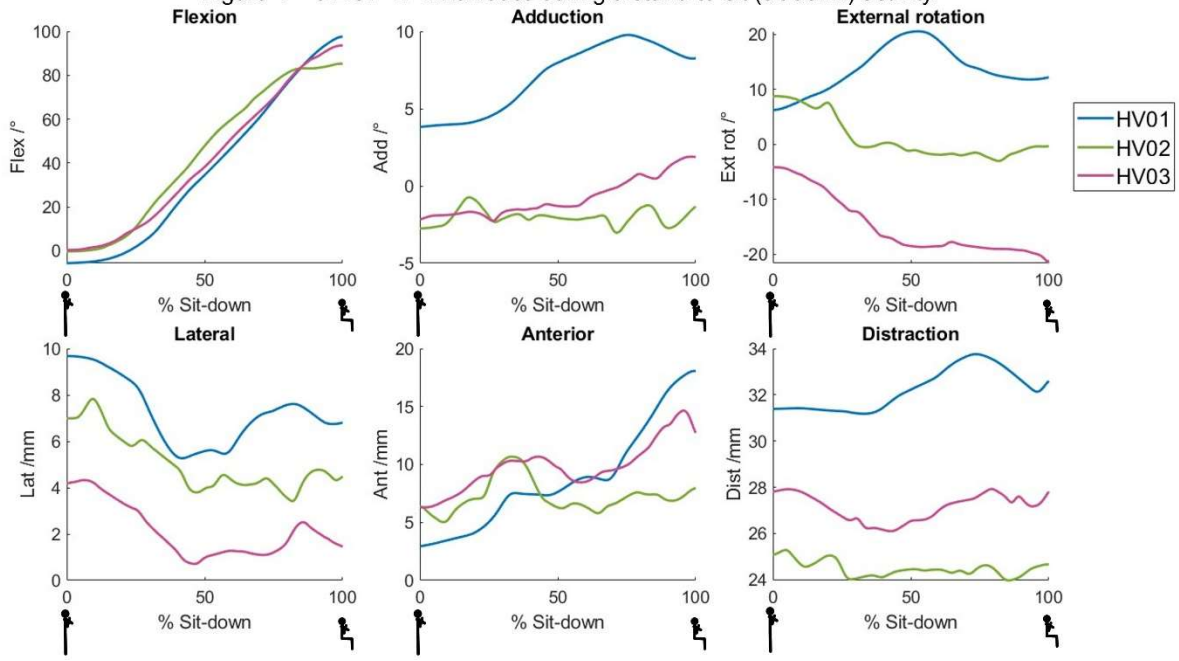
Accurate quantification of tibiofemoral (TF) kinematics in-vivo is essential for understanding how osteoarthritis and total knee replacement (TKR) alter joint function, yet existing motion analysis methods lack the precision to resolve subtle but clinically important abnormalities. Biplanar videoradiography (BVR) combined with MRI allows direct measurement of the bones during different activities of living, enabling accurate calculation of joint kinematics. To be able to evaluate the biomechanical and functional effects of knee disease and treatments it is important to be able to quantify healthy knee function.

Methods

A range of activities were included to investigate the biomechanical function of the TF joint, including level and downhill treadmill walking, step down, stand-to-sit, pivot and knee extension. BVR, and synchronised motion capture, were collected during the dynamic activities in a cohort of healthy volunteers. Image registration was performed (SlicerAutoscoperM [1]) by matching digitally reconstructed radiographs derived from MRI segmented bone models (Simpleware, ScanIP) to BVR X-rays per frame to determine bone poses. Anatomical coordinate systems were applied to the segmented bone models [2]. Six degree of freedom kinematics were calculated (MATLAB, Mathworks) from the bone poses using Grood and Suntay's methodology [3].

Results

Figure 1 presents pilot results for three healthy participants for one activity (stand-to-sit) to demonstrate the use of the processing pipeline.



Discussion

Flexion profiles were highly consistent across participants, and anterior translation indicated a clear femoral rollback pattern in two of the three volunteers. In contrast, adduction and external rotation exhibited pronounced inter-participant variability,

reflecting the different movement strategies adopted to accomplish the stand-to-sit task. Similar flexion and anterior translation patterns have been reported previously in TKR cohorts [4]. This work will be expanded in the future to the rest of the activities, as well as to a pre- and post-TKR patient cohort. The 6 DOF TF kinematics will inform a larger study, incorporating in-vitro and in-silico methods to investigate knee joint function across these cohorts.

P2-071

A Higher Muscle Energy Cost, Not Lower Efficiency, May Explain the Elevated Energy Cost of Joint Work Redistribution

Ms. Lisa Cozma[1], Dr. Jared Fletcher PhD[2]

[1]University of Calgary, Calgary, Alberta, Canada. [2]Mount Royal University, Calgary, Alberta, Canada

Introduction

Mechanical joint work shifts from distal to proximal joints during running, elevating the metabolic cost. It is assumed that metabolic cost increases because muscles crossing the knee are less efficient compared to muscles crossing the ankle [1]. This study compared muscle efficiency of the vastus lateralis (VL) and the gastrocnemius medialis (GM) while performing fixed mechanical joint work.

Methods

13 recreationally-active adults (23±2yrs, 177±10cm, 71.8±9.9kg) performed positive ankle and knee mechanical joint work (Wmech) targeting 50% maximal ankle plantarflexion moment over 50% of joint-specific range of motion on a dynamometer. Indirect calorimetry quantified metabolic cost of performing work (Emet). Positive muscle work (Wm) was calculated from ultrasound-measured GM and VL fascicle shortening and estimated muscle forces [2]. Mechanical (εmech) and muscle efficiencies (εm) were calculated as the ratios of Wmech to Emet and Wm to Emet, respectively. Muscle shortening velocity associated with peak (Vopt) was calculated [3].

Results

Wmech was not significantly different between ankle (24.6±11.5J/cycle) and knee (31.8±11.8J/cycle, p=0.071). Wm and Emet were significantly higher in VL compared to GM (p<0.01). Knee εmech was significantly higher (8.1±2.5%) than the ankle (5.5±2.1%, p=0.005). εm was similar across muscles (7.5±2.4% for GM and 8.9±4.1% for VL, p=0.393). VL shortened 29±12% slower than Vopt while GM shortened 14±11% faster than Vopt. A weak-to-moderate, positive correlation between Wmech and εmech was seen at the ankle (r2=0.21, p=0.25) and at the knee (r2=0.42, p=0.04, Figure1). εm was

independent of Wm for the GM, (r2=-0.11, p=0.70) which was not the case for the VL (r2=0.61, p=0.005).

Discussion

Performing Wmech at the ankle was less efficient than performing Wmech at the knee. These results refute the notion that energy cost of running increases as a result of joint work redistribution. Rather, greater muscle work and muscle energy cost to perform mechanical work in muscles crossing the knee may explain the elevated energy cost seen during running, independent of differences in εm.

Achilles Tendon Structure-Function Varies Across Menstrual Cycle Phases in Participants With and Without Hormonal Contraceptive Use

Ms. Madeleine Krotine, Dr. Stephanie Cone PhD

University of Delaware, Newark, DE, United States

Introduction

Females undergo changes in hormone (i.e. estrogen) levels through the menstrual cycle and hormonal contraceptive (HC) use, directly impacting the biochemical environment of the body with suspected effects on musculoskeletal health [1]. Lowered estrogen levels are thought to impact tendon mechanics and injury incidence in Achilles rupture and tendinopathy [2]. However, mechanisms behind these structure-function hormonal impacts are still poorly understood. This study aimed to compare daily hormone levels and weekly Achilles structure-function metrics across menstrual cycle phases in HC users and naturally cycling (NC) participants.

Methods

Female participants (HC=4, NC=4), aged 18-45 experiencing regular menstrual cycles (21-35 days, <10 days of inter-cycle variation), underwent 12 weeks of daily hormone testing and weekly structure-function testing. Daily at-home hormone testing was performed using commercial monitors. Weekly testing assessed ankle dorsiflexion range of motion (ROM), ultrasound measurement of tendon thickness and cross-sectional area (LOGIQe,10.0 MHz), shear wave tensiometry measurement of walking and running [3], and plantar-flexion maximum voluntary isometric contractions (MVICs) in a prone position and a neutral ankle angle (HUMAC Norm). Menstrual cycles were sorted into four phases and individual strides were segmented for gait measures. A linear-mixed effects model was used to assess statistical difference between weeks and groups.

Results

A significant effect of cycle phase in the HC user group was found for normalized plantar-flexion MVIC and normalized Achilles tendon thickness ($p=0.034$,$p=0.04$), however follow-up mean comparisons did not show phase-specific differences (Figure 1). No significant effects were found in the NC group.

Discussion

These findings indicate strength and structure changes across the menstrual cycle, potentially indicating variations in performance and tendon health. HC users exhibited greater aggregate variation between cycle phases than NC users, possibly related to HC use stabilizing hormone levels and thus cyclic patterns for improved statistical power within this cohort. Between- and within-subject variability was evident at the current sample size, motivating continued study with increased enrollment and advanced analysis of hormone concentrations.

Sex Differences in Hip Contact Forces During Dynamic Tasks in Healthy Adults

Ms. Margaret Harrington BKin, Ms. Dorothy Zeng, Dr. Timothy Burkhart PhD

University of Toronto, Toronto, Ontario, Canada

Introduction

Hip contact forces (HCFs) may influence the risk of developing hip disorders, such as femoroacetabular impingement syndrome (FAIS), and affect treatment outcomes. Movement patterns that may result in abnormal HCFs have been shown in females with FAIS [1], but research quantifying sex-specific HCFs is limited. Therefore, the purpose of this study is to compare HCFs between healthy males and females during dynamic body weight tasks to establish normative values.

Methods

Thirty physically active adults (15 females; aged 18-40 years) with no lower extremity injuries participated in this ongoing study. Whole-body kinematics were captured using Theia3D markerless motion capture, along with simultaneous ground reaction forces, while the participants performed three trials each of squats to maximum depth, gait, forward lunges, countermovement jumps, and side-cut maneuvers. OpenSim was used to estimate joint angles and moments, muscle forces, and HCFs.

Results

Preliminary analysis of the squat task for ten participants (five females) showed sex-related differences in hip kinematics and joint loading. While the mean ± SD peak resultant HCF was the same for both sexes (2.8±1.1 N/BW), and peak hip flexion was comparable (116.1±9.0° vs. 112.3±6.2°), females displayed higher HCFs for a longer duration of the squat cycle, particularly during the descent (~0-50% of the cycle), along with higher hip flexion (Figure 1). Additionally, females demonstrated higher peak anterior pelvic tilt (27.5±10.2° vs. 15.3±3.2°) and hip internal rotation (9.1±6.2° vs. 6.0±4.2°), and less hip abduction (-13.5±5.5° vs. -21.6±6.9°) compared to males, with these patterns maintained throughout the entire time-normalized squat cycle (Figure 1).

Discussion

These preliminary findings support previous research indicating that sex-based kinematic differences may contribute to differences in HCFs [1]. This study aims to establish

normative data on hip loading patterns in young, healthy males and females, to help understand why certain hip disorders disproportionately affect females and why treatment outcomes can differ by sex. Ongoing analysis will include all participants, tasks, and additional variables (e.g., muscle forces), creating a comprehensive data set for future comparisons with individuals experiencing chronic hip pain and disorders.

Images (Optional)

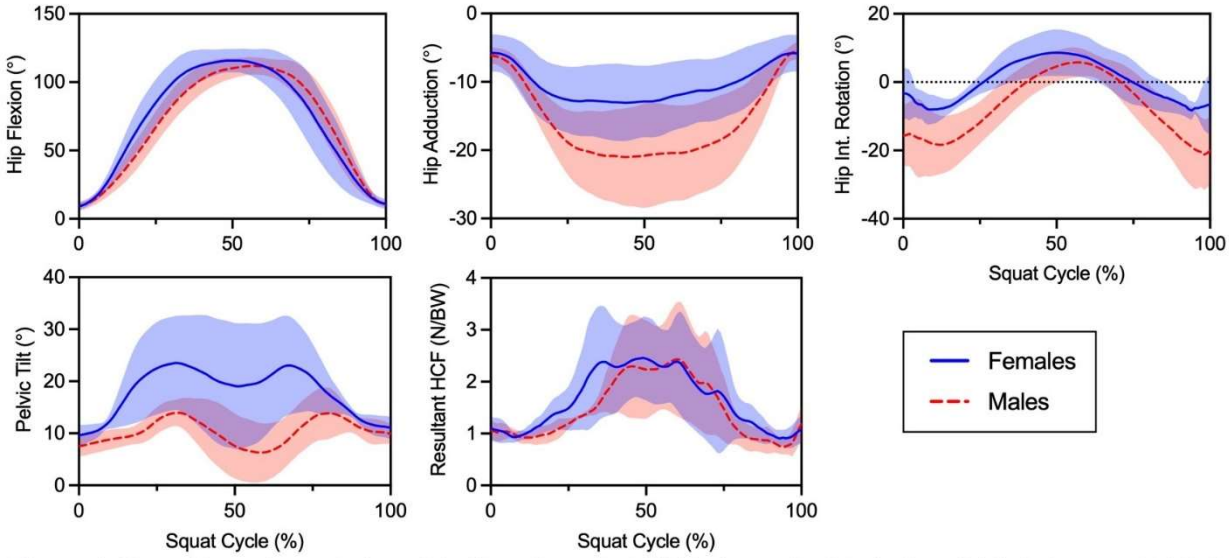

Figure 1. Mean hip angles, anterior pelvic tilt, and resultant HCFs (normalized to body weight) during squat trials for female (n = 5) and male (n = 5) participants. Data was time-normalized to 100% of the movement cycle, with averages calculated from three squat trials and both hips. Shaded areas indicate the standard deviation.

Preliminary Assessment of Knee Joint Mechanics in Children with and without Marfan Syndrome

Ms. Mariana V. Jacobs MS, Dr. Jody L. Clasey PhD, Dr. Christopher S. Fry PhD, Dr. Mary B. Sheppard MD, Dr. Michael A. Samaan PhD

University of Kentucky, Lexington, Kentucky, United States

Introduction

Marfan syndrome (MFS) is a hereditary autosomal dominant connective tissue disorder caused by mutations in the fibrillin-1 (FBN-1) gene. Muscle dysfunction, severe joint pain, and a high incidence of early onset osteoarthritis (OA) is prevalent in adults with MFS. Additionally, adults with MFS ambulate with altered knee joint mechanics that may be associated with OA development. As MFS is a genetic disorder, these aberrant gait patterns may be present at an earlier age during the lifespan. Therefore, the purpose of this study was to compare knee joint kinematics and kinetics during walking in children with and without MFS.

Methods

This preliminary cross-sectional analysis included three children with MFS (2F; age=8.3±2.1 yrs; height=1.6±0.2 m; mass=48.7±28.5 kg) and two healthy, asymptomatic controls (2F; age=7.5±0.5 yrs; height=1.3±0.03 m; mass=24.9±0.3 kg). All participants underwent motion capture while ambulating at a self-selected walking speed. Between-group differences in sagittal, frontal and transverse plane knee joint kinematics and external joint moments were assessed using an independent t-test. Statistical significance was set at $p<0.05$.

Results

There were no significant between-group differences in age, height, mass or gait speed ($p>0.05$; Table 1). Children with MFS exhibited larger frontal plane knee joint range of motion ($p=0.02$; Table 1) and a smaller external knee adduction moment during the second half of stance ($p=0.03$; Table 1) compared to children without MFS.

Discussion

These preliminary data demonstrate that children with MFS ambulate with altered knee joint mechanics when compared to children without MFS. More specifically, children with MFS exhibit more frontal plane knee joint laxity and exhibit a reduced frontal plane knee joint load during the propulsive phase of gait. Our ongoing research will assess knee joint

muscle function (strength and rate of torque development), knee joint bone and articular cartilage health via Dual energy X-ray absorptiometry (DXA) and quantitative ultrasounds, respectively, in a larger cohort size. Our long-term goal is to determine the potential alterations that occur in knee muscle and joint function in children with MFS to help inform interventions to mitigate knee joint disease at an earlier age in the lifespan in individuals with MFS.

Upper-Limb Joint Moments and Muscle Forces During Cup-Transport Reaching Tasks With Different Precision Requirements

Mr. Masaya Suzuki B.S., Prof. Yoshimori Kiriyama Ph.D, Prof. Katsumasa Tanaka Ph.D

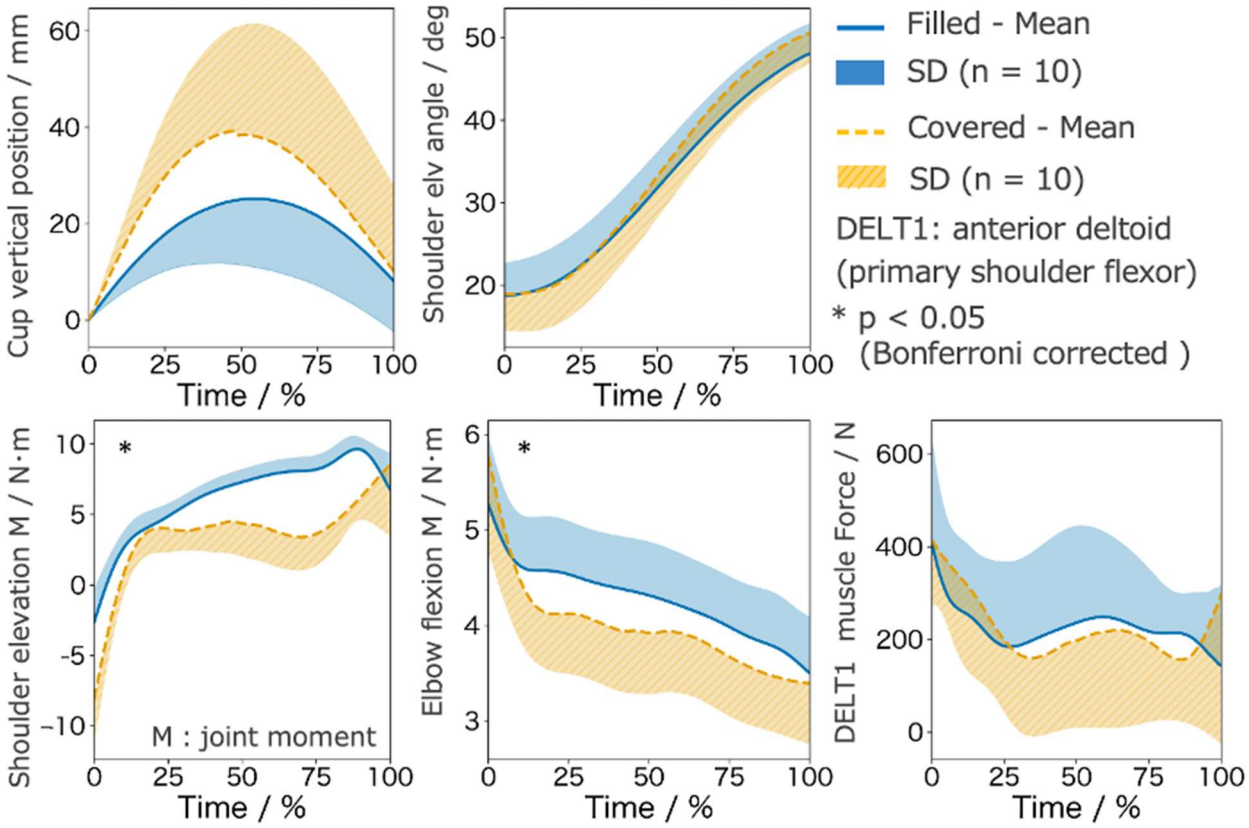
Kogakuin University, Shinjuku, Tokyo, Japan

Introduction

Transporting a liquid-filled cup requires accurate control to prevent spillage, yet its effects on upper-limb joint loading and individual muscle forces remain unclear. Therefore, this study compared a water-filled cup with an exposed liquid surface (Filled) and the same cup with a lid (Covered) during a cup-transport reaching task.

Methods

Ten healthy subjects performed seated forward cup-transport reaching under two randomized conditions (Filled and Covered). Three-dimensional motion capture data were used to scale the Saul et al. upper-limb musculoskeletal model in OpenSim [1]. Shoulder and elbow joint moments were computed by inverse kinematics and inverse dynamics. Individual muscle forces were estimated by static optimization with a sum-of-squared-activations objective. For each subject and condition, waveforms were time-normalized to 0–100% of the reaching phase, and time-integrated shoulder and elbow flexion moments were computed. Condition differences were tested using Wilcoxon signed-rank tests with Bonferroni correction ($\alpha = 0.05$).



Results

Cup and upper-limb joint angle waveforms were generally similar between conditions, with no marked differences in reaching duration or end-point posture. The vertical cup trajectory tended to be lower in Filled than in Covered. Time-integrated shoulder and elbow flexion moments over the reaching phase were significantly larger in Filled ($p < 0.05$), with differences of about 1–5 N·m. Muscle force waveforms largely overlapped between conditions, and no muscle showed a significant condition effect after multiple-comparison correction, although anterior deltoid force tended to be slightly greater in Filled around mid-reach.

Discussion

Participants maintained similar reaching kinematics between conditions, but appeared to accommodate the exposed liquid by lowering the cup slightly and modestly increasing time-integrated shoulder and elbow flexion moments. This adjustment could have helped stabilize the liquid surface against sloshing or perturbations. The additional torque at the shoulder and elbow was small, indicating only limited changes in mechanical load. The trend toward higher anterior deltoid force is consistent with its role as a proximal monoarticular shoulder flexor that could fine-tune shoulder flexion torque while leaving elbow and forearm kinematics largely unchanged, suggesting that the extra torque was generated primarily by a slight increase in its activation.

Shape and Motion of the Trapeziometacarpal Joint

Mr Matthew Oram, Dr Roberto Leonardo-Diaz, Dr Sophie Williams, Dr Marlène Mengoni

University of Leeds, Leeds, West Yorkshire, United Kingdom

Introduction

The trapeziometacarpal (TMC) joint is a saddle-shaped articulation between the trapezium and the first metacarpal that enables much of the thumb's motion and stability. Osteoarthritis is common in the TMC joint and can lead to pain and loss of function. The influence of joint surface shape on range of motion (ROM)—and how this affects surgical outcomes—remains ambiguous. This study used bone surface meshes and kinematics data from the "Open-Source Carpal Database" [1] to investigate whether curvature-based metrics of joint shape are associated with maximum active ROM in healthy TMC joints.

Methods

Wrists from healthy volunteers (n=46; 25 Females, 21 Males; age groups: 18–25 yr, 45–75 yr) were analysed in four maximum active ROM positions. The motion of the first metacarpal relative to the trapezium was quantified by computing rotations about the principal axes of flexion–extension and abduction–adduction. Articular surface regions were extracted from each mesh, and 5^{th} order polynomial surfaces were fitted, from which curvature maps were calculated. Differences in the principal curvatures of opposing points on the trapezial and metacarpal articular surfaces were used to compute a pose dependent measure of joint congruence. Correlations were assessed between ROM, surface-averaged curvatures, and congruence metrics across subjects.

Results

There were large individual differences in active ROM measurements (17°–64°), but no significant correlations were found between ROM and surface-averaged curvature or overall congruence. These trends were consistent across both primary movement directions and across age and sex groups. The strongest observed relationship was a modest positive association between ROM during flexion–extension and congruence in the 18–25 yr group (ρ=0.38), but this trend was not present in the 45–75 yr group (Fig. 1).

Discussion

The absence of a clear relationship between the investigated measures of TMC joint shape and motion, suggests that these metrics alone are not primary determinants of unloaded active ROM in healthy TMC joints. These results indicate that further research into soft tissue factors such as ligamentous constraints, capsular laxity, and muscular control may provide clearer insight into the key drivers of thumb function.

Images (Optional)

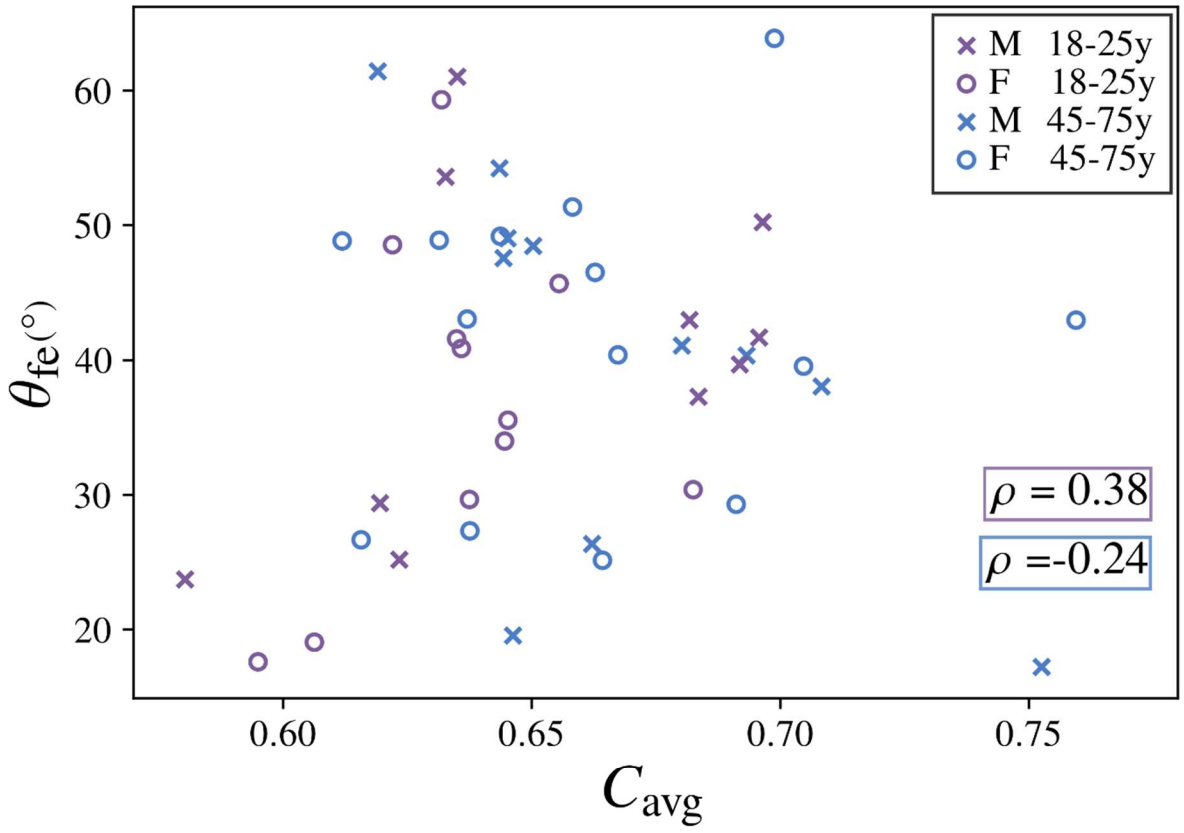

Fig. 1: Relationship between metacarpal principal rotation from the flexed to extended poses (θ_{fe}) and joint congruence averaged across all poses (C_{avg}). Pearson correlation coefficients for both age groups are labelled in the purple (18-25 yr) and blue (45-75 yr) boxes.

Sensitivity of Sit-to-Walk Joint Moments to Age-Related Mass Distribution

Mr. Michael Miller[1], Dr. Eline van der Kruk[2], Dr. Katherine Knaus[1], Dr. Anne Silverman[1]

[1]Colorado School of Mines, Golden, Colorado, United States. [2]Delft University of Technology, Delft, South Holland, Netherlands

Introduction

Sit-to-walk (STW) transitions place substantial mechanical demands on older adults. Generic inertial property definitions may not reflect age-related changes in body mass distribution. Older adults have greater torso and pelvic mass relative to lower limbs compared to younger adults [1], which can require greater joint moments to rise. We systematically increased the relative upper-body mass of a male and female model to determine effects on joint moments during STW.

Methods

A generic model containing 37 degrees of freedom and 22 segments was scaled in size and body mass to the heaviest older male and female participants from a larger study (Male: 53 yrs, 107.3 kg, 1.8 m; Female: 65 yrs, 115.7 kg, 1.67 m). Baseline model mass distributions were 44% in the head, arms and trunk (HAT) and 56% in the lower limbs (male), and 45% HAT/55% lower limbs (female) [2]. Relative segment masses were adjusted to match dual x-ray absorptiometry measurements for older men (47% HAT/53% legs) and women (49% HAT / 51% legs) (aged condition) [1,3]. Then, mass was shifted in 5% total body mass increments from the legs to the HAT until 25% of the mass had shifted, resulting in seven mass-distributed models per participant. Lower limb joint moments calculated using inverse dynamics were normalized to body mass.

Results

Using older segment mass distributions [1,3] increased peak hip extension moments by 4.1% (male) and 2.5% (female), and peak knee extension moments by 1.1% (male) and 1.0% (female) from baseline models (Figure). Ankle plantarflexion moments changed <1%. A 25% mass shift increased peak hip extension moments by 25.1% (male) and 24.5% (female), and knee extension moments by 4.0% (male) and 2.7% (female).

Discussion

Altering generic models to reflect older adult segment mass distributions produced the greatest changes in hip moments, but the percent change was small. Age-related mass distribution has limited influence on joint moments during low-velocity tasks like STW,

particularly at distal joints. More extreme mass shifts substantially altered joint moments at instances with high acceleration at more proximal joints.

Images (Optional)

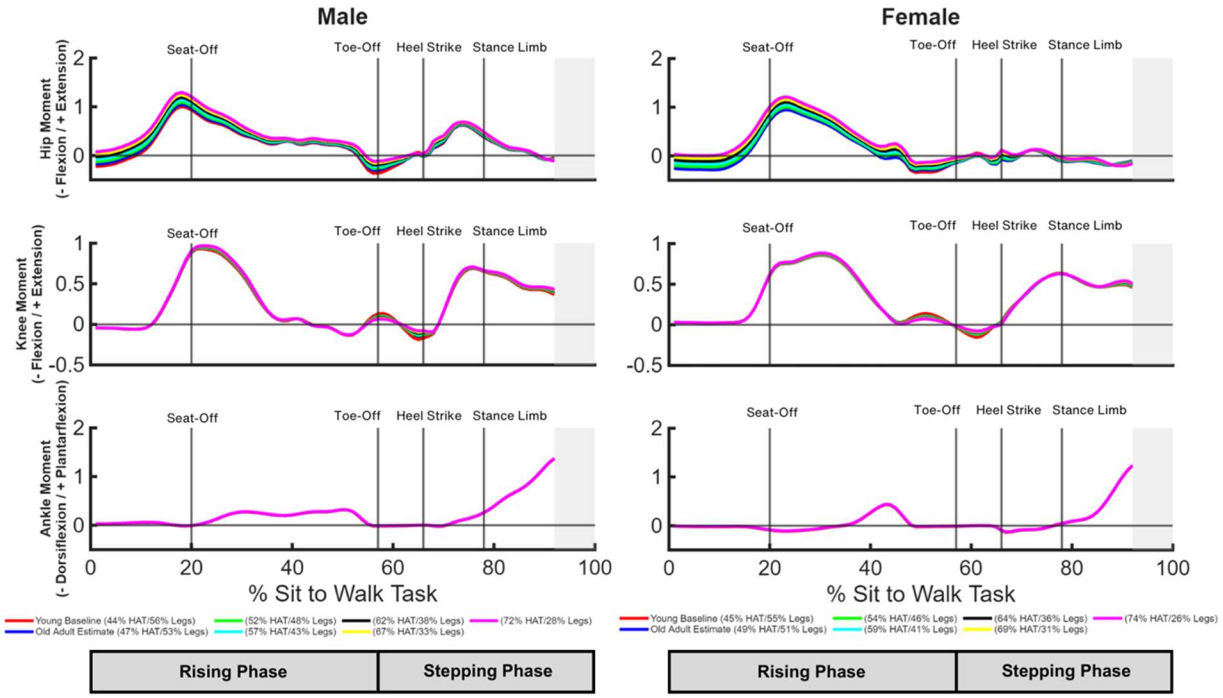

Figure: Body mass-normalized hip, knee and ankle joint moments for male and female models on the stepping limb during STW. STW began when the forward body center of mass velocity exceeded 0.15 m/s and ended when the stepping limb left the second force plate.

Aged Muscle Parameters Affect Muscle Recruitment During Simulations of Sit-to-Walk

Mr. Michael Miller[1], Dr. Eline van der Kruk[2], Dr. Katherine Knaus[1], Dr. Anne Silverman[1]

[1]Colorado School of Mines, Golden, Colorado, United States. [2]Delft University of Technology, Delft, South Holland, Netherlands

Introduction

Musculoskeletal simulations can estimate muscle forces during movements like sit-to-walk (STW) but depend on musculotendon parameters that change with age [1]. We evaluated predicted muscle forces from aged musculotendon parameters in an older adult completing STW. Soleus (SOL), gastrocnemius (GAS), and tibialis anterior (TA) muscle forces were evaluated because of their functions to provide support, forward propulsion, and balance control.

Methods

Whole-body motion and ground reaction forces were collected for an older adult (F, 73 yrs, 51 kg, 1.66 m) performing three STW trials. Inverse kinematics solutions of a body mass-scaled, generic model containing 80 Hill-type musculotendon actuators were determined and musculotendon properties were adjusted in 7 cases: 1) baseline model (no changes), 2) -20% v_{max}, 3) +20% τ_{deact} ,4) +16.67% passive element stiffness, 5) -6% Achilles tendon stiffness, 6) F_{iso} variable muscle reduction , and 7) all property changes combined. The F_{iso} reductions were hip extensors -21%, hip flexors -23%, knee extensors -29%, knee flexors -25%, ankle plantarflexors -32%, and ankle dorsiflexors -8%. Muscle forces and activations were determined using Computed Muscle Control and compared using a repeated measured ANOVA (α= 0.05).

Results

Reducing max F_{iso} induced the largest changes from baseline, increasing SOL (37.4%, $p<0.01$), decreasing GAS (31.8%, $p=0.02$), and increasing TA (111%, $p<0.01$) peak forces. Increasing τ_{deact} increased SOL (20.4%, $p<0.05$) and TA (122%, $p<0.01$) peak forces. Combining all properties increased SOL (33.2%, $p<0.05$), decreased GAS (43.8%, $p<0.05$), and increased TA (95%, $p<0.05$) peak forces. Changes to the other properties in-isolation peak forces ($p>0.05$).

Discussion

Strong effects of F_{iso} are supported by musculotendon sensitivity studies during gait [2]; F_{iso} was the biggest driver of force changes in the combined condition. Greater SOL force

with reduced suggests greater activation, which we observed (Figure). Greater τ_{deact} causing prolonged activation increased antagonist muscle forces in SOL and TA. Aging muscle properties changed muscle force sharing, with greater SOL force and lesser GAS force. This emergent result of aging the model is consistent with plantarflexor muscle recruitment changes with aging [3].

Images (Optional)

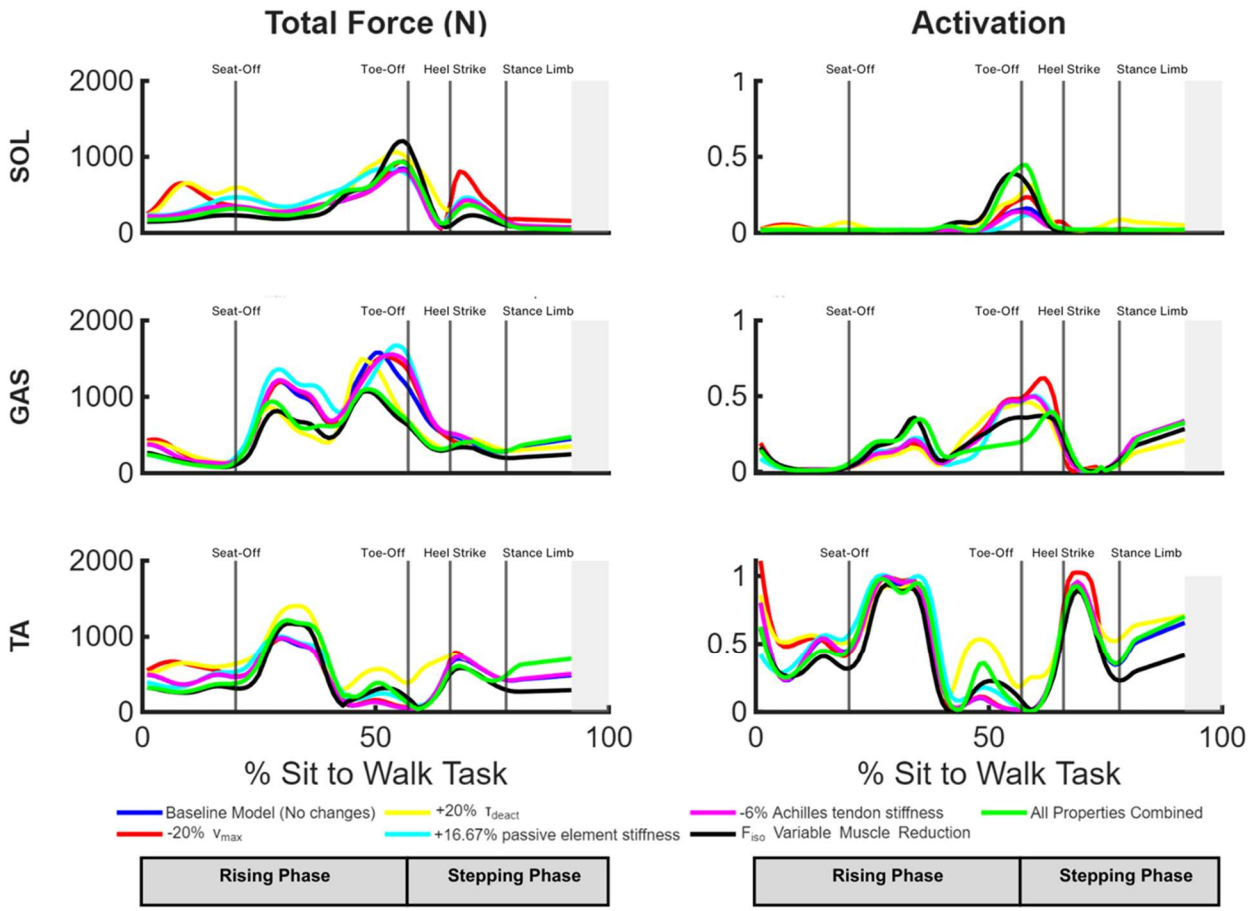

Figure: Total musculotendon force and activation for the stepping limb soleus (SOL), gastrocnemius (GAS), and tibialis anterior (TA). STW began when the forward body center of mass velocity exceeded 0.15 m/s and ended when the stepping limb left the second force plate.

Comparative Analysis of Subtalar Joint Kinematics in Humans and African Great apes

Prof. Michele Conconi[1], Prof. Nicola Sancisi[2], Prof. Rita Sorrentino[3], Prof. Alberto Leardini[4], Prof. Naomichi Ogihara[5], Prof. Claudio Belvedere[4]

[1]Department of Industrial Engineering, University of Bologna,, Bologna, Italy, Italy. [2]Department of Industrial Engineering, University of Bologna,, Bologna, Italiy, Italy. [3]Department of Biological, Geological, and Environmental Sciences, University of Bologna, Bologna, Italy, Italy. [4]Laboratory of Movement Analysis, IRCCS Istituto Ortopedico Rizzoli, Bologna, Italy, Italy. [5]Laboratory of Human Evolutionary Biomechanics, Department of Biological Sciences, The University of Tokyo, Tokyo, Japan, Japan

Introduction

A detailed understanding of articular physiology is critical for elucidating the etiology of musculoskeletal disorders. This study focuses on the subtalar joint and tests the hypothesis—previously supported in the human knee and ankle [1,2]—that functional adaptation shapes the articular surfaces to optimize load transmission across the full range of motion, and that this adaptive principle is conserved between human and non-human African great apes. We infer subtalar joint kinematics in modern humans, chimpanzees, and gorillas from subchondral bone geometry using this optimization principle, and validate these predictions against *in-vitro* kinematic data obtained from sequential CT images.

Methods

Subtalar kinematics was obtained from thirty-two CT scans for three human feet [3], and from two CT scans for two chimpanzees and two gorillas [4]. The experimental poses were expressed using anatomical reference systems and the Euler sequence of rotation [5]. For each specimen, the mean subchondral bone spacing at the anterior and posterior facets of the talocalcaneal joint was measured in the unloaded neutral scan. This spacing was used to approximate a uniform cartilage layer by offsetting the subchondral bone surfaces of both the bones. Talocalcaneal kinematics were then reconstructed by congruence maximization [1,2].

Results

Predicted kinematics were compared with experimental measurements by evaluating the magnitudes of the rotational and translational error vectors. Mean errors were 0.9 ± 0.5° and 1.1 ± 0.3 mm for humans, 1.1 ± 0.6° and 1.6 ± 1.0 mm for chimpanzees, and 2.8 ± 1.7° and 3.1 ± 1.1 mm for gorillas, respectively.

Discussion

The small discrepancies between model predictions and experimental observations (Fig. 1) validate the model and support the hypothesis that cartilage and subchondral bone morphology arise from an adaptive process shared between humans and non-human African great apes. This approach provides insight into joint tissue physiology and offers a method for predicting subject-specific articular kinematics that is applicable across species, facilitating translational and evolutionary studies.

Images (Optional)

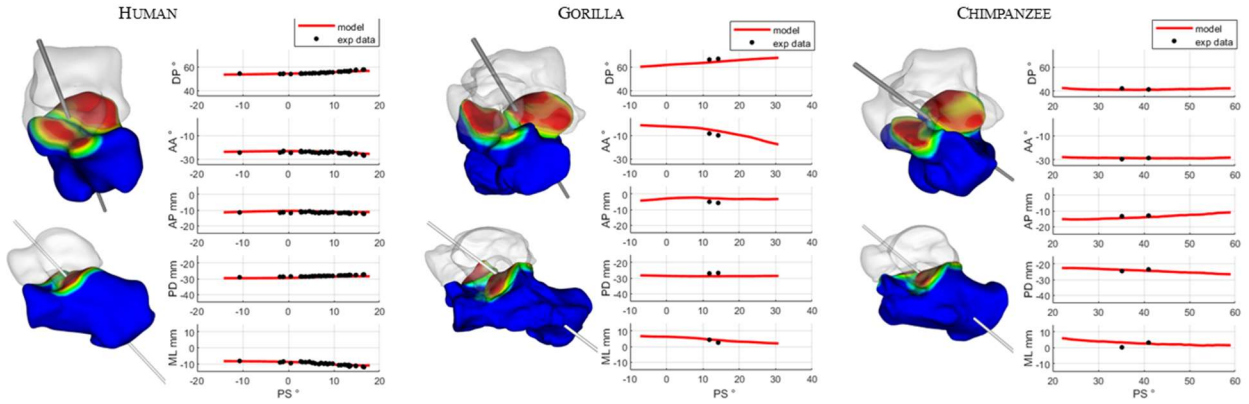

Figure 1: Comparison of predicted (red) and experimental (black dots) subtalar joint kinematics for a human (left), gorilla (center), and chimpanzee (right): the dorsi/plantar (DP) flexion, the abduction/adduction (AA), and the anterior/posterior (AP), proximal/distal (PD), and medial/lateral (ML) translations are plotted versus the pronation/supination (PS) angle. Bone models are shown in the neutral configuration, with colors representing relative inter-surface distance (red: contact; blue: >7 mm). The grey cylinder indicates the mean helical axis of maximum congruence motion.

Effects of Transtibial Bone-Anchored Limb Use on Bilateral Knee Cartilage Contact Pressure During Gait

Mr. Mitchell Ekdahl BS[1], Dr. Cory Christiansen PhD[2], Dr. Jason Stoneback MD[2], Dr. Brecca Gaffney PhD[1,2]

[1]University of Colorado Denver, Denver, CO, United States. [2]University of Colorado Anschutz Medical Campus, Aurora, CO, United States

Introduction

Knee osteoarthritis is nearly 18 times more common in people with unilateral transtibial amputation (TTA) using socket prostheses compared to individuals without amputation, which is largely attributed to chronically altered intra-articular joint mechanics. Bone-anchored limbs (BALs) are an alternative to traditional socket prostheses that attach directly to the residual limb bone. While early work has shown that unilateral transtibial BAL use does not change joint loading in either knee during walking, the direct effects on intra-articular joint mechanics remain unknown.

Methods

Motion capture during overground walking at self-selected speed was collected from fourteen adults (5F/9M, 53.7±13.1y, BMI: 28.5±4.6) with unilateral TTA at two timepoints: before (in socket prosthesis) and one year after BAL implantation. Musculoskeletal knee contact models were developed for each participant. A concurrent optimization approach was used to estimate knee joint kinematics and muscle forces. Cartilage contact pressure in each compartment of the tibiofemoral joint was calculated as a function of overlap depth between the femoral and tibial cartilage surfaces using an elastic foundation model. Mean contact pressure impulse in each knee during each functional phase of the stance period was compared between timepoints using repeated measures ANCOVA, with gait speed as the covariate (α=0.05).

Results

Mean pressure impulse in the medial compartment of the amputated-limb knee was increased during terminal stance after BAL implantation (1.00±0.13 MPa*s (before) vs 1.03±0.14 MPa*s (after), p=0.036). Sound-limb mean pressure impulse was not changed during any functional phase of stance with BAL use.

Discussion

Transtibial BAL use increased amputated-limb dynamic knee cartilage contact pressure during terminal stance but did not affect sound-limb contact pressure. Increased medial compartment pressure in the amputated-limb knee after BAL implantation may be attributed to the direct force transmission created by BALs. Underloading of the amputated-limb knee joint in socket prosthesis users can contribute to articular cartilage degradation. Knee osteoarthritis in people with TTA is more common in the sound-limb, which is mechanistically driven by compensatory overloading of that limb. The absence of changes in sound-limb cartilage contact pressure following BAL implantation may suggest that sound-limb knee osteoarthritis risk is not changed after BAL implantation.

Images (Optional)

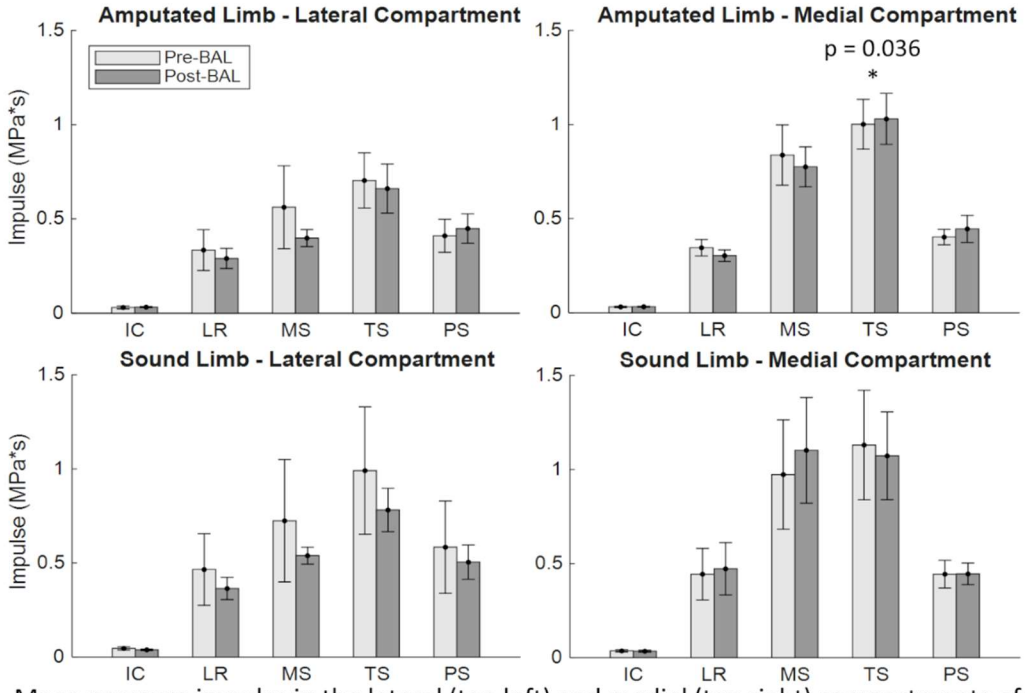

Figure 1. Mean pressure impulse in the lateral (top left) and medial (top right) compartments of the amputated-limb knee joint, and the lateral (bottom left) and medial (bottom right) compartments of the sound-limb knee joint during each functional phase of stance before (light gray) and after (dark gray) BAL implantation. Effects of Footwear Cushioning and Frequency Constraints on the Metabolic Cost of Hopping

Mr. Montgomery Bertschy, Ms. Nicole Sylvain, Dr. Wouter Hoogkamer

University of Massachusetts Amherst, Amherst, MA, United States

Introduction

Footwear cushioning can reduce the metabolic cost of running, with highly resilient materials seeming to have the greatest benefit [1]. However, since midsole materials will always return less than 100% of the mechanical energy stored, with more cushioning, more energy will be lost. If more mechanical energy is lost, athletes need to increase positive net work to compensate. The purpose of this study was to understand the effect of footwear cushioning on metabolic cost, using hopping as a model to minimize variability in gait mechanics. We hypothesized that extreme midsole cushioning would lead to increased metabolic cost due to higher energy losses in the midsole.

Methods

Across two visits, experienced runners performed eight 4-minute hopping trials in four footwear conditions (twice per condition): a minimalist shoe with negligible cushioning (0 cm), minimalist shoe with ~1 cm of resilient foam in the forefoot (1 cm), running shoe with ~2 cm (2 cm), and ~5 cm (5 cm) of foam in the forefoot. Participants hopped to a set height range (7-9 cm) at their preferred frequency (visit 1) and at a prescribed frequency (2.2 Hz metronome, visit 2). We measured net metabolic cost, kinematics, muscle behavior, and ground reaction forces.

Results

Net metabolic cost was highest in the 5 cm footwear condition, driving a significant effect of midsole thickness on net metabolic cost (0.07±0.03 W/kg per 1 cm of cushioning). Preferred frequency was 0.17±0.02 Hz higher than hopping frequency in the prescribed condition, with a 0.64±0.12 W/kg lower metabolic cost. There was no significant effect of footwear on hopping frequency

Discussion

Between the two extreme conditions (0 and 5 cm), the increase in metabolic cost was consistent between frequency conditions. These findings agree with data on the effect of surface damping on net joint work [2]. In the intermediate conditions, the results tend to

diverge between the frequency conditions. Direct analysis of muscle-tendon unit behavior for these footwear conditions may explain the differences in these results.

Multi-Task Learning for Joint Impedance Estimation

Ms. Nana Porter-Honicky B.S., Dr. Elliott Rouse PhD

University of Michigan, Ann Arbor, MI, United States

Ms. Nana Porter-Honicky

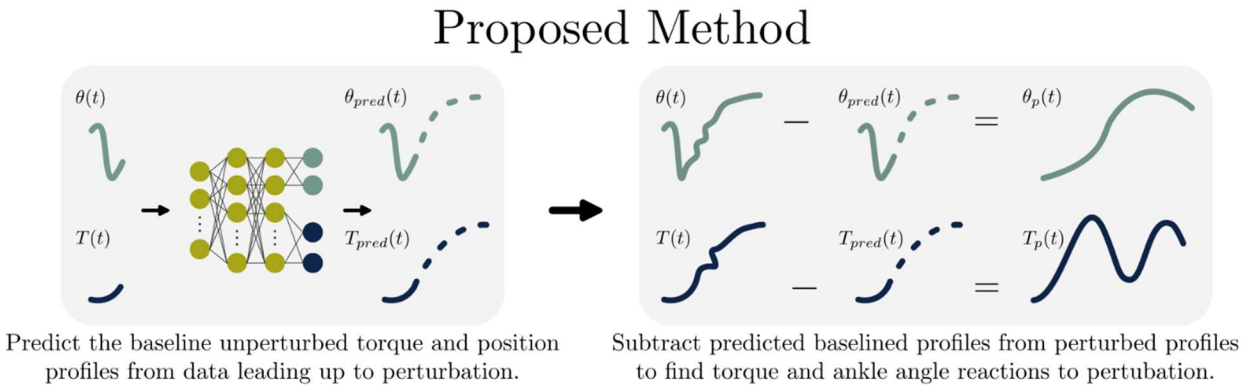
Introduction

The inertia, damping, and stiffness of a joint, or joint impedance, characterize the body as a mechanical system, offering insight into mechanical changes in the body due to conditions like stroke or cerebral palsy [1]. However, quantifying joint impedance is prohibitively difficult due to data constraints. Such quantification requires a perturbation to the joint and unperturbed baseline trials, where the difference between the unperturbed and perturbed joint encodes the properties that make up joint impedance. This difference is parametrically modeled as a second order system. Current methods require hundreds of trials [1], limiting utility outside of research contexts. We propose a method of using a multi-task neural network to predict the unperturbed joint positions and torques and estimate joint impedance without unperturbed trials. Importantly, our model predicts the joint positions and torques needed to calculate impedance values, rather than predict them directly. This maintains the robustness of established estimation pipelines while significantly reducing data collection requirements.

Methods

The joint positions and torques are modeled as a 100^{th}-order Markov chain, where the previous 100 states are used to predict the next 100. The loss function of the model was designed to optimize for the terms in the second-order parametric impedance model. Hyperparameters were chosen via a Bayesian hyperparameter sweep. To optimize data utility, we preprocessed each phase-normalized trial using a windowing method. The model was trained on data collected during previous level-ground-walking ankle impedance estimation studies [1,2].

Results



K-fold cross-validation and leave-one-out validation show torque and position errors considerably lower than the perturbation magnitudes typical in impedance estimation

experiments. Crucially, the resulting predictions account for up to 97% of the variance in the perturbed data when fit to the second-order impedance equation.

Discussion

Impedance is a critical metric for understanding and modeling the mechanical properties of biological joints. Our proposed method to quantify impedance yields similar results to current methods and reduces data requirements by as much as half. This removes barriers to evaluating more impaired populations [2], paving the way for broader clinical applications.

Images (Optional)

Predict the baseline unperturbed torque and position profiles from data leading up to perturbation.

Subtract predicted baselined profiles from perturbed profiles to find torque and ankle angle reactions to pertubation.

$$T_p = I\ddot{\theta}_p + b\dot{\theta}_p + k\theta_p$$

Find inertia I, damping b, and stiffness k with linear regression of joint reaction to perturbation.

Results

Use case	Torque Error (Nm/kg)	Angle Error (rad)	VAF (%)
Subject Dependent	$4.64 \pm 2.27 \times 10^{-4}$	$1.05 \pm 0.47 \times 10^{-2}$	97.4 ± 4.6
Subject Independent	$0.85 \pm 2.20 \times 10^{-4}$	$1.45 \pm 1.15 \times 10^{-2}$	95.7 ± 10.3

Table 1: Mean Absolute Error of torque and angle predictions in the subject dependent and subject independent use cases. Variance Accounted For (VAF) of the predictions fit to perturbation response model.

Causal Dynamic Balance Networks as a Diagnostic Feature for Structural Hip Disease

Mr Brandon Nunley MS[1], Dr Joel Wells MD[2], Dr. Nicholas Fey PhD[1]

[1]The University of Texas at Austin, Austin, TX, United States. [2]Baylor Scott & White, Dallas, TX, United States

Introduction

Developmental dysplasia of the hip (DDH) alters the loading environment of the hip, which can lead to pain and gait compensations [1]. The system-wide effects of this local instability on dynamic balance during locomotion are not well understood. Convergent cross-mapping (CCM) offers a framework for investigating these complex, non-linear interactions [2]. Unlike traditional correlation analyses, CCM can detect causal coupling between time-series in dynamic systems. The purpose of this study was to quantify how local hip instability alters segmental coordination by applying CCM to pairs of segmental angular momentum signals in DDH and control participants.

Methods

Fifteen DDH patients who underwent PAO completed this study. Nine control participants completed a single visit. Patients performed a 1-min treadmill walking trial at self-selected speed for each of three ramp conditions: incline (+10º), level (0º), and decline (-10º). Kinetic and kinematic data were collected using an instrumented treadmill and 10-camera infrared motion capture system. Continuous, normalized segmental angular momenta of the thorax, pelvis, thighs, shanks, and feet were used to reconstruct the phase space dynamics (Figure 1a). For each signal, we constructed a "shadow manifold" using time-delay embedding. Causal coupling strength between pairs of connected segments was quantified by the correlation coefficient between the predicted and observed signals. A causal link was inferred if the prediction skill increases and converges to a stable value as the library size grows. This analysis was performed bidirectionally to distinguish between unidirectional forcing and bidirectional feedback. CCM analysis was performed using the pyEDM software package.

Results

Feature vectors derived from inter-segmental causal connectivity networks revealed distinct coordination patterns between DDH patients and controls. Clustering achieved a classification accuracy of 91.6% in distinguishing DDH subjects from controls (Figure 1b).

Discussion

These findings demonstrate that analyzing causal interactions within the dynamic balance network provides a sensitive measure of localized dynamic hip instability. The high classification accuracy indicates that DDH pathology drives distinct, non-linear compensatory strategies that persist beyond local joint mechanics. This causality-based framework offers a novel functional biomarker to complement static radiography.

Rearfoot and Midfoot Joint Rotations under Isolated and Combined TA-TP Tendon Force Perturbations

Miss Niharika Pathare, Dr. Anthony Le, Dr. Amy Lenz

University of Utah, Salt Lake City, Utah, United States

Introduction

Several neuromuscular conditions are characterized by altered muscle synergies that disrupt midfoot and hindfoot alignment at initial contact during gait. However, joint-level foot kinematics cannot be isolated in vivo due to neural compensation, soft-tissue variability, and measurement limitations. This study tested whether isolated and combined perturbations to tibialis anterior (TA) and tibialis posterior (TP) tendon loading produce systematic changes in passive multisegment foot alignment at heel strike in cadaveric feet.

Methods

With IRB approval, four cadaveric lower limbs (male; 58.8 ± 12.7 yrs, 78.1 ± 16.8 kg) were prepared with bone-embedded optical markers to quantify 3D joint rotations; only male specimens from the donor pool allowed occlusion-free marker placement. Each specimen was vertically loaded to 20% body weight (BW) and tested in a controlled heel-strike posture to reproduce 5% BW early-stance loading. Specimen-specific scaled baseline tendon forces for TA, extensors, peroneal brevis and longus, flexors, TP, and Achilles were derived from OpenSim. Three conditions, each with three steady-state trials, were tested by perturbing TA and TP forces relative to baseline heel strike: TA_{50} TP_{100}, $TA_{100}TP_{50}$, and TA_{50} TP_{120}; the subscripts denote the percentage of the corresponding tendon's baseline force. Joint angles were computed relative to the anatomical axes of the proximal bone via Euler decomposition. Linear mixed-effects models assessed condition effects with Tukey contrasts and Cohen's d effect size for pairwise comparisons (α=0.05).

Results

Significant synergy-dependent joint angle changes were observed across multiple joints ($p < 10^{-4}$ to 10^{-9}), with talonavicular and subtalar joints demonstrating changes across all three anatomical planes. Except for subtalar sagittal motion, $TA_{50}TP_{100}$ and $TA_{50}TP_{120}$ produce similar rotational patterns across joints, whereas $TA_{100}TP_{50}$ consistently shows larger and directionally distinct deviations. Talonavicular joint angles deviate the most from baseline across conditions, with several pairwise contrasts that involve $TA_{100}TP_{50}$ reaching large effect sizes ($|d| \approx 0.8–2.35$). Subtalar rotations show similar

patterns between conditions but with smaller angle magnitudes, while demonstrating substantial between-condition differences (|d| up to 2.1).

Discussion

These findings demonstrate that TA-TP synergy patterns significantly reorganize rearfoot-midfoot kinematics at heel strike, with talonavicular and subtalar joints showing the greatest sensitivity to coordinated tendon loading.

Images (Optional)

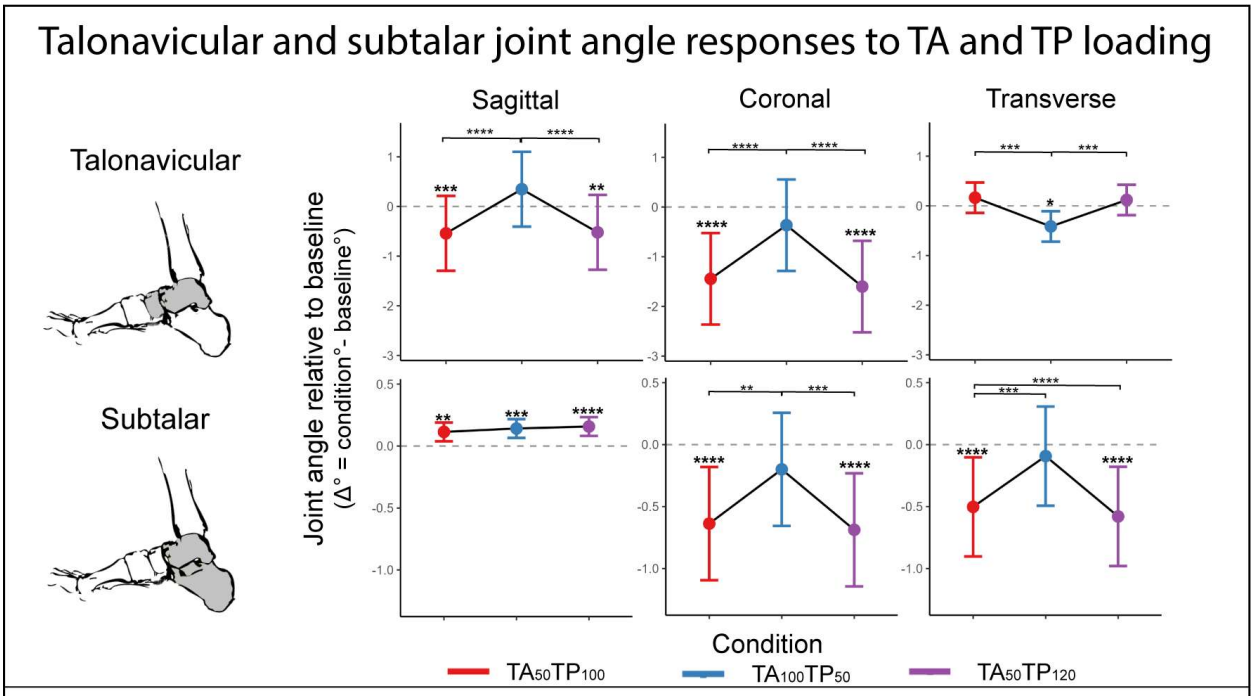

Fig. 1: Estimated marginal means (EMMs) of talonavicular and subtalar joint angle changes (Δ° ± SE) across sagittal, coronal, and transverse planes under $TA_{50}TP_{100}$ (red), $TA_{100}TP_{50}$ (blue), $TA_{50}TP_{120}$ (purple). Talonavicular rotations showed the largest deviations across conditions. Horizontal brackets indicate significant Tukey-adjusted pairwise differences; *, **, ***, **** correspond to $p < 0.05$, 0.01, 0.001, 0.0001, respectively.

Ligament contributions to talus motion during walking and running

Mr Quinn Yetman, Dr. Michael Rainbow

Queen's University, Kingston, Ontario, Canada

Introduction

The foot and ankle coordinate their mechanics to enable efficient upright locomotion [1]. This coupling occurs at the talus, which is uniquely passive, meaning only ligaments and cartilage drive its motion. Although ligaments are essential for constraining talus motion and maintaining ankle stability, how they coordinate their mechanics to stabilize the talus across locomotor tasks has not been explored in-depth. Given the substantial variation in ligament properties [2] and articular morphology across people [3], we question whether some individuals require more ligament support than others.

Methods

We quantified the ligament contributions to talus motion using a subject-specific, biplanar videoradiography (BVR) driven model. BVR captures individual 6 degree-of-freedom bone kinematics with errors < 2°. The model, implemented in ArtiSynth, simulated talus motion with cartilage contact and ligament forces during walking and running for 5 participants (Figure 1a). Ligament contributions were assessed by comparing simulated talus kinematics with and without ligaments using root-mean-square helical-axis orientation error (RMSE) relative to BVR-measured talus motion.

Results

Removing ligaments increased the RMSE for 3 of 5 participants for walking and 4 of 5 participants for running (Figure 1b). The magnitude of this effect varied across individuals (-10% to +23%) and across subphases of stance. Removing ligaments had a large effect on error during running propulsion (average increase of +17%) with mixed responses in other subphases, including decreases in some participants. Participants with larger increases in RMSE when ligaments were removed tended to exhibit lower BVR-measured talocrural inversion, and net ankle dorsiflexion and internal rotation range of motion (ROM) during loading.

Discussion

We saw variability in how ligament removal affected talus-tracking error. Two participants showed larger increases in error, motivating the hypothesis that reliance on ligament support varies meaningfully across people. There was some correlation between increased error from removing ligaments and lower ROM, supporting this idea. The substantial increase in error during running propulsion highlights the critical role of ligaments in stabilizing the talus during this subphase. Future work will test these hypotheses and look for predictors of ligament sensitivity.

Images (Optional)

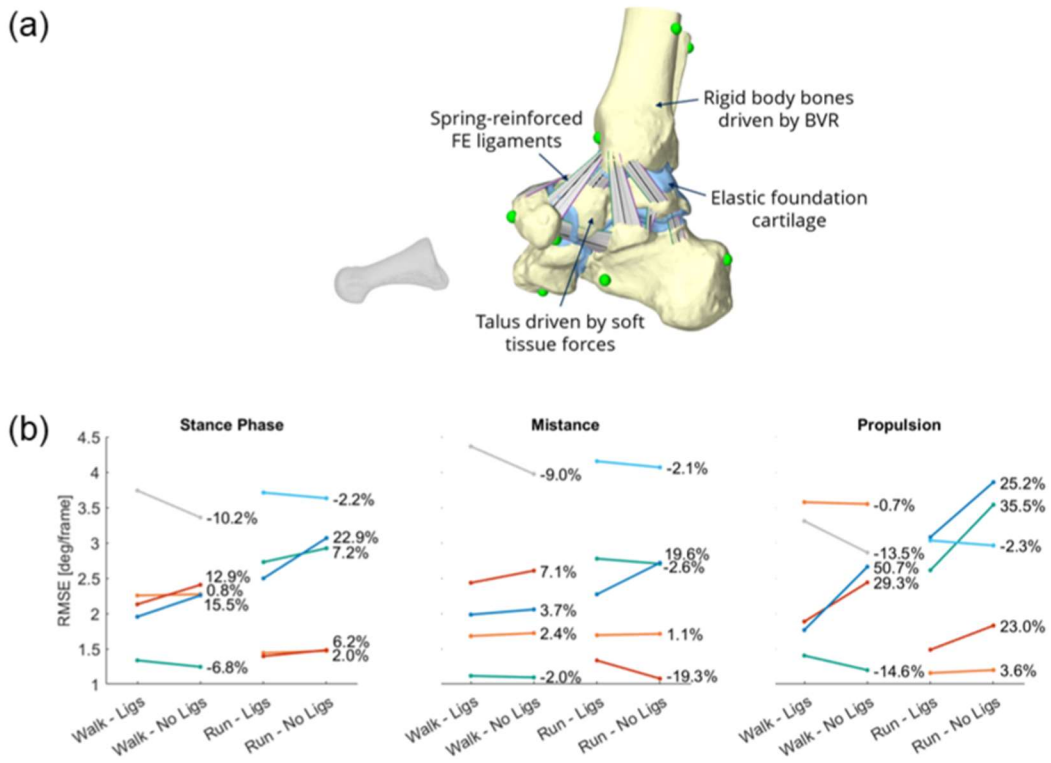

Figure 1: (a) The ankle joint complex model in ArtiSynth. Bones and cartilage were modelled as rigid bodies, and ligaments as spring reinforced finite element membranes. Kinematics from biplanar videoradiography drove bones surrounding the talus while the talus was driven by cartilage contact and ligament forces. Soft tissue material properties were found by minimizing the RMSE using a design of experiments approach using kinematics separate from those used for analysis. First metatarsal is included in the image to give context but was not simulated. (b) The effect of removing all ligaments from the simulation on RMSE over all of stance, midstance (when the entire foot is contacting the ground), and propulsion (heel rise to toe off).

The (K)need for Speed: Optimizing In Vitro Joint Testing for Speed

Dr. Tara Nagle PhD, Miss Elizabeth Pace BS, Dr. Robb Colbrunn PhD

Cleveland Clinic, Cleveland, Ohio, United States

Introduction

In vitro joint biomechanics testing requires the use of a 6-DOF joint simulator to apply loads. In some cases, when viscoelastic properties are important, achieving high speeds is crucial. The goal of this study was to evaluate how test variables contribute to 1) minimum achievable simulated gait duration and 2) % RMS load errors, when testing a cadaveric knee on a 6-DOF joint simulator.

Methods

A modified ISO-gait profile (Fig. 1A) was applied to a cadaveric knee (male, 65) using a Jupiter-3000 simVITRO system. Three variables were investigated to determine the optimal testing setup: 1. Fixturing, 2. Trajectory Interpolation, and 3. Control Method.

Fixturing included a) Standard or b) L-bracket, where the femur was mounted such that the knee's flexion axis was aligned to robot axis-6. Trajectory Interpolation included a) Linear or b) Spline. Control methods included a) Force control (F-Ctrl) or b) Position control *with* adaptive compensation (P-Ctrl), where commanded joint kinematics were iteratively optimized over five 30-second gait cycles to achieve the desired loads, and kinematics determined for the 5^{th} cycle were applied in position control over various durations. Tuning parameters remained consistent. Gait durations of 120, 60, 30, 15, 10, 6.7, 5, 4, and 3 seconds were attempted, and shortest achievable duration, % RMS-error and failure mode were recorded for each combination.

Results

The fastest achievable gait duration was 4 seconds and was completed with L-bracket fixturing, linear interpolation, and P-Ctrl. The fastest achievable duration was 15 seconds with F-Ctrl, and 10 seconds with standard fixturing and P-Ctrl. In all unsuccessful cases, failure occurred due to robot motor torque overload on axis-6.

For all DOF, % RMS-error reduced with P-Ctrl compared to F-Ctrl. For Anterior force and ER torque, % RMS-error was lower with L-bracket fixturing compared to standard (Figure 1B-D). Interpolation showed only minor effects on % RMS-error.

Discussion

Selecting L-bracket fixturing and P-Ctrl is optimal for high-speed testing. This makes sense because by aligning the flexion axis to axis-6, stress is reduced on the motor with the lowest torque rating, and robots are designed for P-Ctrl. Future work will examine other variables that affect performance, like tuning parameters, and will include additional specimens.

Images (Optional)

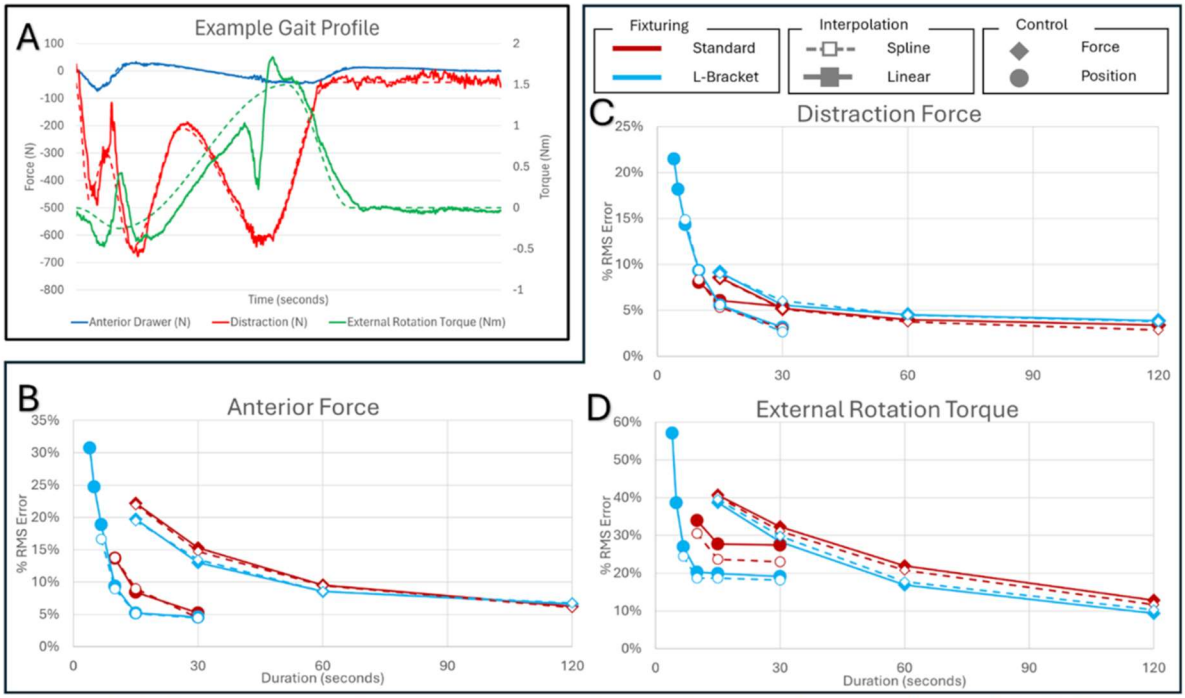

Figure 1: A) Commanded gait profile (dotted) and example actual loads (solid), and % RMS error across each gait cycle as a function of duration, fixturing, interpolation and control method for B) Anterior Force, C) Distraction Force and D) External Rotation Torque.

Talonavicular Kinematics: Matching Healthy Controls to Clinical Populations

Mr. Robert Chauvet[1,2], Ms Emily Smith-Bregeda[1,2], Ms Janae Ruzicki[1,2], Dr. Koren Roach[1,2]

[1]McCaig Institute for Bone and Joint Health, University of Calgary, Calgary, Alberta, Canada. [2]Department of Biomedical Engineering, University of Calgary, Calgary, Alberta, Canada

Introduction

In clinical gait studies comparing pathological populations to healthy controls, participants are typically matched by age and sex [1]. Given the variability in foot shape and its potential influence on joint kinematics of the midfoot, it is worth considering whether matching for foot shape should also be standard practice [2]. This study investigates how confounding variables such as age, sex, body mass index (BMI), and foot shape affects talonavicular (TN) kinematics.

Methods

Eight healthy participants (4F/4M; age: 36.6±14.1yrs; BMI: 22.5kg/m^2; Meary's angle: 0.8±5.3°; calcaneal tilt: 23.2±2.5°), were recruited (REB19-1743). Participant feet and ankles were imaged at 120 Hz with a dual fluoroscopy system while participants performed activities of daily living: walking, step up, and step down. A computed tomography (CT) scan was acquired of the mid-tibia through toe tips. Clinical radiographs were taken and evaluated for Meary's angle and calcaneal tilt. The tibia, talus, calcaneus, and navicular were segmented on the CT images to generate 3D bone models. A 2D-3D registration process was used to align bone models with 2D DF images and determine joint angles and range of motion (ROM) throughout each activity. Joint angle ROMs were compared against demographic variables using stepwise multiple regression analysis and between age groups, split by median age, using a Wilcoxon signed-rank test.

Results

Age was the strongest predictor of TN ROM (R^2 = 0.52, p = 0.043). Younger (age: 21.1±2.68yrs) participants exhibited significantly greater (p = 0.029; Cohen's d = 1.95) TN ROM (13.15±4.50°) compared to older (5.85±0.88°) participants. No significant associations were found between TN ROM and foot shape or any other demographics.

Discussion

Age as a predictor of TN ROM may be explained by soft tissue stiffening and degenerative changes reducing midfoot flexibility [3]. These preliminary results suggest age-matching is

more important than foot shape or other demographics. However, these results encompass a narrow range of arch heights, and we are currently recruiting additional controls with low and high arches to investigate how foot shape affects TN joint kinematics.

Images (Optional)

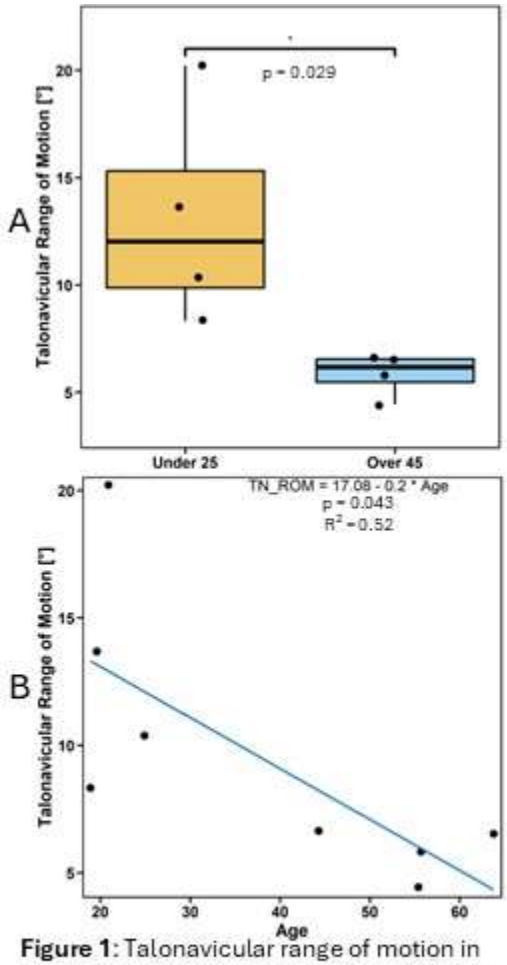

Figure 1: Talonavicular range of motion in walking (TN_ROM) (A) for the over 45 (blue) and under 25 (yellow) groups and regression analysis (B) showing the linear fit between age and talonavicular range of motion variables.

Acute Medial Femoral Condyle Cartilage Response Following a Running Bout

Mr Ryan Evans MSc[1], Mr Harry Battersby MSc[1], Mr Tom Boers[1], Dr Richard Willy PT, PhD[2], Dr Derek Pamukoff PhD[1]

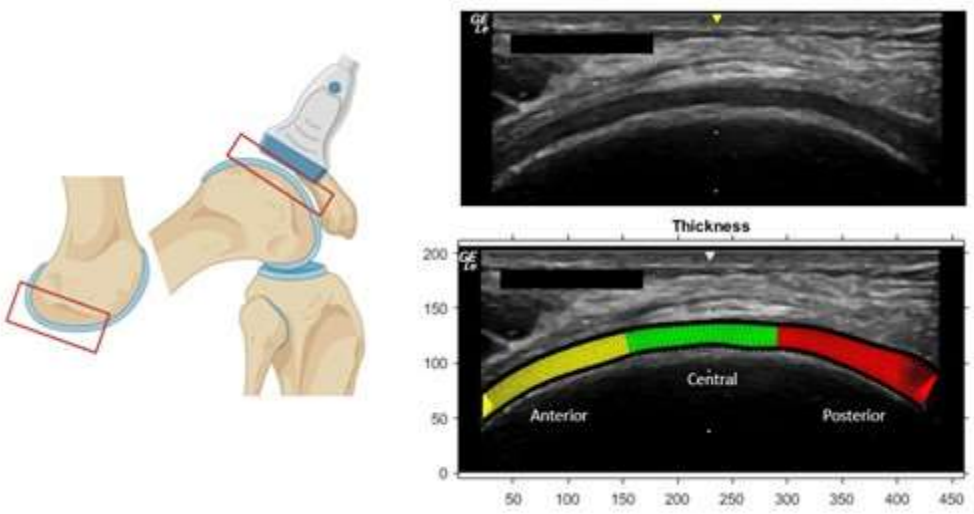
[1]Western University, London, ON, Canada. [2]The Ohio State University, Columbus, OH, United States

Introduction

Studies using ultrasound assessed immediate cartilage response to loading have focused on the patellofemoral joint. Tibiofemoral joint contact forces during weight-bearing activities are well documented, but their internal tissue response remains unclear. We examined medial femoral condyle cartilage deformation after running, resting thickness, and their relationship with knee loading.

Methods

Thirty-one distance runners participated. Medial femoral condyle cartilage was evaluated using ultrasound prior to and following a 35-minute run at a self-selected pace on a force instrumented treadmill while kinematic (240Hz) and kinetic (2400Hz) data were collected. Peak medial tibiofemoral joint force (TFJF) was extracted using a musculoskeletal model and normalized to body weight. A (3) region, by (2) time ANOVA assessed changes in cartilage thickness, and post hoc pairwise comparisons were made using a Bonferroni correction. Pearson's r examined associations among magnitude of deformation, resting thickness, and joint loading.



Results

There was a significant region by time interaction effect ($F_{2,28}$=8.067, p=0.005, partial η^2=0.218). Post hoc comparisons demonstrated that the anterior region decreased from pre- to post-measurement (mean difference = -0.291 (-0.169, -0.412) mm, p<0.001), but not in the central (mean difference = -0.085 (-0.156, -0.013) mm p=0.022) or posterior (mean difference = -0.024 (-0.160, 0.113) mm p=0.728, η^2=0.004) regions. Higher peak medial TFJF was not associated with cartilage deformation in the anterior (r=-0.161, p=0.397), central (r=-0.106, p=0.577) and posterior (r=0.149, p=0.433) regions. Higher peak medial TFJF was moderately associated with central (r=0.392, p=0.029), but not associated with anterior (r=-0.326, p=0.074) or posterior (r=0.005, p=0.978) resting medial femoral condyle cartilage thickness.

Discussion

The anterior region of the medial femoral condyle cartilage may respond differently following running than the central and posterior regions, likely due to joint contact patterns. Peak medial TFJF may not influence acute cartilage response following a running bout, but may contribute to thicker resting cartilage in the central region of the medial femoral condyle. External peak medial TFJF may not represent internal femoral condyle tissue response due to the number of loading cycles taken while running. However, thicker central region resting cartilage suggests peak medial TFJF during running may contribute to positive cartilage adaptation over time.

Associations Between Changes in Knee Gait Mechanics and Changes in Frontal Plane Laxity After Sustained Kneeling

Ms. Sarah Hallman B.Sc., Mr. Daniel Mines M.Sc., CPE, Dr. Stacey Acker PhD

University of Waterloo, Waterloo, Ontario, Canada

Ms. Sarah Hallman

Mr. Daniel Mines

Introduction

Sustained kneeling is a risk factor for knee osteoarthritis (KOA), resulting in altered gait mechanics [1]. Increase in frontal plane laxity (FPL), present through the progression of KOA, is a hypothesized but understudied mechanism for these gait modifications [1,2] by reducing the passive resistance of ligaments [1,3].

This study aimed to determine the relationship between changes in knee gait mechanics and FPL following an acute kneeling exposure. It was hypothesized that there would be significant correlations between FPL and all gait mechanics that exhibited significant changes post-kneeling.

Methods

15 healthy young adults (8M, 7F) underwent 3 FPL measurements in a custom sled device, followed by 3 gait trials at a self-selected pace, with right leg motion (and ground reactions, during gait) recorded before and immediately following kneeling (three 10-minute kneeling bouts alternating with 5-minute seated rest periods [1]).

Knee angles were calculated using an extension-abduction-internal rotation Cardan sequence. Net external joint moments were calculated using inverse dynamics, normalized to %BW*Ht, and expressed in the tibial coordinate system.

One-tailed paired t-tests (α=0.05) tested for significant differences (post- versus pre-kneeling) in FPL and gait outcomes, with a Holm-Bonferroni correction for multiple comparisons. For the gait outcomes (Figure 1) that exhibited significant change, Pearson

correlations (r) were calculated between the average within-participant change and the average within-participant change in FPL.

Results

Post-kneeling, there was a significant increase in the knee flexion angle at heel strike (p=0.010), peak knee flexion angle during early stance (p=0.015), and peak knee adduction moment during early stance (p=0.049). No significant differences were observed in the other gait variables or FPL (p>0.05).

Two of the significantly changed gait outcomes had significant moderate (r=0.4-0.699) correlations with the change in FPL (Figure 1).

Discussion

Associations between osteoarthritic-like changes in gait mechanics and changes in FPL were found following an acute exposure to sustained kneeling, supporting this potential mechanistic pathway. Future longitudinal research is warranted to elucidate the causal relationships between kneeling exposures and KOA.

Images (Optional)

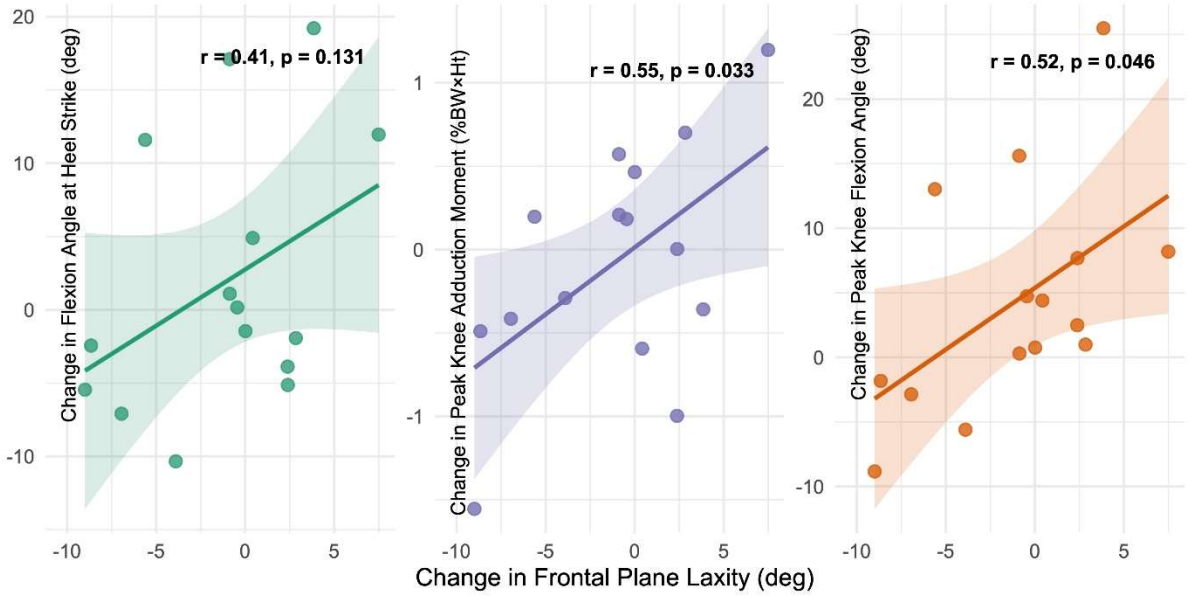

Figure 1. Correlations between the average change in FPL and average change in gait outcomes that exhibited significant changes after the kneeling exposure.

Note: The shaded region represents the 95% confidence interval and positive change indicates an increase from pre- to post-kneeling.

Effects of Static Stretching on Achilles Tendon Hysteresis: A Pilot Study

Mr. Simon Embaye[1,2], Mr. Jimmy Stanley[1], Dr. Jared Fletcher PhD[1]

[1]Mount Royal University - Department of Health and Physical Education, Calgary, Alberta, Canada. [2]University of Alberta - Faculty of Kinesiology, Sport, and Recreation, Edmonton, Alberta, Canada

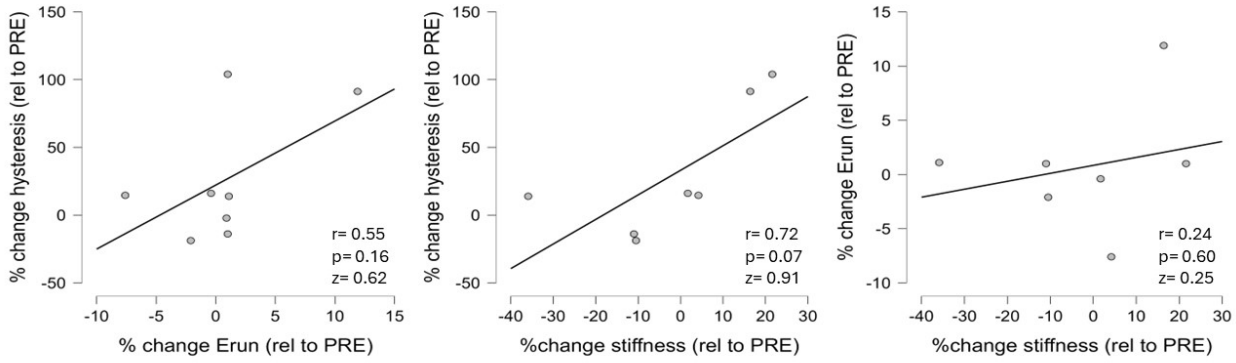
Introduction

During locomotion, the compliant, viscoelastic Achilles tendon (AT) is stretched, storing elastic strain energy contributing to economical locomotion. AT energy storage is quantified from AT stretch and estimated AT forces. A portion of the AT strain energy is lost during AT recoil, known as hysteresis. Prolonged static stretching has been shown to increase AT hysteresis, potentially contributing to greater AT strain energy loss during running. How changes in AT hysteresis impacts the energy cost of running (E_{run}) remains to be shown. The purpose of this pilot study was to evaluate the effect of static stretching on tendon hysteresis and their impact on E_{run}.

Methods

AT hysteresis prior to and following 10-minutes of static stretching was assessed in 8 male and female participants (29±11 years, 182±9cm, 78.5±6.1 kg). AT hysteresis was calculated from AT length change from ultrasound imaging and calculated AT force from loading and unloading of the AT during a maximal voluntary contraction (MVC) on a dynamometer. E_{run} was quantified prior to and following the stretch using indirect calorimetry. Cohen's d was used to quantify the effect size.

Results



Stretching did not impact changes in MVC (Pre: 122±33 Nm vs. Post: 119±42 Nm, p=0.822, d=-0.089) nor changes in AT stiffness (Pre: 309±217 $N \cdot mm^{-1}$ vs. Post: 283±180 $N \cdot mm^{-1}$, p=0.34, d=0.39). A medium effect of stretching was seen for AT hysteresis: from 38.0±10.5% prior to stretching to 45.7±14.1% following stretch (d=0.56). No meaningful change in E_{run} (post stretch increase of 0.6%) was seen following stretching

(p=0.72, d=0.13). Moderate correlations were found between both the changes in AT hysteresis and the change in E_{run} and the change in AT hysteresis and AT stiffness (Figure 1).

Discussion

These results suggest that 10 mins of static stretching causes a moderate increase in AT hysteresis, which is moderately correlated to the increased E_{run} following stretch. This may be due to static stretching reducing AT strain energy return. If the reduced AT hysteresis persists during running, this may negatively impact the energy cost of running.

FINITE ELEMENT MODELLING OF THE FOREARM AND WRIST TO SIMULATE GYMNASTICS-TYPE LOADING IN ADOLESCENT WRISTS

Miss Stefania DiLeo[1], Mr. Mahziyar Darvishi[1], Dr. Ryan Paul[2], Dr. Andrea Chan[2], Dr. Timothy Burkhart[1]

[1]Faculty of Kinesiology and Physical Education, University of Toronto, Toronto, Ontario, Canada. [2]Divisions of Orthopaedic and Plastic Surgery, University of Toronto, Toronto, Ontario, Canada

Introduction

Distal radius physeal stress reaction, or Gymnast Wrist (GW), is prevalent in adolescent gymnasts due to repeated high force loading at the extended wrist. Finite element (FE) modelling has proven valuable for advancing knowledge on injury biomechanics in a safe and ethical manner. However, previous FE models have neither examined gymnastics-type wrist loading nor have they modelled the distribution of loads across the open distal radius physis (DRP) of an adolescent with GW. Therefore, this study aimed to develop an FE model of the GW-affected wrist to estimate the magnitude and distribution of loads across the open distal forearm physes during a front handspring.

Methods

A CT scan of the GW-affected wrist was obtained from a single 14-year-old female gymnast. The solid 3D geometry of the distal radius, ulna, and their physes were developed using 3D Slicer (The Slicer Community, Boston, USA). Models were meshed in 3-Matic (Materialise, Leuvan, BEL) prior to assigning material properties in Mimics (Materialise, Leuvan, BEL). The peak hand impact force for a front handspring (retrieved *in vivo* from a youth gymnast) was applied in Abaqus (Dassault Systèmes, Vélizy-Villacoublay, FRA) to estimate the stresses/strains through the distal radius and ulna physes, as well as contact pressures at their epiphyseal-physeal and metaphyseal-physeal interfaces.

Results

A concentration of von Mises stress was found along the DRP volar rim (Fig. 1). The minimum principal stress (-48.1MPa) and strain (-1.15MPa) occurred within the volar aspect of the DRP. The radius experienced greater mean contact pressures than the ulna at the epiphyseal-physeal (2.94 vs 2.15MPa) and metaphyseal-physeal (2.97 vs 2.21MPa) interfaces.

Discussion

This study presents a novel FE model for estimating stresses and strains across the distal forearm physes in an adolescent with GW. The concentration of peak stresses/strains within the DRP volar rim may suggest that the continued application of gymnastics-type loads through a wrist with GW leads to their redistribution toward the DRP volar rim, though further validation of findings is necessary. Results may be crucial for identifying risk factors in the development/progression of GW in adolescent gymnasts, helping to enhance the long-term wrist health of these vulnerable athletes.

EMG-Informed OpenSim Analysis to Assess Firefighter Helmet Effects on Cervical Spine Loading

Mr. Gustavo Paulon Ph.D. Student, Dr. Suman Chowdhury Associate Professor

University of Florida, Gainesville, Florida, United States

Introduction

Musculoskeletal modeling platforms, like OpenSim, are widely used to determine how external loads, such as heavyweight, unbalanced helmets, alter cervical spinal joint reaction forces (JRFs). Particularly, OpenSim generic approaches—static optimization (SO) or computed muscle control (CMC)—estimate JRFs using a cost function (e.g., minimizing the squared muscle activations). However, they do not reflect a subject's true physiological muscle recruitment and underpredict intervertebral JRFs. Therefore, this study aimed to assess individualized estimates of cervical JRFs by implementing an EMG-informed optimization approach in order to investigate the biomechanical demands of various heavyweight, unbalanced firefighting helmets.

Methods

We analyzed 12 male and 12 female firefighters' kinematics and electromyography (bilateral sternocleidomastoid, infrahyoid, upper and cervical trapezius) data acquired during dynamic neck flexion-extension movements and maximum isometric flexion and extension exertions under three helmet conditions: No-helmet, US-helmet (1.77kg; COM: (anterior, superior, left) 0.002m, 0.152m, -0.006m) and EU-helmet (2.02kg; COM: (anterior, superior, left) 0.019m, 0.094, -0.008m). We used OpenSim MASI model and the Calibrated EMG-Informed Neuromusculoskeletal Modeling (CEINMS) Toolbox to calculate subject-specific cervical JRFs in the inferior-superior (IS), anteroposterior (AP), and mediolateral (ML) directions (Figure 1) with optimal weights (alpha=1~100, beta=1~1000, and gamma=1~1000) that minimized the overall RMSE ($RMSE_{overall}$= $RMSE_{ID}$ + $RMSE_{muscles}$) for each subject, task, and helmet type. We employed Friedman's test to evaluate the effects of *helmets* on the non-normal JRFs.

Results

Helmet use significantly increased IS-JRFs during static flexion ($p<0.005$, US-helmet: 14.0%, EU-helmet: 7.70%), extension ($p>0.05$, US-helmet: 4.34%, EU-helmet: 1.39%), and dynamic flexion-extension ($p<0.014$, US-helmet: 15.16%, EU-helmet: 7.62%) across all joints. The US-helmet showed higher AP-JRFs during static flexion (6.98%) and flexion-

extension (4.70%) than EU-helmet, but decreased the AP-JRFs during static extension (37.59%).

Discussion

Despite being 250g lighter, the US-helmet's high COM (5.8 cm above the EU-helmet) increased MOI by 10% at C0-C1, leading to higher compressive and shear forces. However, US-helmets reduced JRFs across all cervical joints. Since firefighter helmets increase cervical intervertebral maximum flexion angles, prolonged helmet use can increase the risk of disc degeneration and muscle injury. Incorporating subject-specific parameters to estimate cervical loading can yield accurate estimates of injury likelihood in the cervical spine.

Continuous Estimation of Elbow Joint Angle and Force from Surface EMG Using Machine Learning

Mr. Taehyung Kim, Ms. Kyungmin Lee, Prof. Gwanseob Shin

Ulsan National Institute of Science and Technology, Ulju-gun, Ulsan, Korea, Republic of

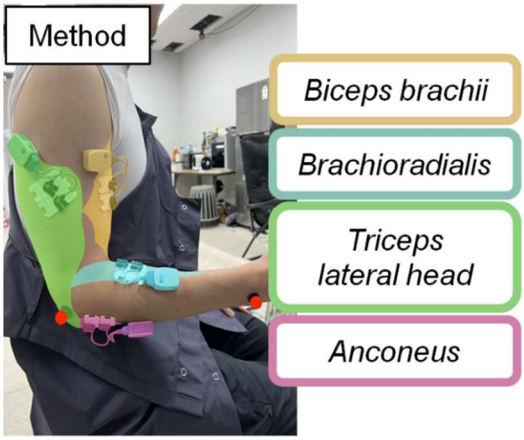
Introduction

Conventional methods for estimating elbow joint angles have mainly relied on motion capture systems or inertial sensors, which restrict measurement environments and make it difficult to directly obtain information on actual muscular force or external load. In addition, most previous studies using electromyography (EMG) to estimate joint kinematics have treated joint angle and force as separate targets. This study aims to develop a machine learning–based model that simultaneously and continuously estimates elbow joint angle and load using only surface EMG signals.

Methods

Surface EMG signals were recorded from four muscles—biceps brachii, triceps brachii (lateral head), brachioradialis, and anconeus—during elbow flexion–extension tasks in five subjects. After preprocessing, short-time window (0.2s)–based feature extraction was applied, and the extracted features were used as inputs to the machine learning models. Ground-truth joint angles were obtained using a motion capture system, and load was normalized as a percentage of maximum voluntary contraction (MVC). The performance of several models, including Random Forest (RF), XGBoost (XGB), multilayer perceptron (MLP), one-dimensional convolutional neural network (1D-CNN), and recurrent neural network (RNN), was compared.

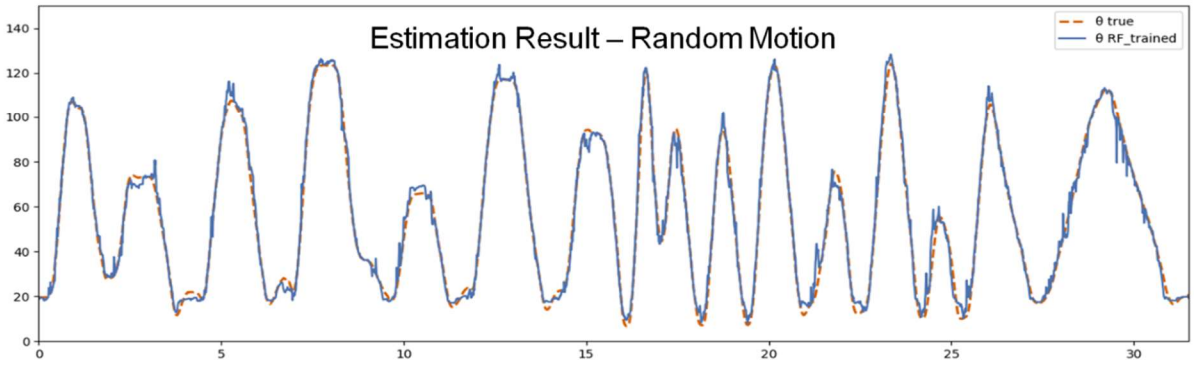
Results



Using a temporal split evaluation in which the last 20% of each sequence was reserved as test data, the RF model achieved an RMSE of approximately 20° with a correlation coefficient of $r \approx 0.84$ for joint angle estimation. For load prediction, the model yielded an RMSE of approximately 1.4% with $r \approx 0.88$. These results indicate that continuous estimation of joint angle and load using only surface EMG is feasible.

Discussion

Although this study experimentally demonstrates the feasibility of surface EMG–based estimation of joint angle and load, several limitations remain, including the non-uniqueness of EMG signals, inter-subject variability, insufficient validation in real-time



environments, and limited exploitation of temporal dynamics. Future work will focus on personalized learning strategies and the development of dynamic models that better capture the relationship between muscle activation and joint motion. Further investigation is also required to evaluate generalization performance under various loading and movement conditions.

Impact of Gait Modifications on Growth Plate Loads and Femoral Growth Trajectories in Children: Results from a Proof-of-Concept Study

Assoc. Prof. Dr. Hans Kainz[1], DI Clara Egner[1], BSc Laura Rathmair[1], BSc Kevin Kitir[1], Assoc. Prof. Dr. Claudio Pizzolato[2], Prof. Dr. Peter Pivonka[3], MD Gabriel Mindler[4], Dr. Willi Koller[1]

[1]University of Vienna, Vienna, Vienna, Austria. [2]Griffith University, Gold Coast, Queensland, Australia. [3]Queensland University of Technology, Brisbane, Queensland, Australia. [4]Orthopedic Hospital Speising, Vienna, Vienna, Austria

Introduction

Bone growth and shape are influenced by mechanical loads during daily activities. Torsional femoral deformities—characterized by abnormal anteversion angle (AVA)—are common and can lead to pain, altered gait, and increased osteoarthritis risk [1]. While gait modifications can alter joint loads and disease progression in adults [2], their impact on pediatric growth plate loading and subsequent bone growth is unknown. This proof-of-concept study examined whether gait modifications can change femoral growth trajectories in a child.

Methods

One typically developing child underwent lower-limb MRI and 3D gait analysis (Vicon,Oxford,UK) on a force plate–instrumented treadmill (AMTI,Watertown,USA). The participant walked with natural gait and with prescribed in-toeing and out-toeing modifications of varying magnitude. MRI of the pelvis, femur, and tibia was segmented to build a personalized musculoskeletal model using OpenSimCreator ModelWarper. Musculoskeletal simulations in OpenSim estimated muscle forces and joint contact forces (JCF) across 5–7 trials per condition; forces from one representative trial per condition were used for finite element (FE) analysis. A subject-specific FE model of the femur was generated using our previously developed workflow [3]. Muscle and JCF outputs were applied as nodal loads to compute compressive and shear stresses in the proximal femoral growth plate. The osteogenic index was derived from these stresses and input into a calibrated mechanobiological model [4] to predict growth trends, focusing on changes in AVA and neck–shaft angle (NSA).

Results

Relative to natural gait, in-toeing reduced hip JCF, modified shear stress distributions in the growth plate, and primarily influenced predicted AVA development. Out-toeing increased

hip JCF during early stance, altered shear stresses, and predominantly affected predicted NSA development (Figure 1).

Discussion

Gait modifications based on personalized multi-scale simulations may alter femoral growth plate loading, with the potential to redirect femoral growth trajectories. If validated in larger cohorts—including children with torsional deformities—early, non-invasive gait interventions could reduce the need for later de-rotation osteotomies. Future work will quantify dose–response relationships and determine the duration of gait modifications needed to achieve clinically-meaningful growth corrections.

Preliminary Findings Demonstrate Fatigue Induced by Unilateral Eccentric Plantarflexion Decreases Localized Muscular Capacity to Perturb Single Leg Hopping Mechanics

Mr. William Feldman[1], Ms. Caroline Turner[1], Ms. Lindsay Dietz[1], Ms. Kyle Grote[1], Dr. Luke Jessup PhD[2], Dr. Monica Daley PhD[2,3], Dr. Katherine Knaus PhD[1], Dr. Anne Silverman PhD[1]

[1]Colorado School of Mines, Golden, Colorado, United States. [2]University of California, Irvine, Irvine, California, United States. [3]Henri Samueli School of Engineering, Irvine, California, United States

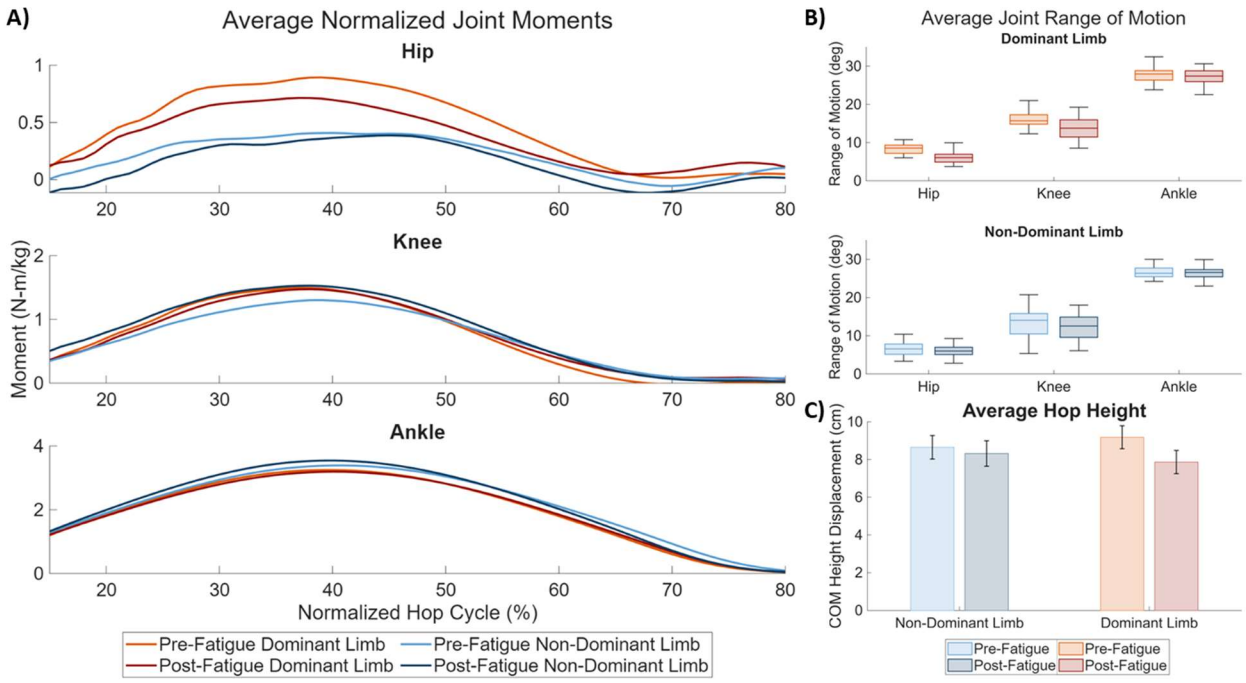
Introduction

Decreased musculoskeletal capacity can lead to compensatory movements [1]. Investigating hopping elucidates relationships between muscle mechanics and human performance [2], however, changes in hopping mechanics due to localized reduced muscular capacity are not well understood. To probe this interaction, we quantified how unilateral ankle plantarflexor muscular fatigue affects single-leg hopping mechanics. We hypothesized that, after unilateral fatigue, hopping on the fatigued limb would demonstrate changes in body center of mass (COM) height and lower limb joint kinematics and kinetics from decreased force production capacity. We expected no changes in hopping mechanics in the non-fatigued limb.

Methods

Kinematics were collected and synchronized with ground reaction forces on a single participant (M, right leg dominant, 38yrs, 188cm, 92kg). Preferred hopping frequency was determined from unconstrained double-leg hopping and then prescribed for all trials of 15s single-leg hopping on each leg before and after fatigue. The fatiguing exercise consisted of isokinetic eccentric-dominant ankle plantarflexor contractions on a dynamometer until 25% decrease in maximum isometric torque was achieved. An eight-segment dynamic model was used to compute lower-limb sagittal-plane joint angles and moments, and COM height, and was normalized in time from ground contact to subsequent ground contact.

Results



The participant had 38 ± 2 cycles per limb before and after fatigue at 2.68 ± .07 Hz. Following fatigue, the fatigued limb had 26% and 16% decreases in respective hip and knee range of motion (ROM), compared to 6.4% and 6.8% decrease in the non-fatigued limb. The

fatigued limb had 18% smaller peak hip moment and 14% decrease in hop height, compared to 5.3% and 3.8% decreases in the non-fatigued limb, respectively.

Discussion

Dominant ankle plantarflexor fatigue decreased ROM, hop height, and peak hip moment in the fatigued limb, indicating smaller force production in this muscle group. Smaller hip moments suggest altered muscle activity and movement control with fatigue. Results demonstrate fatiguing exercise as an effective perturbation of muscular capacity to investigate effects on hopping mechanics. Future work will extend to additional participants to generalize the results.

Markerless Motion Capture to Characterize Ground Contact Time and Joint Coordination During Depth Jumps Using an OpenCap to OpenSim System

Mr. William Spradlin

Roanoke College, Salem, VA, United States

Introduction

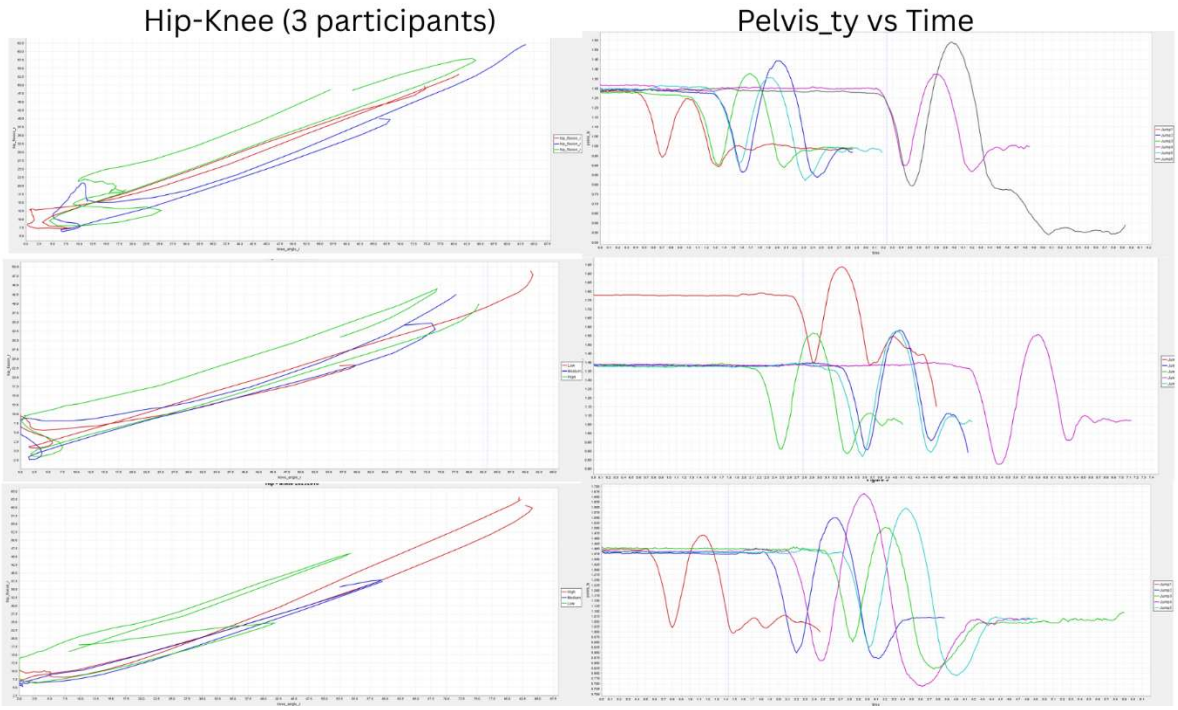
Depth jumps are commonly used to assess reactive strength and lower-limb coordination, but typically require force plates and marker-based motion capture. Markerless systems such as OpenCap, combined with musculoskeletal modeling in OpenSim, may enable accessible assessment of jump mechanics outside of laboratory environments. This study evaluated whether an OpenCap–OpenSim workflow can differentiate intentionally varied ground contact times (GCTs) and characterize associated hip–knee coordination patterns during depth jumps.

Methods

Seven healthy college-aged athletes performed depth jumps from a 30-cm platform. After landing, participants were cued to produce low, medium, or high GCT rebound jumps. Movements were recorded using three synchronized smartphones running OpenCap. Kinematic files were exported and processed in OpenSim.

Ground contact was identified from pelvis vertical displacement (pelvis_ty), with landing defined as the local minimum preceding the downward acceleration phase. GCT was measured from landing to takeoff. Representative GCT ranges were approximately: low: 0.20–0.25 s, medium: 0.28–0.34 s, high: 0.38–0.45 s. Inverse dynamics outputs were used to refine event boundaries and reduce noise around impact and propulsion. Three participants were randomly selected for detailed coordination analysis, and one trial per GCT category was plotted. Hip flexion was mapped against knee angle to form joint coordination loops for low, medium, and high GCT jumps.

Results



Pelvis_ty trajectories showed clear and systematic differences in contact duration across conditions, confirming that participants successfully modulated GCT in accordance with

instructions. Hip–knee coordination loops demonstrated distinct movement strategies: low-GCT jumps produced compact, rapid flexion–extension cycles; medium-GCT jumps displayed intermediate loop widths and balanced hip–knee contribution; and high-GCT jumps exhibited substantially larger loops with prolonged hip flexion and greater knee excursion. These patterns were consistent across participants.

Discussion

This study demonstrates that a markerless OpenCap–OpenSim workflow can identify changes in GCT and capture corresponding alterations in hip–knee coordination during depth jumps. The results support the feasibility of low-cost, field-deployable tools for assessing reactive strength and movement strategies. Future work will integrate force-plate validation, automated event detection, and larger participant samples.

Knee joint contact forces in the medial and lateral compartment during cycling

Dr. Wouter Schallig[1], MSc Sabrina Hörmann[2], Ir. Joost van den Broek[1,2], prof. dr. ir. Jaap Harlaar[1,2], dr. Ajay Seth[2]

[1]Erasmus Medical Center, Rotterdam, Zuid-Holland, Netherlands. [2]TU Delft, Delft, Zuid-Holland, Netherlands

Introduction

Joint loading contributes to the development of knee osteoarthritis, with the medial compartment typically experiencing higher loads during walking. Cycling is promoted as a low-impact exercise. However, the medial–lateral distribution of knee joint contact forces during cycling remains unknown. Moreover, it likely depends on bike-fitting parameters and cycling technique, which are usually optimized for performance rather than joint health. Therefore, we aim to quantify medial and lateral knee compartment forces during cycling and evaluate their sensitivity to common bike-fitting parameters.

Methods

We modified a cycling-specific musculoskeletal OpenSim model [1] by incorporating a medial-lateral knee model [2]. Cycling motion analysis data of 5 participants was selected from an open-access dataset [1] and used in the original and medial-lateral compartment (MLC) model. Scaling, inverse kinematics, static optimization and joint reaction analysis in OpenSim were used to estimate the tibiofemoral contact forces and its medial-lateral distribution. We included 5 participants with matched characteristics who cycled at matched power output and cadence and with EMG-electrodes on seven lower-limb muscles to assess agreement between measured and estimated muscle activations with cross-correlations.

Results

Total tibiofemoral compressive force and estimated muscle activations were not different between the original and MLC model. In all participants, the tibiofemoral compressive force was larger on the lateral compared to medial compartment (Fig.1). Muscle activation agreement was high ($R>0.9$) for vastus lateralis and medialis, but lower ($0.4<R<0.8$) for the other muscles.

Discussion

These preliminary results suggest that during cycling the lateral compartment is loaded more than the medial compartment, which would be especially relevant for medial knee osteoarthritis patients. However, muscle activations may not be sufficiently representative of subject coordination. Also considering the high muscle forces and co-contraction rates during cycling, an EMG-informed model may be needed. To improve muscle activation validation, we will soon include 15 additional healthy participants to perform a marker-based cycling motion analysis including both force pedals and EMG. Adjustable bike parameters (e.g. cadence, saddle positioning, foot orientation) will be systematically varied to determine their effect on compartmental knee loads with a EMG-informed musculoskeletal model.

Titanium–Hydrogel Hip Resurfacing Implant Featuring a Gyroid TPMS Fixation Stem

Dr. Xiaoyu Du, Ms. Isabelle Wüthrich, Prof. Stephen Ferguson

ETH Zurich, Zurich, Zurich, Switzerland

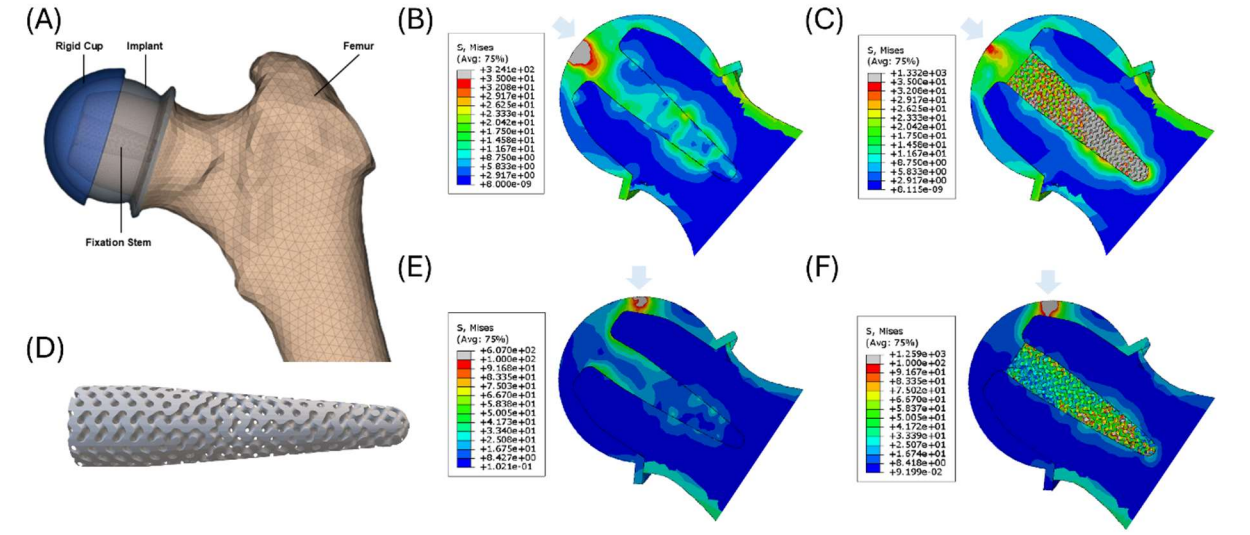
Introduction

Hip resurfacing arthroplasty offers a bone-sparing option compared with total hip replacement. Our earlier work introduced a titanium–hydrogel resurfacing implant designed to deliver ultra-low friction and effective shock absorption through a hydrogel-on-hydrogel interface [1]. However, a traditional solid stem can still trigger loosening and stress shielding. In this study, we explore a gyroid fixation stem, using finite-element analysis to evaluate its feasibility to reduce stem stiffness, enhance osseointegration, and enable physiological load transfer within the femoral head.

Methods

A stepwise finite-element workflow was used (Abaqus 2023). Parametric compression tests on unit-cell gyroid lattices examined how relative density and cell size affected stiffness; a 50% density, 2 mm cell design was selected. Solid and gyroid stems were then compared under displacement-controlled compression. The implant was evaluated in a femur model under two loading scenarios: axial compressive loading applied through the acetabular cup, and superior compression applied via a horizontal rigid plate with the implant aligned according to the ISO 7206-4.

Results



The gyroid lattice reduced unit-cell stiffness by nearly 80% compared with solid structures, with the D50U2 design selected for the final stem (25.7 GPa vs. 129.0 GPa). Under axial compression, peri-implant cancellous bone experienced higher and more uniformly distributed stresses with the gyroid stem, with peaks slightly above 35 MPa. The cancellous bone surrounding the solid stem showed similar peak stresses but in more localized regions, and principal strain followed the same trend. Under ISO-based loading, these patterns persisted, with the lattice actively contributing to internal load transmission, particularly transferring stress to the distal stem and surrounding bone.

Discussion

The TPMS fixation stem promoted a broader stress distribution within the peri-implant cancellous bone. Integrating a gyroid TPMS lattice into the fixation stem can effectively tailor implant stiffness and improve physiological load sharing, thereby reducing the risk of

stress shielding and implant loosening. However, some higher local stresses in the TPMS lattice arise from mesh artifacts and thin or highly curved regions that are more sensitive to load concentration. These areas will be optimized in future designs.

Effects of a New Self-Guided Foot Intervention on Lower-Body Pain, Intrinsic Foot Muscles Development, and Arch Function: A Case Report.

Mr Yaron Glazer

Counterspiral, San Francisco, California, United States

Introduction

Chronic lower-extremity musculoskeletal pain can be associated with limited foot mobility, intrinsic muscle weakness, diminished arch function, and reduced proprioceptive control. These deficits may contribute to dysfunctional loading patterns, impaired gait mechanics, and persistent pain. This case report describes the experience of a 40-year-old male with chronic musculoskeletal pain who developed and implemented a self-directed foot training program after limited improvement with conventional treatments. The program targeted foot and toe range of motion, intrinsic muscle strength, toe flexor strength, arch function, stability, and proprioception.

Methods

The participant performed a progressive foot-training program 6–7 days per week for the past 10 years. The core exercise of the training program involves maximally clenching the toes of both feet, maximally inverting both ankles, and maximally externally rotating both hips. The feet are placed in contact and rotated medially against each other, engaging in symmetric and simultaneous rotations to increase the range of motion. This core exercise was performed in several variations as shown in Figure 1. Self-reported pain levels, functional capacity, perceived motor control, and qualitative changes in arch structure, proprioception, and foot grip strength were recorded throughout the training period.

Results

The participant reported progressive reductions in pain intensity and frequency, ultimately achieving complete pain resolution. Functional capacity during daily and recreational activities improved significantly. Observed biomechanical changes included increased definition and functional reconstruction of the medial longitudinal arch, enhanced activation, control and endurance of intrinsic foot muscles, proprioception, visible strengthening and elevation of the transverse arch. Toe grip strength and metatarsophalangeal joint mobility also improved significantly. These adaptations

contributed to improving balance and stability. Although self-reported and observational, the improvements were consistent, progressive, and maintained to the present day.

Discussion

This case describes how a structured, self-directed foot training program is capable of producing meaningful improvements in intrinsic muscle strength, arch morphology, foot range of motion, balance, stability, and proprioception, alongside significant reductions in chronic lower-extremity, back and neck pain. The observed outcomes highlight the potential value of foot-focused interventions and support further controlled research to investigate their mechanisms and clinical applicability in larger populations.

The Effect of ACL Status on the *in Vitro* Mechanics of the Porcine Tibiofemoral Joint During Simulated Rehabilitation Exercise

Miss Zhané Murrell-Smith, Professor Sarah Astill, Professor Louise Jennings, Dr Aiqin Liu

University of Leeds, Leeds, West Yorkshire, United Kingdom

Introduction

Anterior cruciate ligament (ACL) injuries are among the most common knee pathologies. Rehabilitation following ACL reconstruction (ACLR) restores function and facilitates return to activity, however protocols lack a gold standard or biomechanical basis. Subsequently, ACLR patients may develop osteoarthritis at a similar rate to those who remain ACL deficient.

The aim of this study was to compare tibiofemoral kinematics and contact mechanics in an *in vitro* porcine model of the knee in ACL intact (ACLI), ACL deficient (ACLD), and ACLR conditions during simulated rehabilitation exercise.

Methods

Six porcine right hind limbs were dissected to the knee joint and mounted in a six-degrees-of-freedom knee simulator. Simulated profiles of squat and lunge exercises were developed from 3D motion capture data and verified via literature. Samples were simulated first with the native ACL intact. The anterior-posterior and internal-external tibial rotation axes were run in force control to measure kinematics. Tekscan pressure sensors were secured underneath the menisci with the axes ran in displacement control to measure tibiofemoral contact mechanics. The simulations were repeated in samples with the ACL resected and ACL reconstructed using a synthetic graft.

Results

During squat, anterior displacement
was significantly larger in the ACLD condition compared to ACLI ($p = 0.006$) and ACLR ($p = 0.010$) conditions. Larger anterior
displacements were also found during lunge between ACLD and ACLI condition ($p = 0.029$) and ACLR condition ($p = 0.021$), with no significant differences between ACLI and ACLR ($p > 0.05$). No significant differences were found for tibial rotation kinematics in between any ACL status for both exercises ($p > 0.05$).

During squat, peak contact pressure in the medial tibial compartment was significantly higher in the ACLD than following ACLR ($p = 0.017$). ACLR also significantly reduced peak

contact area in the medial compartment compared to the ACLD knee ($p = 0.005$). No significant differences in contact mechanics were found during simulated lunge ($p > 0.05$).

Discussion

In an *in vitro* porcine model, ACLR recovered kinematics and contact pressure during simulated exercise, although contact area in the medial compartment was reduced. Consistent with previous studies, ACL deficiency significantly altered both anterior-posterior displacements and medial tibiofemoral contact pressure.

An Inverse Dynamics Model for Hindlimb Joint Kinetics in Sheep

Dr. Aaron Henry PhD[1], Dr. Dana Gaddy PhD[1], Dr. Larry Suva PhD[1], Dr. Andrew Robbins PhD[2]

[1]Texas A&M University, College Station, Texas, United States. [2]University of Texas at Tyler, Tyler, Texas, United States

Introduction

Sheep are frequently used animal models of musculoskeletal diseases, yet methods for modeling their biomechanics are significantly underdeveloped. In particular, no broadly generalizable inverse dynamics (ID) models of sheep have been presented to date. To address this shortcoming, an ID model for calculating intersegmental forces and moments of the hindlimbs in sheep was developed.

Methods

The ID model comprised five segments (pastern, metatarsus, crus, thigh, pelvis) used to estimate kinetics of hip, stifle, hock, and metatarsophalangeal joints. Marker trajectories and force plate data were used to construct the model. Body segment inertial properties and joint centers were estimated using previously reported predictive models [1,2], while intersegmental forces and moments were calculated using expanded Newton-Euler equations of motion. A preliminary sensitivity analysis evaluated shortcomings by applying random perturbations to markers defining the right hock.

Results

Kinematic and kinetic endpoints were calculated for the four bilateral joints, with occasional constant offsets between left and right joint angles observed before normalization. Stifle internal/external rotation remained at 0 degrees due to the shared flexion axis between the thigh and crus segments. Endpoint means over the gait cycle did not show substantial sensitivity to marker perturbations; however, variability clearly increased. Notably, non-sagittal plane endpoints were more sensitive to perturbations (Figure 1).

Discussion

This ID model is the first to utilize predictive equations for hindlimb joint centers and inertial properties, allowing calculation of intersegmental forces and moments without sacrificing the animal to directly measure the inertial properties. However, the model is subject to skin movement artefacts and positional errors, as confirmed by the sensitivity

analysis in which non-sagittal endpoint variability substantially increased. Although improvements are warranted, the present model provides a foundation for future work.

Images (Optional)

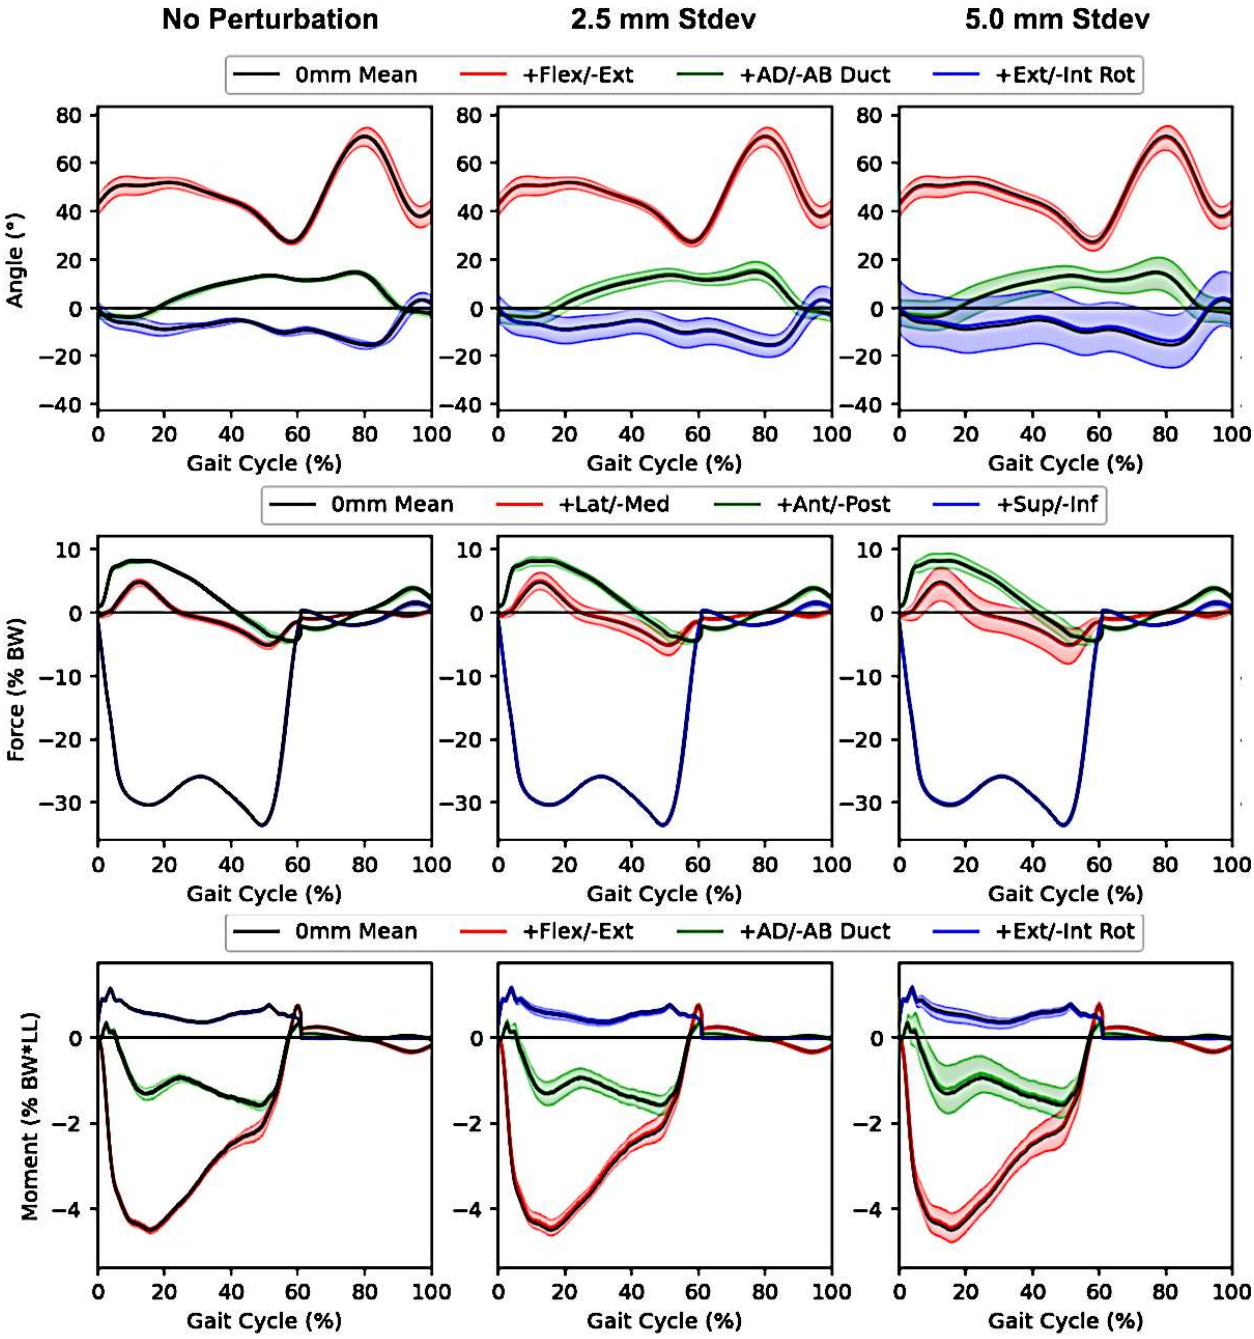

Figure 1: Model outputs for the right hock joint are shown for no perturbation, 2.5mm and 5 mm. As the perturbations increase, the variability (indicated by the standard deviation) increases.

Initial Development of a Probabilistic Metric of Risky Biomechanics Related to Anterior Cruciate Ligament Injury Risk

Ms. Alexandra Lynch MS[1], Dr. Fatemeh Aflatounian PhD[1], Dr. David Saxby PhD[2], Dr. Scott Monfort PhD[1]

[1]Montana State University, Bozeman, MT, United States. [2]Griffith University, Gold Coast, QLD, Australia

Introduction

Anterior cruciate ligament (ACL) injury risk factors are often assessed using single-limb drop jumps (SLDJ) with biomechanical variables averaged over several trials. However, many ACL tears appear to occur acutely rather than due to an accumulation. Thus, averaging performance across repeated trials may mask variability in performance and overlook less frequent but higher risk mechanics. The purposes of this study were to 1) develop a probabilistic metric[1] to characterize risky biomechanics (i.e. probability of injurious load (P_{INJ})[Fig.1A]) during SLDJ, and 2) determine how the number of jump landings in a dataset influence P_{INJ}.

Methods

Eight healthy participants (3F/5M;23.3±3.3years;171.7±10.6cm;71.0±8.7kg) performed reactive SLDJ. Body motions, ground reaction forces, and electromyograms (9 lower-limb muscles) were collected. Calibrated electromyography-informed neuromusculoskeletal modeling was used to estimate muscle forces[2] and linked sequentially to a model of ACL loading to estimate force in the ACL (F_{ACL}) for each SLDJ[3]. Eight SLDJ landings per participant were analyzed. For each participant, a probability density function was calculated and the probability of an injurious load (P_{INJ})[1] was estimated by integrating above a sex-, height-, and mass-adjusted estimate of ACL failure load (F_{INJ})[4]. P_{INJ} was recalculated after removing 0-5 jumps and the resulting (log-transformed) P_{INJ} estimates were compared using a mixed-effects model.

Results

P_{INJ} estimates varied by participant[Fig.1C] and were influenced by the number of jumps used in their estimate($p=0.032$).

Discussion

P_{INJ} was calculated for SLDJ landings, which aims to reflect relative risk (i.e., higher is riskier), incorporating mean and variance measures relative to ACL failure strength[Fig.1A]. Notably, P_{INJ} is not a direct probability of sustaining an injury and the clinical utility of this metric must still be established. This study provides initial development of P_{INJ} as a tool for assessing ACL injury risk. P_{INJ} varied across the number of jumps used in its estimation, with the highest number of trials (8) not yet establishing an effect size asymptote[Fig.1B]. Ongoing efforts will explore higher numbers of trials (>8), with effects expected to stabilize as more trials and participants are included.

Images (Optional)

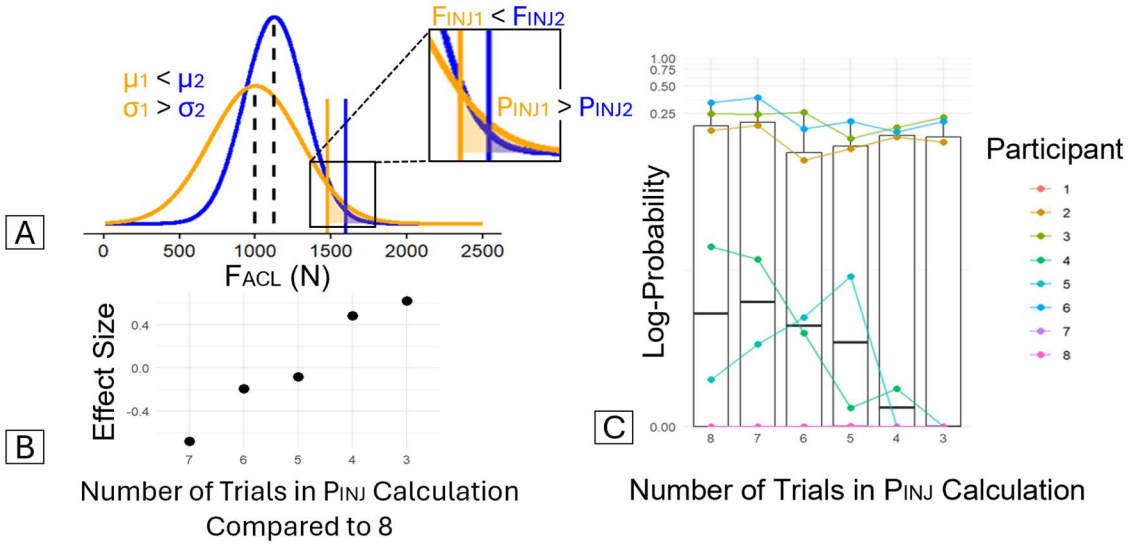

Figure 1: A) Example probability density functions (PDF) are calculated from the mean (μ_1, μ_2)and standard deviation (σ_1, σ_2) of F_{ACL} for two participants. Probabilities of injury (P_{INJ1}, P_{INJ2}) are found by integrating the PDFs above ACL failure strengths (F_{INJ1}, F_{INJ2}). Despite $\mu_2 > \mu_1$, $P_{INJ1} > P_{INJ2}$ because of greater variability and ACL failure strength, illustrating a pitfall of using mean F_{ACL} alone. B) Effect sizes on log-transformed data between n8 and all other trials were calculated using paired Cohen's d. C) Log-probability plot of raw P_{INJ} values on a log-scale. Minimum P_{INJ} values for Participants 1, 7, and 8 approach 0. A significant pairwise difference existed between n8-n3 (d = 0.62, p = 0.019).

Introduction

Musculoskeletal modeling allows for the analysis of internal mechanics that can be indicative of injury risk. However, these approaches have rarely been applied in high-impact activities performed outside of laboratories, such as military parachute jumps.

Methods

Whole-body kinematic data from 15 wearable inertial measurement units (IMUs) and normal force data from pressure-sensing insoles were collected from a male participant (1.72m, 85.2 kg) performing a training parachute jump. A musculoskeletal model was scaled in segment length and body mass. The inverse kinematics solution was calculated in OpenSim from the IMUs by minimizing the sum of weighted squared orientations errors between the model and experimental kinematics.

Unmeasured net external forces and moments during descent were estimated using three techniques: 1) as a baseline, no external load was applied to the model, 2) external forces were estimated using center-of-mass (COM) linear acceleration data, 3) the output reaction forces and moments from inverse dynamics (ID) in OpenSim were used to define external loads at the pelvis. A residual reduction algorithm was executed to assess dynamic consistency. The root-mean-squared (RMS) residual forces and moments were compared between techniques.

Results

The ID method had the lowest errors, quantified as RMS values for residual forces and moments, in all directions, except for the transverse moment (Table 1). The greatest overall decrease in RMS values was the vertical force.

Discussion

Results indicate that the ID method effectively estimates unknown external loads in austere environments. However, a limitation to this approach is that it also incorporates

dynamic errors due to modeling assumptions and experimental errors that are not part of the physical, external loads in the system. The estimated loads agree well with expected loads during a descent [1], but these loads can vary widely due to environmental conditions. This framework applies outside the laboratory to realistic environments with limitations in data collection to drive musculoskeletal models. Future work will extend these approaches to the ground contact phase and examine the muscle recruitment solution and internal joint contact forces during these parachute landings.

A Comparison of Maximal Rate of Force Development between Burst and Maximum Voluntary Contractions: Reliability and Neuromuscular Determinants

Mr. Andrew Nickel BSc Biomechanics, Mr. Anoush Rehmani, Mr. Zachary McClean, Mr. Nathan Boon-van Mossel, Mr. Nathaniel Morris, Mr. Matthew Zukowski, Dr. Walter Herzog, Dr. Matthew Jordan

University of Calgary, Calgary, Alberta, Canada

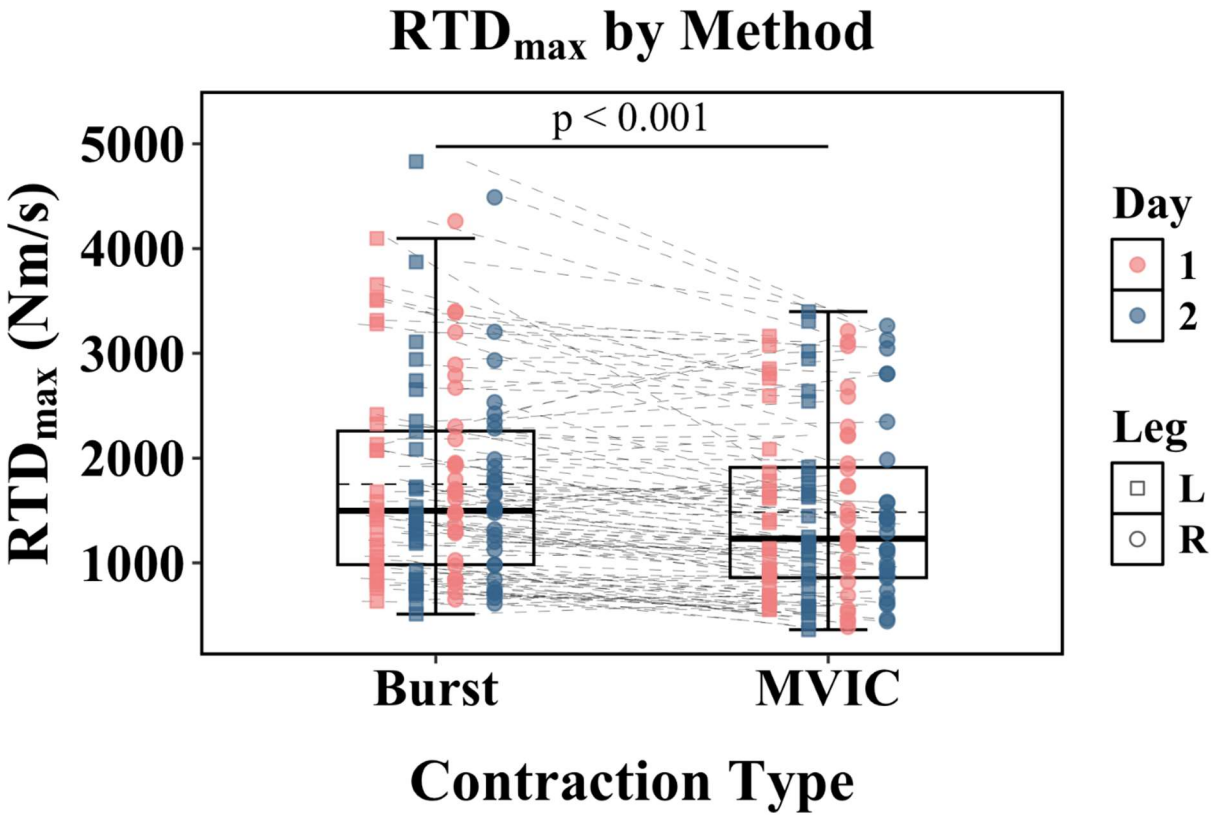
Introduction

Explosive strength, defined as the neuromuscular capacity for rapid force production, is critical for evaluating athletic potential, maintaining functionality, and injury rehabilitation. Knee extensor explosive strength can be quantified as the maximal rate of torque development (RTD_{max}), and is traditionally evaluated isometrically during either maximum voluntary isometric contractions (MVIC), where maximal torque is generated "as fast and as hard as possible" over a contraction lasting ~3 seconds, or rapid 'burst' contractions, where torque is developed "as fast as possible" during a ~1 second contraction to a submaximal torque target. However, the optimal approach for evaluating RTD_{max} is unclear, and neuromuscular activation between MVIC and burst contractions has not been compared. Furthermore, compliance within commercial dynamometers reduces RTD_{max} reliability, prompting recommendations for the use of custom-built devices. The purpose of this study was to compare the reliability, RTD_{max} output, and neuromuscular activation between the burst and MVIC methods using a rigid, custom-built isometric dynamometer.

Methods

Strength-trained (n = 30; females = 13) participants completed maximal effort knee extension MVIC and burst contractions. Neuromuscular activation was assessed by the rate of rise of the vastus medialis (VM) and vastus lateralis (VL) electromyography (EMG) root mean square (RMS) signal normalized to the intra-repetition peak EMG RMS amplitude (RER_{max}). RTD_{max} was computed from the numerical derivative of the torque-time curve as the average RTD around the instant of the peak knee extensor RTD using a ±25 ms window.

Results



RTD_{max} demonstrated excellent reliability for MVIC (right: ICC = 0.87; left: ICC = 0.93) and burst (right: ICC = 0.86; left: ICC = 0.88) contractions. Linear mixed effects models revealed

an effect of contraction type on RTD_{max} (β = -257.80, SE = 44.58, $p < 0.01$) and RER_{max} (VM: β = -0.60, SE = 0.15, $p < 0.05$; VL: β = -0.72, SE = 0.14, $p < 0.05$), indicating that explosive strength and neuromuscular activation were higher during burst contractions.

Discussion

Explosive strength capacity is directly related to human ballistic motor performance. These findings advance scientific knowledge on reliable testing methodologies for explosive strength assessment, carrying important applications for athletic performance and healthy aging.

Integration of Weight-Bearing Computed Tomography and Magnetic Resonance Imaging for Advanced Musculoskeletal Statistical Shape Modeling of the Foot and Ankle

Ms Melissa Requist BS, Mr Andrew Peterson MS, Dr Curran Reddy MD, PhD, Dr Megan Mills MD, Dr Amy Lenz PhD

University of Utah, Salt Lake City, Utah, United States

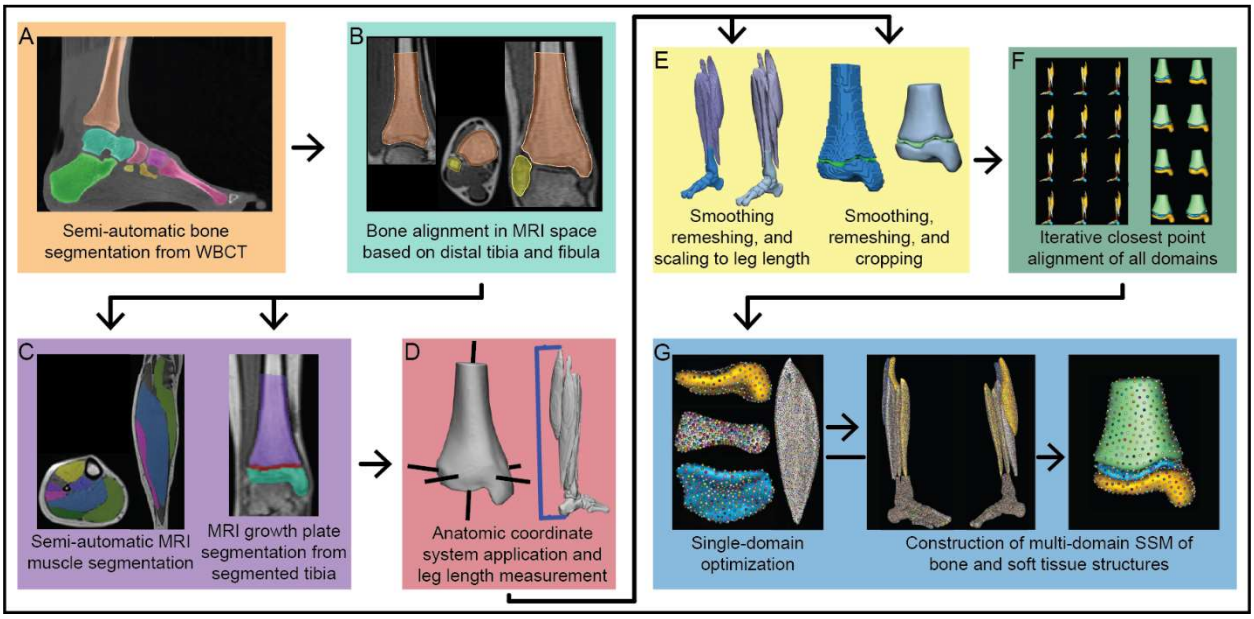
Introduction

Statistical shape models (SSM) describe three-dimensional (3D) anatomic morphology. SSM relies on accurate anatomic structure segmentation with weight-bearing computed tomography (WBCT) being used to characterize skeletal deformity in the foot and ankle. While WBCT provides satisfactory osseous segmentation it is less accurate for soft tissue structures. Magnetic resonance imaging (MRI) provides improved evaluation of the soft tissue structures but less accurate segmentation of osseous structures. This analysis describes methods for coregistration of anatomical structures from MRI and WBCT for SSM illustrated by two examples, a combined musculoskeletal model and a distal tibia growth plate model.

Methods

Bilateral WBCTs of the mid-tibia through toe-tip with 0.37mm isovoxel and bilateral T1-weighted DIXON MRIs of the knee through toe-tip with 0.1mm isovoxel were collected from 13 pediatric participants (age 8-18). 14 bones were semi-automatically segmented from WBCT (Figure 1A) and manually aligned with the in-phase MRI scan based on distal tibia and fibula outlines (Figure 1B). From this scan, muscles of the leg were segmented semi-automatically and the distal tibia growth plate was manually segmented within the previously segmented bony structure (Figure 1C). Anatomical axes of the tibia were calculated (Figure 1D) and used to crop bone segmentations and normalize the combined bone and muscle structures to leg length. 3D parts were smoothed and remeshed (Figure 1E). For each model, structures were aligned using iterative closest point alignment (Figure 1F) and SSMs were generated using a single-domain optimization for multi-domain model pipeline (Figure 1G).

Results



This method yielded two SSMs, one demonstrating combined bony and muscle morphology of the leg and the other showcasing growth plate anatomy in the distal tibia,

showing a decrease in growth plate thickness with age. Both models demonstrated compactness, specificity, and generalization comparable to previously published SSMs.

Discussion

Coregistration of WBCT and MRI structures allows for application of SSM to novel questions in musculoskeletal morphology. Limitations include manual registration of structures between imaging modalities and resolution constraints in MRI. This analysis presented examples of muscle and growth plate models, but other MRI sequences could allow for inclusion of ligaments, tendons, or articular cartilage in the future.

Case Study: A Novel Multi-Domain Neuro-mechanical Assessment Comparing Repeatability of Neuromuscular Communication

Ms. Yara Izhiman[1], Ms. Annika Schaeffer[1], Mr. Ethan Haight[1], Dr. Vesna Novak[1,2], Dr. Thomas Talavage[1], Dr. Brian Grawe[3], Dr. Frank Noyes[4,1], Dr. Eric Nauman[1]

[1]Department of Biomedical Engineering, University of Cincinnati, Cincinnati, Ohio, United States. [2]Department of Electrical Engineering and Computer Science, University of Cincinnati, Cincinnati, Ohio, United States. [3]Orthopaedics and Sports Medicine University of Cincinnati, College of Medicine, Cincinnati, Ohio, United States. [4]Noyes Knee Institute, Cincinnati Sports Medicine and Orthopaedic Center, Cincinnati, Ohio, United States

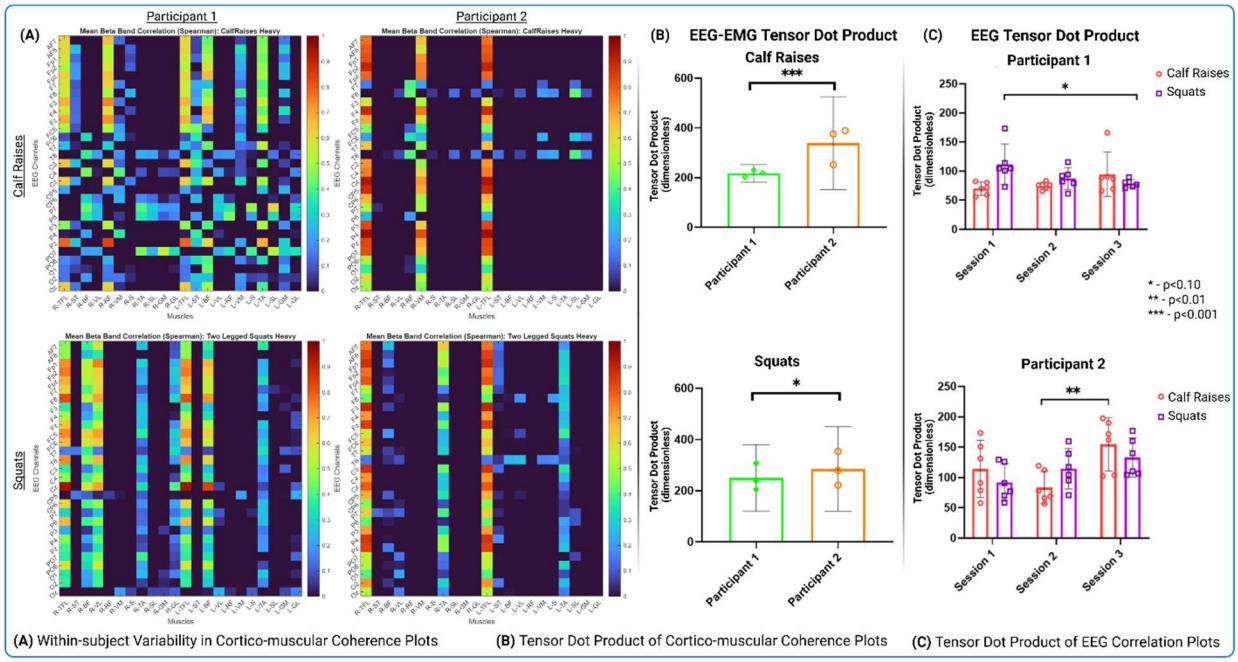
Introduction

This study examines differences in cortico-muscular communication across two male recreational athletes during two types of functional movements. The goal was to employ electromyography (EMG) and electroencephalography (EEG) as a joint cortico-muscular communication quantification tool. While these two tools have long been used independently, we propose an approach to examine the interactions between the nervous and musculoskeletal systems. This approach demonstrates the potential for quantifying patterns of cortico-muscular dynamics across dynamic functional movement and identifying markers of injury and state of recovery. In this study, we investigate the within-subject variability in cortico-muscular communication along with the repeatability of measures across three testing sessions.

Methods

Data acquisition involved athletes performing a series of functional movements with and without additional weights. Steady-state recordings and weighted sets served as baselines for subsequent data normalization. During each segment, EEG, EMG, and motion capture data were recorded concurrently to ensure synchronized multimodal datasets. The raw signals were processed through a custom MATLAB pipeline that expanded on standardized signal processing procedures for cross-modal comparative analysis. Correlation and coherence maps describing neural, muscular, and cortico-muscular dynamics were generated for EEG, EMG, and EEG-EMG data, respectively.

Results



Our preliminary findings highlight the repeatability of our approach with no significant effects observed across three different experimental sessions of the same exercises. Furthermore, comparisons between individuals demonstrated statistically significant

differences, especially when comparing squats to calf raises, suggesting that variability was more pronounced at the inter-individual level than within sessions. In addition, the increased neuromuscular and cortical demands in squats, compared to calf raises may explain the greater variability observed between participants.

Discussion

The reported repeatability of cortico-muscular dynamic characterization allows for utilizing cortical and muscular dynamics as markers for neuromuscular communication across functional performance in athletes. In addition, within-subject cortico-muscular dynamic variability further highlights the promise of this approach in personalizing comprehensive functional performance characterization. These findings further invite the expansion of this investigation to evaluate performance as a function of athletic caliber, injury, and rehabilitation.

Comparing Scaling Approaches and Their Impact on Joint Kinematics in Markerless and Marker-Based Motion Capture Systems

PhD student Sandra Salvador-Lis, PhD student Andy Man Kit Lei, PhD Student Sara Oliveira, Dr Antonio P. Veloso, Dr João Brito, Dr Silvia Cabral

CIPER, Faculdade de Motricidade Humana, Universidade de Lisboa, Lisbon, Lisbon, Portugal

Introduction

OpenCap is a new open-source 3D markerless motion capture (MOCAP) system. To validate new MOCAP systems, it is essential to use the same model and data processing to identify the differences between systems. The scaling process has a high importance in musculoskeletal modelling because it can significantly impact segment lengths and, consequently, joint kinematics, moments and muscle forces. When scaling is performed using pairs of markers, identical procedures cannot always be replicated on different MOCAP systems without additional software. The goal of this study is to estimate the effect of using different pairs of pelvis markers for scaling on side-cutting kinematics.

Methods

Four female football players (aged 23±1 years) performed 90° side-cutting manoeuvres while data were acquired simultaneously using OpenCap and marker-based MOCAP system. Segments length and joint angles estimated with OpenCap were compared with those analysed in OpenSim with: 1) data collected with OpenCap and using a) the same pair of markers [hip joint center(HJC)] and b) the Anterior Superior Iliac Spines (ASIS); and 2) data collected with marker-based system using a)HJC, b)ASIS and c)the midpoint between ASIS and posterior superior iliac spines. The root mean square error (RMSE) over the full time series of joint angles was calculated.

Results

In the estimation of joint angles (Table 1), except for the pelvis tilt, pelvis list and ankle sagittal plane of motion, the RMSE exceeded more than 5°. Discrepancies were larger when comparing marker-based with OpenCap than when comparing methods within the same MOCAP system. However, within-system differences were below 2° for OpenCap and below 3° for marker-based. A similar pattern was observed for femur length and pelvis width, where the greatest differences occurred between systems.

Discussion

These findings in joint angles align with results reported elsewhere[1] when comparing marker-based MOCAP system with OpenCap. No comparable results have been found for the segment measurements. Therefore, it can be concluded that different marker pairs within the same system do not cause substantial variations (<3°) in kinematics, and any of them may be used to validate OpenCap.

A Novel Kinematics-Driven Muscle Force Control System Improves Biofidelity of *in Vitro* Gait Simulation

Dr Antony Crossman, Dr Angela Kedgley

Imperial College London, London, Greater London, United Kingdom

Introduction

In vitro gait simulators are important tools in surgical and implant innovation. They recreate *in vivo* gait data, giving insights into the body's internal mechanisms. Previous simulators applied average pre-calculated muscle forces, leaving kinematics unconstrained. Unconstrained kinematics resulted in linear correlations of $r_{xy} > 0.87$, between achieved and desired ankle joint kinematics, with no mention of error magnitudes [1]. The hypothesis of this study was that the biofidelity of *in vitro* gait simulators can be improved through kinematic control, eliciting trial-specific muscle forces.

Methods

A novel kinematics-driven, three-stage cascade control system, developed as a plugin for the simVITRO gait module, controlled a custom built, five-segment, nine-muscle foot and ankle model. The torque needed to achieve *in vivo* kinematics of gait was calculated using PID control and input into a muscle force minimisation algorithm, which determined trial-specific forces and actuator positions.

Ten repetitions of stance were simulated. Kinetic (vertical ground reaction force (vGRF)) and kinematic (plantar-/dorsiflexion (PD), hallux flexion/extension (Hal-FE)) accuracies were assessed through mean absolute errors between achieved and desired data. Repeatability was defined as the mean standard deviation of kinetics and kinematics between repetitions. Physiological muscle timing was assessed using phase correlation between *in vivo* EMG data and executed muscle forces for the gastrocnemius (GN), tibialis anterior (TA) and peroneus brevis (PB).

Results

The kinematic accuracy and repeatability were 0.48° ± 0.56° and 0.20° ± 0.07° for PD, and 1.78° ± 1.67° and 0.59° ± 0.42° for Hal-FE with kinematic correlations of $r_{xy} \geq 0.99$ (Figure 1a). The muscle force patterning was excellent for $P_{TA} = 0.94$, $P_{PB} = 0.88$ and $P_{GN} = 0.83$. Accuracy of vGRF was 7.7 N ± 4.8 N with a repeatability of 3.7 N ± 1.5 N (Figure 1b).

Discussion

Biodfidelity of the stance phase of gait was successfully improved using a kinematics-driven control system when compared to force control [1]. Excellent muscle patterning, high kinematic and kinetic accuracy and repeatability demonstrates the successful implementation of cascade control for gait simulation.

Variations in the Expressed Section of the Force-Length Curve of the Human Soleus

Ms. Axelle M. Wasiak, Dr. John H. Challis

The Pennsylvania State University, University Park, Pennsylvania, United States

Introduction

The force-length relationship is well established in isolated muscle, but muscles *in vivo* do not necessarily operate over the entire range of the theoretical force-length curve. For the bi-articular gastrocnemius and rectus femoris muscles, using dynamometry, it has been demonstrated that *in vivo* the expressed section of the force-length curves can vary between individuals. The purpose of this study was to determine, *in vivo,* the properties of the human soleus muscle-tendon complex using a combination of dynamometry, ultrasound imaging, and modeling. It was hypothesized that the ratio of tendon slack length to fascicle optimum length will dictate the expressed section of the force-length curve.

Methods

Thirteen participants (6M 7F) provided informed consent for this study. The soleus moment arm was determined using the tendon excursion method, with the tendon excursion tracked using ultrasound. For strength testing, to eliminate the gastrocnemius contribution to the ankle plantarflexion moment, the knee was flexed until gastrocnemius buckling was observed in ultrasound images (40° to 70° knee angle). Participants performed maximal voluntary isometric plantarflexions at eight ankle angles (15° dorsiflexion to 30° plantarflexion). The ankle moment was recorded using a dynamometer. The soleus architecture, tendon slack length and elongation were imaged simultaneously using a dual probe ultrasound.

Results

Eight participants operated on the ascending limb of the force-length curve, two on the plateau region, and three on the descending limb. No significant differences were found between ascending and descending groups in maximum tendon extension (p=0.34), optimum fascicle length (p=0.33), and maximum force (p=0.34), but tendon slack length (p=0.013), and the ratio of tendon slack length to fascicle optimal length (p<0.001) were significantly different. Those participants whose soleus operated on the ascending limb of the force-length curve had longer tendon slack lengths and a larger ratio of tendon slack length to fascicle optimal length.

Discussion

This study successfully characterized the soleus force-length relationship *in vivo*. Variations in the expressed region of the force-length curve can be explained by individual differences in the ratio of tendon slack length to fascicle optimal length. This characterization has implications for understanding the function of the soleus *in vivo*.

Direct Comparison of GPOPS-II and CasADi for Generating Predictive Simulations of Human Movement

Prof. B.J. Fregly Ph.D., Mr. Spencer Williams B.S.

Rice University, Houston, Texas, United States

Introduction

Predictive simulations of human movement can potentially be used to design personalized treatments for movement impairments. While direct collocation optimal control solvers GPOPS-II (commercial) [1] and CasADi (open-source) [2] are commonly used to generate predictive simulations, no studies have compared solver convergence properties for identical human movement prediction problems. This study performed such a comparison within the Neuromusculoskeletal Modeling (NMSM) Pipeline [3].

Methods

A three-dimensional full-body torque-driven soccer kicking tutorial problem available with the NMSM Pipeline was modified for use in this study. The modification involved adding a deformable foot-ground contact model under the left foot. Three torque actuators controlled the sagittal plane motion of the right hip, knee, and ankle. The motion of the remaining sagittal plane joints was tracked, while the motion of all non-sagittal plane joints was prescribed.

The NMSM Pipeline works with GPOPS-II, and a limited prototype implementation of CasADi was added to permit solver comparison. Both solvers were applied to a sequence of three optimizations. First, a Tracking Optimization (two formulations) eliminated the sagittal plane residual forces and moment on the pelvis while closely reproducing the experimental motion of all non-prescribed joints and the experimental inverse dynamics moments for the right leg. Next, a Verification Optimization verified that the torque controls from the first optimization reproduced the motion of the right leg without tracking it. Finally, a Design Optimization (predictive simulation) predicted how the right leg control torques and full body motion should change to increase the anterior velocity of the right toe by 10% at ball contact.

Results

Both solvers successfully solved all three optimization problems. GPOPS-II performed better for Tracking Optimization while CasADi performed better for Verification and Design Optimization. Solutions produced by both solvers were nearly identical for Tracking and

Verification Optimization, while GPOPS-II predicted more knee flexion and less hip extension than did CasADi for Design Optimization.

Discussion

With refinements for Tracking Optimization, CasADi appears to be a viable open-source alternative to GPOPS-II within the NMSM Pipeline.

The effect of triceps surae force-length behavior on jumping performance

Mr. Ben Perrin, Dr. John Challis

The Pennsylvania State University, State College, PA, United States

Introduction

In vivo it has been found that the expressed region of the force-length curve for the triceps surae varies between individuals, which introduces the possibility that this variation influences performance. For a jump, it is of interest whether the high-to-low force production potential of the ascending limb, or vice versa for the descending limb, would yield greater jump heights. The purpose of this study was to investigate this question for a jump in which the joints above to the ankle were locked. It was hypothesized that a greater jump height would be achieved when muscles were operating on the ascending limb.

Methods

A model consisting of a multi segment foot, that had been previously validated using kinematic and kinetic data from five human participants, was used in this study. Two model variations were created by altering the tendon slack length of the soleus and gastrocnemius where in Model 1 they acted on the ascending limb of the force-length curve, and in Model 2 the descending limb. Maximal vertical jump optimizations were simulated for each model, and jump performance and muscle behavior were compared. Upper body inertial properties of the models were altered, and simulations were rerun to see if this accentuated any differences.

Results

Model 2, which acted on the descending limb, jumped 10.5% higher than Model 1. A Brake-Spring-Motor index indicated that the gastrocnemius and soleus were acting almost entirely as movement producers (motors) for both models. In Model 2 the gastrocnemius did 2.4% and the soleus 13.3% more work compared with Model 1. When the mass of the upper body was increased by 50%, these differences were magnified as Model 2 jumped 20.2% higher and the soleus did 48.7% more work compared with Model 1.

Discussion

The results of this study indicate that having the triceps surae operate on the ascending limb is not optimal for maximal jumping tasks. Given that for both muscles it has been found that the majority of people operate on the ascending limb, the question is raised as to what movements they may be optimized for.

Sex-Specific Differences in Hip Abduction Moment Arms Reveal Limitations of Scaled Musculoskeletal Models

Mr. Brendan S. Shea

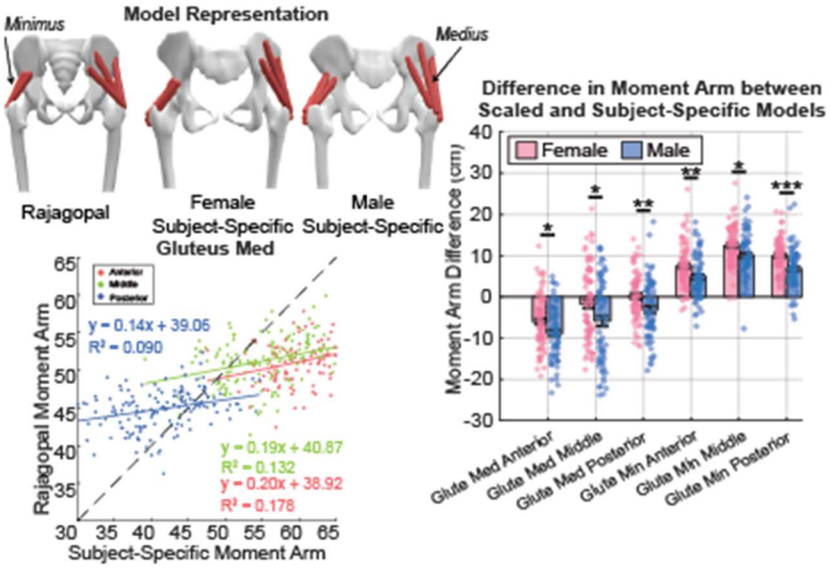
University of Virginia, Charlottesville, VA, United States

Introduction

Computational models of the lower limb are widely derived from male-only datasets or from sex-averaged data, despite the well-documented sex differences in skeletal morphology, muscle architecture and strength. These limitations are relevant given that women are at increased risk for musculoskeletal pain and discomfort [1]. Therefore, models that explicitly incorporate sex-specific anatomy are needed to accurately characterize movement biomechanics as the unique placements of attachment points influence moment arms.

Methods

Seventy-seven healthy adults (40F, 37M; Age 20-49 years) underwent full MRI scans of both lower limbs and motion capture gait analysis (Vicon Nexus). Lower limb muscles and bones were segmented using a trained AI algorithm with manual validation (Springbok Analytics,Charlottesville,VA).The 2016 Rajagopal model [2] was scaled in OpenSim using static motion capture data and subject mass. Gluteus medius and minimus muscle attachment points for the subject-specific models were located in a semi-automatic manner using bony landmarks, anatomical data, and visual inspection. Peak moment arms were extracted as the maximum absolute value of each muscle's moment arm curve using the OpenSim API for both the scaled Rajagopal model and the subject-specific models. Peak moment arms from the two models were compared for each subject and muscle.



Results

Across all gluteus medius muscle compartments, the scaled Rajagopal model showed a greater magnitude of difference from the subject-specific models in male subjects compared to female subjects. In contrast, the gluteus minimus compartments exhibited the opposite pattern, with female models demonstrating larger differences across all compartments. Significant differences in moment arms were observed across all compartments and muscles, with the posterior compartment of the gluteus minimus showing the largest and significant difference ($p<0.001$).

Discussion

These findings demonstrate that current generic scaled models better represent the male anatomy than female anatomy. This work underscores the need for sex-specific muscle modeling to accurately capture anatomy and function of both sexes. Future work will investigate the relationships between moment arms and anthropometric measures to further elucidate the sources of sex-based differences in moment arm output.

Mr. Brian Keller

Introduction

Increasing availability of portable force plates has enabled a broader adoption of data-driven approaches to sports training and rehabilitation[1]. Despite rapid growth and accessibility of biomechanical datasets, tools for extracting deeper physiological and clinical insight remain limited. Our project aimed to address this gap by developing generalized deep learning models that predict below knee muscle forces between younger and older adult populations according to clinical thresholds using ground reaction force (GRF) data.

Methods

Kinematic and kinetic data from prior gait studies were collected from 20 older adults[2] (OA; 14 females, 72.7±5.4 yrs old) and 10 younger adults[3] (YA; 4 females, 26.4±4.1 yrs old) during walking trials performed at various speeds. Ground-truth muscle forces were estimated in OpenSim[4] using scaled generic models[5], inverse kinematics/dynamics and custom static optimization pipeline[3]. In total, 1500 stance phases of estimated muscle force and GRF (50-50 split OA/YA) were divided into training, validation, and testing sets. Four deep learning architectures, a LSTM (LongShortTermMemory), CNN-LSTM (ConvolutionalNeuralNetwork-LongShortTermMemory), LSTM with attention, and transformer, were trained to predict stance-phase forces in 11 ankle-crossing muscles

using input GRF data. Model results were evaluated using a threshold derived from literature quantifying the difference in ankle moments between OA and YA populations (<3.03N/kg)[6].

Results

The model with lowest mean absolute error normalized by bodyweight (MAE) was the LSTM (MAE=1.20N/kg), followed by the transformer (MAE=1.23N/kg), LSTM with attention (MAE=1.26N/kg), and CNN-LSTM (MAE=1.69N/kg). All models had overall normalized MAE below our clinical threshold.

Discussion

Normalized model errors for predicted muscle forces being less than the clinically derived difference between OA and YA gait indicate these models can discriminate between those populations in a clinically relevant way. Their generalizability across healthy populations makes these models valuable tools for indirectly extracting muscle force information and establishes deep learning models as effective methods for getting more complete biomechanical data.

Pilot Study for THUMS Spine Model in Proximal Junctional Kyphosis Investigation

Mr. Chin Rhong Koh BEng (Hons)[1], Dr. Philip Purcell PhD[1], Dr. Stephen Tiernan PhD[1], Prof. Seamus Morris MB BCh BAO MMedSci MCh FSEM AFRCSI FRCS (Tr & Orth)[2]

[1]Technological University Dublin, Tallaght, Dublin, Ireland. [2]Mater Misericordiae University Hospital, Dublin, Dublin, Ireland

Introduction

Proximal junctional kyphosis (PJK) is a major postoperative complication following spinal deformity correction, with reported incidence rates as high as 61.7% [1]. Finite element analysis (FEA) is frequently employed to explore preventative strategies. However, published FEA studies exhibit substantial methodological inconsistencies, encompassing diverse modelling approaches, boundary conditions, and loading criteria. To address this lack of standardization, the present study aims to develop and validate a standardized FEA framework using the Total HUman Model for Safety (THUMS) for quasi-static analysis in the investigation of PJK mechanisms. A pilot study was carried out using the L3-L4 functional spinal unit (FSU) model from THUMS.

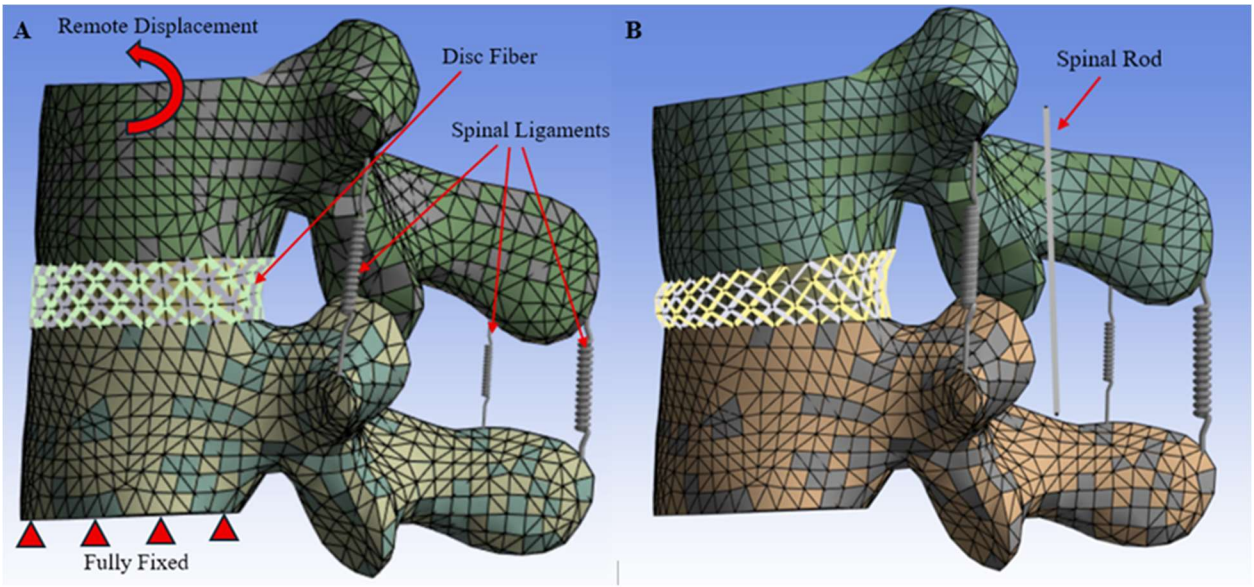
Methods

The L3-L4 FSU model was imported into ANSYS Mechanical 2024R1 with ligaments and disc fiber modelled as LINK180 tension-only elements (Figure 1A). Facet joint interaction was defined by frictionless contact with pure penalty formulation. The model was validated against THUMS published data.

After validating, the model was deformed by applying remote displacement (Figure 1A), and the deformed model was exported as base model for simulation with screws and rods modelled as simplified beam element remotely attached to the vertebrae (Figure 1B).

Results

The model was validated flexion-extension, compression, and lateral bending, which showed similar trends to results published by THUMS. However, the range of motion (RoM) for flexion was underestimated by 13%.



Furthermore, deformed FSU with spinal rods showed 40% reduction in RoM for flexion compared to deformed FSU without spinal rods.

Discussion

The underestimation of RoM in flexion could be partly attributed to overly stiff posterior ligaments. As the tension-only posterior ligaments play a more significant role in flexion. Simplified spinal rods modelled as circular beam elements remotely attached to vertebrae showed promising preliminary results, reducing the computational power required.

This ongoing validation framework will be carried out with longer T12-L5 spinal segment, and lastly the full spine column C1-S5 from THUMS, including rib cage. The realization of this framework will enable future investigations on optimizing spinal deformity correction surgeries to mitigate PJK risk, such as identifying the optimal fixation length and instrumentation devices.

Choosing a Back Support Exoskeleton From Among Different Designs: Considerations Related to Cumulative Spinal Loading, Muscle Fatigue, Physiological Strain, and Discomfort During a Repetitive Lifting Task

Dr Christian Larivière Ph.D.[1], Dr Étienne Goubault Ph.D.[1], Dr Guillaume Durandau Ph.D.[2], M. Hakim Mecheri M.Sc.[1], Dr Denys Denis Ph.D.[3], Dr Gabriel Diamond-Ouellette Ph.D.[4]

[3]Département des sciences de l'activité physique, Université du Québec à Montréal (UQAM), Montréal, Québec, Canada. [4]TOP-MED: Recherche et innovation en santé, Québec, Québec, Canada

Introduction

Warehouse and healthcare workers frequently develop back pain due to repetitive lifting tasks, yet conventional lifting training programs often fail to prevent it. Back-support exoskeletons (BSEs) may help by reducing muscle fatigue and spinal loading, but selecting the appropriate design is challenging because it depends on multiple criteria. This study aimed to compare three BSE designs (**Table**) based on different criteria.

Methods

Nineteen male participants completed five laboratory sessions: one for task/measurement familiarization and BSE assistance adjustments and four for testing randomized conditions (no BSE, BSE1, BSE2, BSE3). The task was 60-min symmetric lifting/lowering (7 cycles/min) of a crate from floor to hip height; the load set at 10% of lifting strength. Measurements included cumulative spinal compression (spinal shrinkage), muscle fatigue (static lifting strength; perceived fatigue using a Borg CR-10 scale), heart rate, and discomfort at BSE support points (shoulders, upper back, chest, pelvis, thighs). Data were analyzed using repeated-measures ANOVA, Tukey pairwise comparisons, and Hedge's *g* effect size (ES) estimates interpreted as negligible ($g < 0.20$), small (0.20 to 0.49), medium (0.50 to 0.79) and large (≥ 0.80).

Results

Spinal shrinkage (large ES) and reduced lifting strength (small ES) occurred during the 60-minute task ($P < 0.001$), but none of the BSEs mitigated these effects compared to the control condition (negligible to small ES). However, BSE2 significantly reduced perceived lower back muscle fatigue and heart rate (by 10–13 bpm) compared to other conditions ($P <$

0.01; medium to large ES). Overall discomfort ratings were acceptable, though BSE3 caused greater discomfort at the thighs and shoulders ($P < 0.05$; medium to large ES).

Discussion

The absence of BSE impact on spinal shrinkage and objective fatigue measures may reflect that these devices do not assist trunk extensor muscles throughout the full range of motion (e.g. standing and slight flexion). Conversely, subjective fatigue ratings suggest that BSE2 reduces low back muscle forces, as further supported by the decrease in heart rate. Discomfort with BSE3 likely stems from longitudinal forces transmitted to extremity supports (shoulders and thighs). These results may not generalize to females and to static or asymmetrical lifting tasks.

Images (Optional)

Table. Characteristics of the back support exoskeletons (BSEs)

BSE model:	**BSE1: UpLift Lite**	**BSE2: Laevo FLEX**	**BSE3: Biolift**

Toward Real-Time EMG-Informed Neuromusculoskeletal Modelling: Validation of a Differentiable-Physics Calibration Approach

Dr Matthew Worsey PhD, Mr Matthew Hambly Masters, BEng, Miss Yumei Sun Masters IT, AProf David Saxby PhD, AProf Laura Diamond PhD, AProf Claudio Pizzolato PhD

Griffith University, Gold Coast, Queensland, Australia

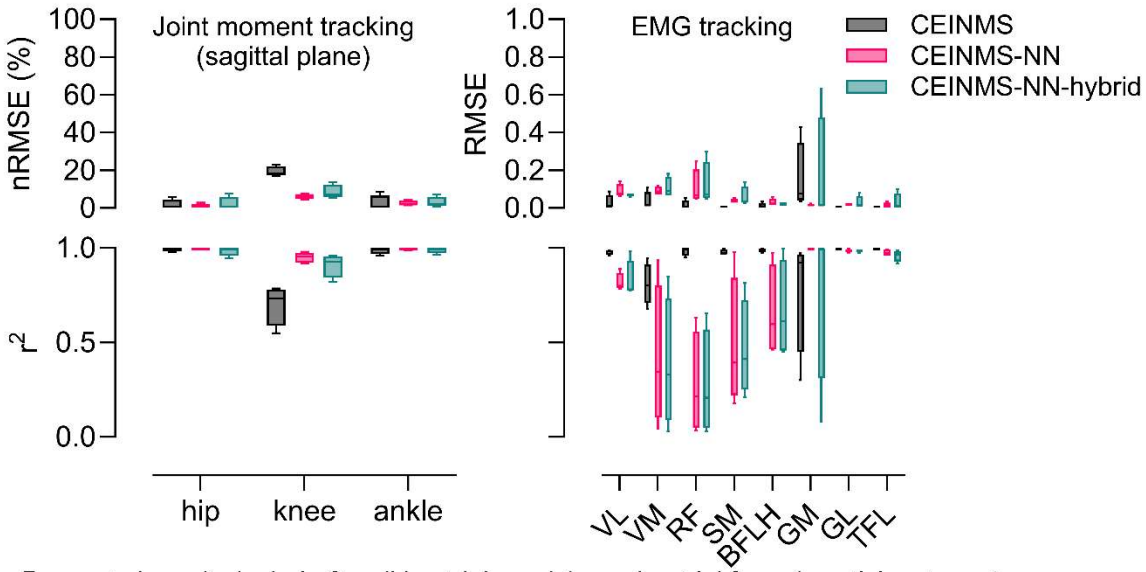
Introduction

Since the inception of calibrated electromyogram (EMG)-informed neuromusculoskeletal modelling [1], numerous calibration and execution strategies have been presented without comprehensive assessment of generalisability. We recently implemented an EMG-informed neuromusculoskeletal model using differentiable physics incorporating a Meyerhof-Hill-type muscle model and auto-differentiable elastic tendon (CEINMS-NN) [2]. We evaluated whether novel differentiable-physics calibration workflows achieve joint-moment and EMG tracking comparable to established workflows. We assessed three calibration methods: traditional CEINMS, CEINMS-NN, and CEINMS-NN-hybrid. Both traditional CEINMS and CEINMS-NN optimise excitation-to-activation and musculotendon parameters to match inverse-dynamics joint moments using recorded EMG signals; however, CEINMS-NN performs this optimization within a differentiable-physics framework. CEINMS-NN-hybrid synthesizes EMG for unrecorded muscles to improve moment tracking. All models were calibrated using identical optimization weights and executed using CEINMS EMG-assisted mode to evaluate whether the new optimization framework maintains tracking accuracy.

Methods

Fifty-two participants (n=52, 29.7±6.5 years, 45 females) performed 264 overground walking and 141 running trials while optical motion capture, ground-reaction forces, and EMG from eight knee-spanning muscles were recorded. Walking and running trials were processed to obtain joint kinematics, inverse-dynamics moments, musculotendon lengths, moment arms, and normalized EMG inputs for calibration (124 trials) and execution (281 trials).

Results



Models calibrated using the new optimisation framework achieved hip and ankle torque tracking comparable to the established CEINMS pipeline (Figure 1). Knee-moment tracking improved substantially with both CEINMS-NN variants relative to CEINMS. In contrast, EMG-tracking performance was lower for CEINMS-NN and CEINMS-NN-hybrid than for

CEINMS. Calibration times for CEINMS-NN and CEINMS-NN-hybrid were substantially reduced (21 seconds and 25 seconds respectively) compared to CEINMS (27 minutes).

Discussion

The differentiable-physics calibration improved knee moment tracking while maintaining comparable accuracy at the hip and ankle, albeit with reduced fidelity in reproducing recorded EMG. Optimisation of EMG-assisted execution weights could improve EMG tracking. Despite this trade-off, combining the novel calibration methods with traditional CEINMS EMG-assisted execution provided a practical and valid workflow. The substantially reduced calibration time supports future real-time applications and integration into CEINMS-RT, offering a fast and flexible alternative for EMG-informed neuromusculoskeletal modelling.

The Forward-Leaning Kinematic Adaptations Seen in Older Adults During Sit-to-Stand Movements seems to Reflect a Strategy to Reduce Hip and Knee Torques

Mr. Daehoon Kwon, Ms. Xiaofan Liu, Mr. Jingcheng Shi, Ms. Yiwen Bao, Prof. Francisco J. Valero-Cuevas

University of Southern California, Los Angeles, CA, United States

Mr. Daehoon Kwon

Ms. Xiaofan Liu

Mr. Jingcheng Shi

Ms. Yiwen Bao

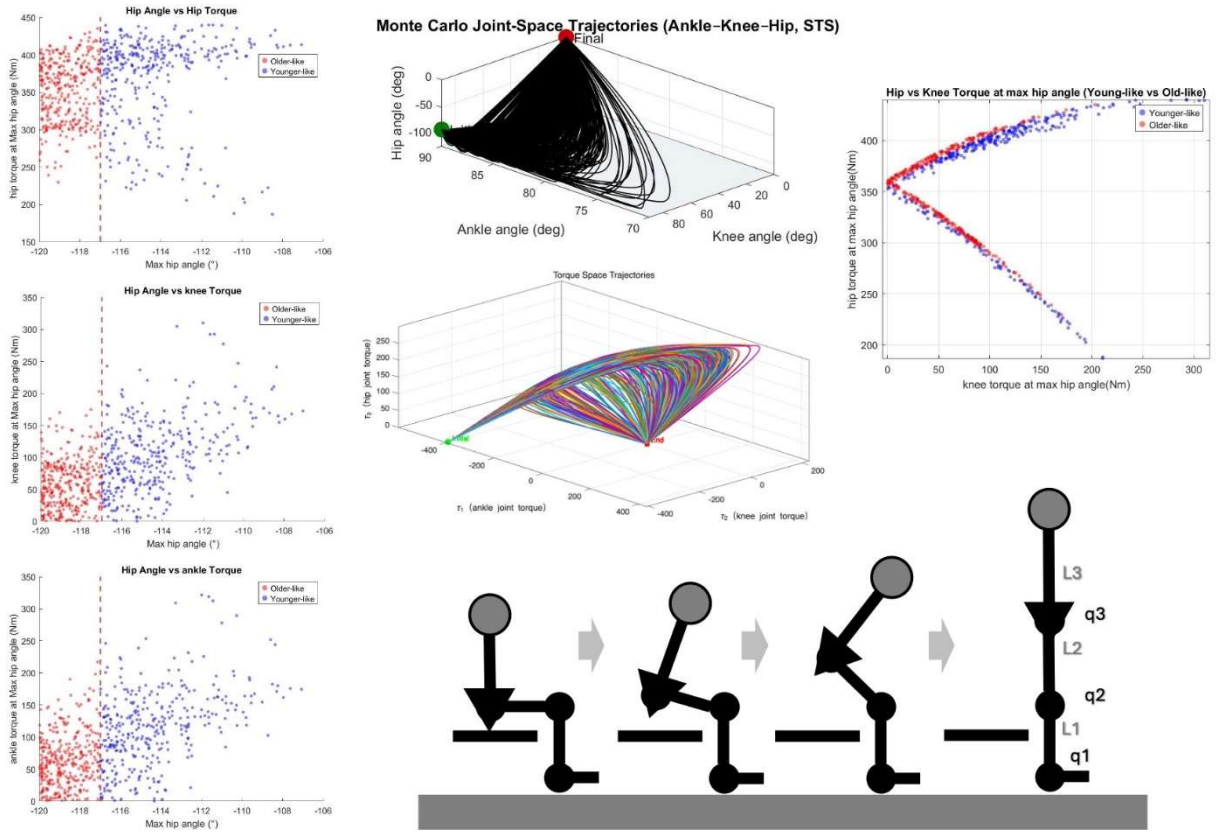
Introduction

Frailty in healthy aging, driven by sarcopenia, can make every day tasks such as sit-to-stand (STS) difficult. For example, older adults often adopt a forward-leaning, hip-flexed strategy during STS [1], but whether this is an adaptation to sarcopenia or to balance/vestibular comorbidities in ageing is not known. Using principles of mechanics [2], we tested whether the forward-leaning strategy reduces hip and knee joint torques, and is therefore an adaptation to sarcopenia.

Methods

We modeled the lower limb in the sagittal plane as a 3-DOF linkage with ankle, knee, and hip joints, and segment lengths followed 50th-percentile adult male anthropometry(L1, L2, L3), with the body weight, w, concentrated as a point mass on the torso [3]. This allowed us to calculate hip, knee and ankle torques as a vector τ for any posture q as $\tau = J(q)^T w$. Similar to [4] Monte Carlo simulations generated 1,000 reasonable STS joint trajectories from a same sitting posture to a target standing posture, via interpolated piecewise-cubic Hermite polynomials all within physiological limits. Those below and above the median

peak hip flexion were labeled “older-like” and “younger-like,” respectively. We then calculated hip and knee torques at maximum hip flexion angle.



Results

The group of older-like trajectories showed lower mean torques than the younger-like trajectories (t-tests, $p < 0.01$). At maximum hip flexion, older-like trajectories exhibited significantly smaller mean hip (≈352.5±41.7 vs 368.3±59.4 N·m), knee torques (≈59.1±38.04 vs 105.4±56.4 N·m) and ankle torques (≈63.99±41.07 vs 115.68±59.80 N·m). As strength decreases, high-torque, knee-dominant trajectories are eliminated first, leaving a narrow region of low-demand, hip-dominant solutions.

Discussion

We can conclude that hip-flexion patterns observed in older adults reflect an appropriate compensation to sarcopenia independently of other comorbidities in aging . Identifying such low-torque STS trajectories and muscle weakening that drives them can guide targeted strengthening, safer training, assistive-device design, and early-warning tools for functional decline.

Multi-Scale Modelling of Obesity-Driven Cartilage Degeneration in Subject-Specific Knee Joints

Mr Juntong Lai[1,2], Professor Damien Lacroix[1,2]

[1]Insigneo Institute, University of Sheffield, Sheffield, South Yorkshire, United Kingdom. [2]School of Mechanical, Aerospace and Civil Engineering, University of Sheffield, Sheffield, South Yorkshire, United Kingdom

Mr Juntong Lai

Introduction

Articular cartilage degeneration, a primary sign of osteoarthritis (OA), involves complex mechanobiological regulations at multi-scale. Excess adipose tissue resulting from obesity is not only associated with mechanical overloading but also with the regulation of OA inflammation. This subject-specific research aimed to investigate the subject-specific obesity effects on cartilage degeneration, using an advanced multi-scale modelling framework.

Methods

Three validated subject-specific finite element models [1] of the human knee joint were integrated into a multi-scale modelling framework to simulate the biomechanical and inflammatory effects of obesity on cartilage degeneration. S1-LTKN8941 and S2-LTKN1468 are two healthy left knees, in contrast to S3-RTKN0668, a right knee showing osteoarthritic changes on the lateral femoral cartilage. An axial knee force was scaled proportionally to BMI levels, representing repetitive loading at each iteration. The duration of each iteration was estimated by coupling variations in cartilage poroelasticity and inflammatory activities. To study the endotype of obesity-driven OA across subjects, cartilage degeneration was simulated for 5 years at different BMIs. The interquartile range (IQR) and distribution of the degeneration level were visualised.

Results

Obesity resulted in a more uniform distribution of the cartilage degeneration in S1, whereas degeneration in S2 and S3 was primarily localised to the lateral cartilage (Figure 1a). The median degeneration level of medial cartilage was 23.3% (IQR 23.1% - 25.3%) in S1 and 0%

in S2 at a normal BMI (Figure 1b). At a low BMI, the degeneration level was concentrated to 24.5% (IQR 23.3% - 28%) in the femoral cartilage of S3, compared to diverging degeneration in both S1 (IQR 12.8%-23.5%) and S2 (IQR 1.6%-23.5%).

Discussion

The variations in cartilage degeneration level and distribution demonstrate the subject-specificity of obesity-related OA, whereas a decrease in BMI can reduce overall degeneration. This study, for the first time, integrated the mechano-biological regulations of obesity to study the subject-specific cartilage degeneration, demonstrating a potential computational approach that can be individualised to assess the effectiveness of BMI reduction.

Evaluating Automatic Tracking to Determine Tibiofemoral Kinematics From Biplane Videoradiography

Miss Janine Flohr, Dr Lauren Swain, Prof Cathy Holt, Dr David Williams

Cardiff University, Cardiff, Wales, United Kingdom

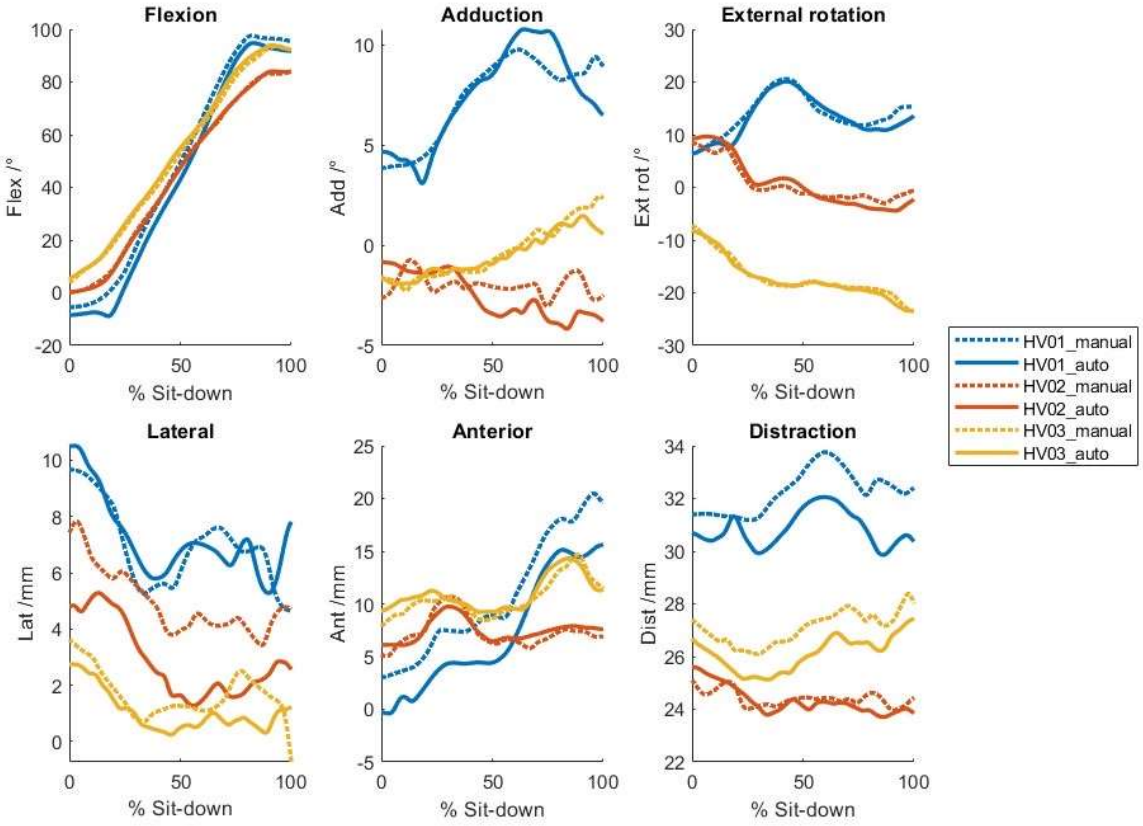
Introduction

Biplane videoradiography (BVR) is a method for deriving joint kinematics. Manual Image Registration (IR) involves aligning digitally reconstructed radiographs (DRRs) of bone geometry onto biplane radiographs and can take 20-40 hours per trial. An automated framework (Autotrack) was developed at University of Denver (DU) to register computed tomography (CT) geometry of the femur and tibia-fibula to biplane radiographs. This has been implemented at Cardiff University (CU) with magnetic resonance imaging (MRI) geometry. The current work aims to assess the accuracy of Autotrack at CU when compared to manual registration for three trials.

Methods

Autotrack's method is detailed in prior publication from DU [1]. At CU, three healthy participant's knees (PD Space) and whole leg (T1 TSE) were MRI scanned. Participants then completed BVR for a stand-to-sit (S2S) activity. Manual IR was performed using bone geometry in SlicerAutoscoperM. For Autotrack, the knee and whole leg were coregistered and merged to create one geometry with a fine resolution at the region of interest and a courser geometry at the diaphysis, proximal femur, and distal tibia-fibula. Both sets of 6-degree of freedom (6-DOF) kinematics were determined according to ISB recommendations and smoothed using a 10Hz low-pass Butterworth filter. Root-mean-square error (RMSE) was determined for the difference between the manual and Autotrack kinematics.

Results



Average RMSEs across participants were: flexion-extension 2.44mm; adduction-abduction 0.90mm; external-internal rotation 1.19mm; lateral translation 1.30deg; anterior translation 1.64deg; distraction translation 0.97deg. Figure 1 shows the kinematics throughout the S2S trial for each participant using both manual IR and Autotrack.

Discussion

Flexion-extension and anterior translation had the largest RMSE, likely due to flexion-extension being the largest rotation range and tibial anterior translation having the largest

translation range in the knee. Agreement between the tracking methods somewhat diverges towards the end of the trial, due to occlusion of x-rays caused by soft tissue. Additionally, the Autotrack training data has not previously included S2S trials, and there is likely scope for improvement when the model is retrained incorporating S2S and other new activities. Future work will be to increase sample size, expand activities, and include osteoarthritic patient data.

Comparison of Subjective and Objective Fatigue Responses to an Aerobic, Isometric, and Aerobic-Anaerobic Fatigue Protocol

Ms. Dveeta Lal Master's Student, Mr. Quinn Mulligan Master's Student, Dr. Timothy Burkhart Assistant Professor

University of Toronto, Toronto, Ontario, Canada

Introduction

Neuromuscular fatigue (NMF) may increase ACL injury risk by causing deleterious alterations in lower extremity kinematics that subsequently lead to increased strain on the ACL. However, there is conflicting evidence regarding this theory. Due to inconsistencies in the way fatigue has been induced and measured, drawing meaningful and consistent conclusions remains difficult. Consequently, the true role NMF plays in ACL injury risk, remains a point of contention. The purpose of this research is to assess three common methods of inducing NMF, and two methods of quantifying the onset of NMF, to determine if an optimal method exists.

Methods

26 healthy participants will be recruited and exposed to three fatigue protocols over two days: i) Aerobic – stationary bike task where participants increase resistance every five minutes (till 200W); ii) Isometric – sustained contraction (50%$_{max}$) of the quadriceps at 90º; and iii) Aerobic-Anaerobic – sets of five squat jumps and 30 seconds high-knees. Participants will continue each protocol until volitional fatigue (cannot sustain the protocol) or objective fatigue (determined through muscle activity). Bilateral sEMG data will be collected from three quadricep muscles, and the mean power frequency (MnPF) of the EMG signal, in response to a 50% MVIC contraction, will be monitored in real-time. A 10% decrease from baseline MnPF will indicate objective NMF. Participants' subjective rating of perceived exertion (RPE) will also be recorded, where a rating of 8+ indicates fatigue.

Results

Analyses from five participants revealed that objective NMF was achieved by 0%, 60%, and 60% in the aerobic, isometric, and aerobic-anaerobic protocols, respectively. Conversely, subjective fatigue was achieved by 60%, 70%, and 60% of the participants, respectively. Further analysis demonstrated that 40%, 50%, and 20% of the participants in the aerobic, isometric, and aerobic-anaerobic conditions, respectively, had matching subjective and objective fatigue outcomes.

Discussion

These preliminary findings demonstrate that fatigue responses varied quite substantially across the protocols, suggesting that fatigue protocols do vary in their ability to induce NMF. Additionally, agreement between subjective and objective fatigue measures was poor, suggesting that the RPE scale may not be a reliable measure and therefore cannot be used in place of a more objective measure like MnPF.

Rocky steps: The effect of loose surfaces on the kinetics of gait

Mr Dylan Mulligan MS, Dr Clare Milner PhD

Drexel University, Philadelphia, PA, United States

Introduction

Force plate-based studies of gait kinetics are typically conducted on level surfaces. However, different conditions may be encountered walking outdoors, such as unstable surfaces. Outdoor surfaces like loose rocks have greater force dispersal as the surface moves under the foot during walking. Determining how loose rocks affect kinetics may deepen our understanding of gait in real-world environments. The purpose of this study was to compare ground reaction forces (GRFs) while walking on loose rocks and level ground. We hypothesized that GRFs would decrease on loose rocks compared to level ground.

Methods

As part of an ongoing study, 5 healthy young adults provided written consent to participate (4 female, 1 male, age 23.4 (0.5) years, height 1.70 (0.05) m, weight 74.4 (13.8) kg). All procedures were approved by the Institutional Review Board. GRF data were sampled at 1000Hz as participants walked over level ground and loose rocks in sneakers. Level ground was instrumented with an embedded force plate. The loose rocks were instrumented with a portable force platform isolated within a 3.00x0.43x0.05 meter frame and covered with loose rocks. Data were processed in Visual3D and MATLAB, where GRFs were extracted for three steps per condition per participant. The GRF variables extracted were passive, active, braking, propulsive, medial, and lateral peaks. Vertical, braking, and propulsive impulses were also calculated. Effect sizes were used to evaluate differences, with large effects being considered meaningful.

Results

Loose rocks had a large effect on decreasing the magnitude of anterior posterior (AP) GRF variables as well as vertical impulse compared to level ground (Table 1). All other variables were similar on both surfaces.

Discussion

Loose rocks decreased GRF variables during walking particularly in the AP direction compared to level ground. GRF decreased because the applied force was dispersed through many moving loose rocks, primarily in the AP direction as the person progressed through the gait cycle. Vertical impulse also decreased as it is a summary measure representing the force dispersal over the entire stance phase. This instrumented loose rock obstacle design provides researchers with objective measurements of how loose surfaces affect gait kinetics.

Images (Optional)

Table 1: Mean and standard deviations of GRF variables on level ground and loose rocks. BW: Body Weight, SD: Standard Deviation

Allowing Metatarsophalangeal Motion Alters Intact Limb Knee Joint Loads During A Walking Simulation of an Individual with Transtibial Amputation

Dr. E. Daniel Syrett PT, DPT, PhD, OCS[1], Dr. Benjamin Darter PT, PhD[2]

[1]Central Virginia VA Hospital, Richmond, VA, United States. [2]Virginia Commonwealth University, Richmond, VA, United States

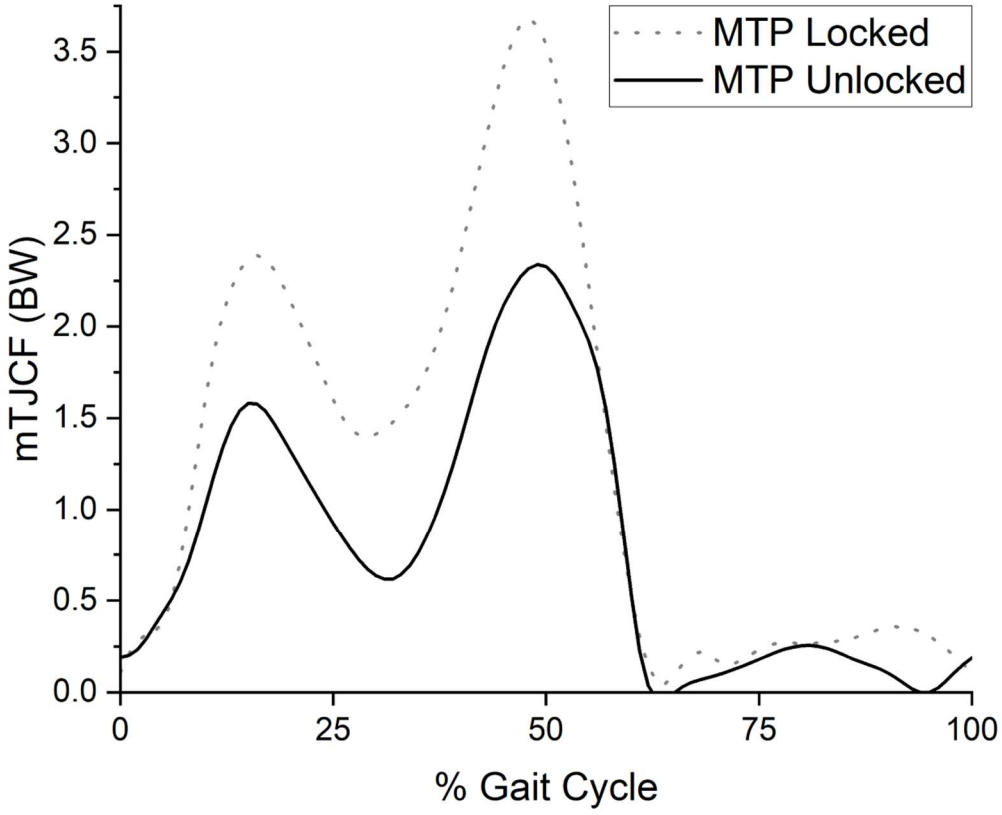
Introduction

Many researchers who perform muscle-driven simulations model the foot as a rigid lever, disallowing motion at the metatarsophalangeal (MTP) joints. However, permitting motion at this joint during simulations can alter variables which contribute to tibiofemoral joint contact force (TJCF) [1,2]. As TJCF is linked to knee OA [3], and those with lower limb amputation (LLA) have elevated intact knee OA risk [4], accurate TJCF estimates are critical. However, the effect of MTP locking on TJCF in LLA is unknown. This preliminary study examined how locking MTP joints affects TJCF in a tracking simulation of an individual with LLA.

Methods

Averaged treadmill gait data from one female with unilateral transtibial amputation (TTA, age 54, 59 kg, 1.7 m) drove two OpenSim Moco tracking simulations using a gait2392 model adapted for TTA [5]. Simulations used identical goals, weights, initial guesses, and tracking data. One allowed bilateral MTP motion (tracking 0°); the other contained welded MTP joints. Intact limb stance-phase medial TJCF (mTJCF) was normalized to body weight and compared using Pearson's *r*, RMSE, Sprague-Geers metrics, and qualitative peak/impulses differences.

Results



Kinematics and GRFs were similar between conditions. mTJCF patterns were also similar (Figure 1), though the locked MTP condition showed consistently higher stance-phase magnitude (r = 0.97, RMSE = 0.63 BW). Sprague-Geers: magnitude "poor" matching (0.55), phase "really good" matching (0.05). Peaks (BW): 1st - Locked 2.39 vs. Unlocked 1.58; 2nd - Locked 3.68 vs. Unlocked 2.34. Impulse (BW-s): Locked 1.15 vs. Unlocked 0.73.

Discussion

Preliminary results suggest locking the MTP increases stance phase intact limb mTJCF during walking simulations for an individual with TTA. Allowing MTP motion decreased the compressive force of the joint, likely due to power absorption occurring at the MTP joint [1]

and reduced gastrocnemius force during push-off [2]. Researchers should consider these effects when interpreting simulation-based estimates of knee joint loading.

Validity and Reliability of Theia3D, OpenCap and Marker-Based Motion Capture Systems in Evaluating Joint Angles and Body Segments Trajectories

M.Sc. Eleonora Bonelli[1,2], B.Sc. Cecilia Mazzola[1,2], Dr. Anna C. Render[2], Prof. Alessandro Colombo[1], Prof. Peter C. Fino[2], Dr. Cecilia Monoli[2]

[1]Politecnico di Milano, Milano, Italy, Italy. [2]University of Utah, Salt Lake City, UT, United States

Introduction

Marker-based motion capture is considered the gold standard in motion analysis, but it is limited by soft-tissue artifacts and other factors, such as time consumption and reliance on expert operators for subject preparation, and controlled environments. Recently, markerless systems have emerged to address these limitations. While many validation studies still use marker-based systems as a reference, both marker-based and markerless systems are prone to errors. This study aims to evaluate the performance of Theia3D, OpenCap, and Vicon in controlled tasks, using fixed joint angles and body segment distances as references.

Methods

In this IRB-approved pilot study, we simultaneously used a marker-based mocap system (VICON Nexus 2.16), and two markerless mocap systems – Theia3D and OpenCap. Two participants completed a series of tasks focused on feet, hands, and pelvis displacement. Afterwards, we analyzed major joints angles using fixed angles as objective reference: shoulder (flexion, abduction, rotation), elbow (flexion), hip (flexion, abduction, rotation), and knee (flexion).

Results

Our preliminary results (see Table 1) aimed to investigate the validity of the systems, as the Root Mean Squared Error (RMSE) between the mocap system outcome and reference measure, along with the reliability (Coefficient of Variation, CV) across multiple repetitions of each task. Overall, results are consistent across systems. Particularly when multiple body segments move simultaneously, isolating and assessing a single degree of freedom appears challenging (e.g., shoulder rotation, hip abduction and rotation). In some tasks, OpenCap's low RMSE may appear to indicate better accuracy, but it could actually result from incomplete tracking of complex movements (e.g., shoulder and elbow flexion, hip rotation). This highlights the need for additional trials.

Discussion

These preliminary results provide some of the first data comparing multiple markerless and marker-based motion capture systems, especially in the novelty of assessing their performance in reference to ground-truth constraints. Indeed, each mocap system uses a different model, introducing another source of error and making system comparison more challenging. Building on the results of this pilot study, our goal is to further investigate the simultaneous evaluation of different systems aiming to improve the robustness of the evaluation.

Virtual Mouse Twin to Predict Bone Adaptation Due to Pharmacological and Biomechanical Treatments for Osteoporosis

Prof Enrico Dall'Ara[1], Dr Sara Oliviero[1], Dr Bryant Roberts[2], Dr Saira Farage-O'Reilly[1], Dr Thomas Valerio[1], Dr Hector Manuel Arredondo Carrera[1], Dr Tegid Watkin[1], Mrs Jingzhi Zhang[1], Mrs Silvia Dirstaru[1], Dr Sanjay Singh[1], Dr Vee San Cheong[1]

[1]University of Sheffield, Sheffield, Yorkshire, United Kingdom. [2]University of Adelaide, Adelaide, South Australia, Australia

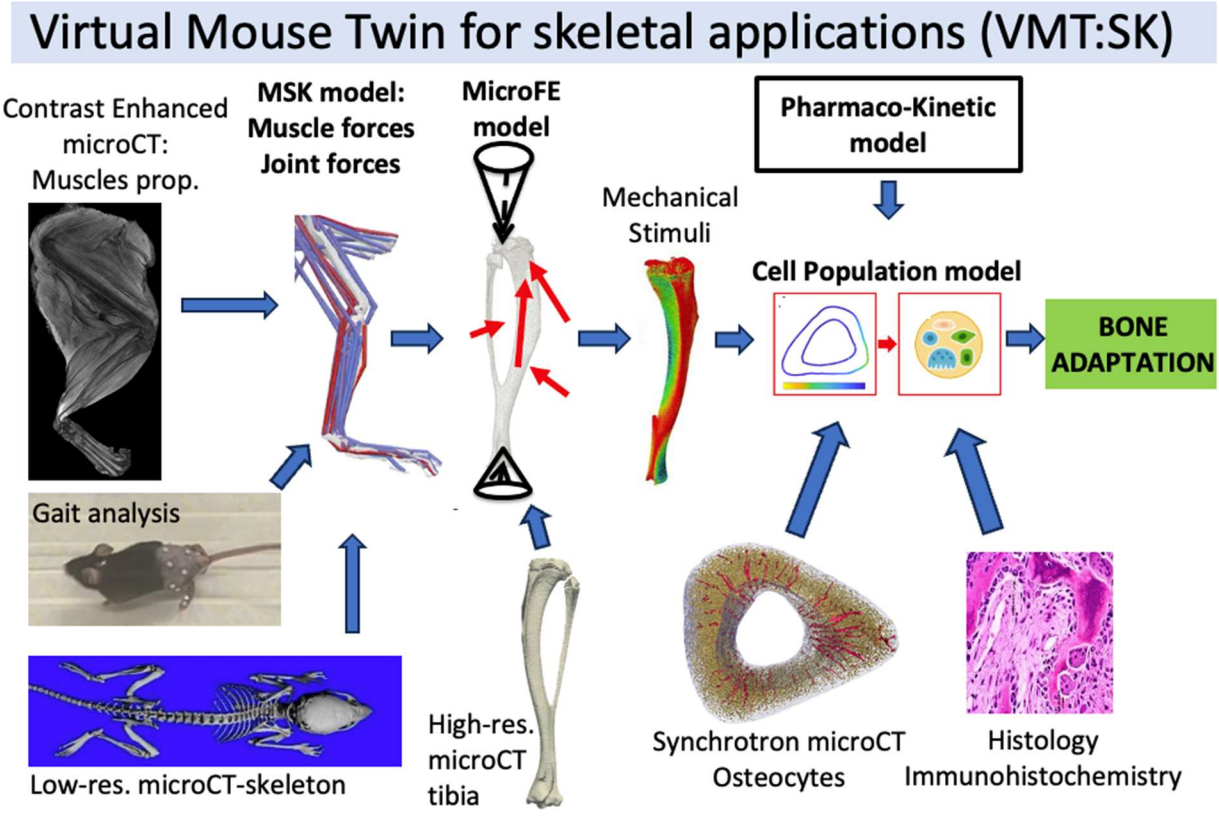
Introduction

Osteoporotic patients have lower bone strength and higher fracture risk. Combined biomechanical and pharmacological treatments have great potential but testing all possible combinations in animals is too expensive and unethical. The goal of this study was to develop and validate the virtual mouse twin for skeletal applications (VMT:SK), a multiscale computational model that predicts bone adaptation over time associated with osteoporosis treatments.

Methods

We developed pipelines to create micro-Computed Tomography (microCT) based micro-Finite Element (microFE) models that predict the mechanical properties of the mouse tibia *in vivo*. The models have been validated against compressive test performed on 20 mouse tibiae [1]. We evaluated the effect of mechanical loading and/or Parathyroid Hormone treatment on the bone strength for ovariectomised female C57Bl/6 mice microCT-scanned and treated between week 18 and 24 of age (total 30 mice, 3 time-points, N=6 per group) [2]. We developed mechano-regulation models to predict bone adaptation and compared their outputs to longitudinal microCT images [3].

Results



The microFE models predicted normalised compressive strength with errors of ~10-15% [1]. PTH alone or in combinations with mechanical loading increased bone strength by 15-20% and 19-31%, after 2 or 4 weeks of treatment, respectively [2]. The mechano-regulation models predicted well the tibia bone mineral content (no differences between predicted and measured values after 2 weeks of treatment; 4% differences after 4 weeks of

treatment) and the local bone formation (between 45% and 95%), but less well local bone resorption (below 40%) [3].

Discussion

The results, similar or better than those for the vertebrae, highlight that most bone formation is mechano-regulated. However, models should improve for bone resorption. The VMT:SK (Figure1) is being improved by: 1) defining realistic joint/muscle forces from multibody dynamics models informed by mouse gait analysis; 2) considering heterogeneous mechano-sensation and mechano-regulation informed by the distribution of osteocyte lacunae; 3) considering the biochemical signalling by adding cell population models informed by histology and immunohistochemistry.

The Impact of Normalization Method on the Interpretation of Surface Electromyography Signals in Dynamic Tasks

Mr. Evan Curd MSc, PhD (c), Ms. Margaret Harrington BSc, PhD (c), Dr. Timothy Burkhart PhD, Ms. Claire McLaughlin

University of Toronto, Toronto, ON, Canada

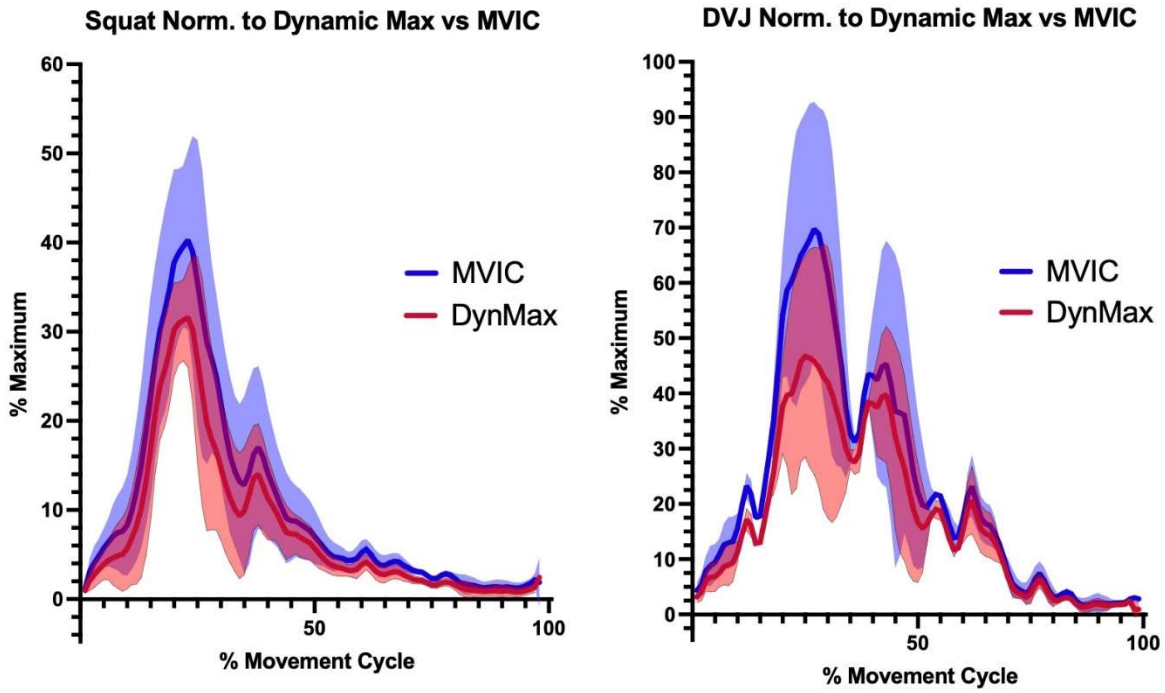
Introduction

Normalization of surface electromyography (sEMG), relative to an individual's maximal voluntary isometric contraction (MVIC), is a common signal processing method to reduce inter-individual variability in sEMG magnitudes. One limitation of MVIC, is participants may not be able to produce a true maximal activation voluntarily, potentially underestimating the true magnitude. This is demonstrated in dynamic tasks where supramaximal (>100%) activation levels are observed when normalized to MVIC. The purpose of this study is to assess the effect of four EMG normalization methods on sEMG amplitudes in response to dynamic tasks.

Methods

Recreationally active participants (18-29 years) were included. Four sEMG sensors (TrignoTM wireless system; Delsys Inc. Natick MA) were affixed over the muscle bellies of the rectus femoris, vastus lateralis, biceps femoris, and semitendinosus. The participants were instructed to perform four normalization methods: i) MVIC; ii) quiet-laying trial - participants laid on a table completely relaxed; iii) activated static baseline - participants stood static with their knees in minimal flexion; iv) dynamic maximum - participants performed three maximal squat jumps. The maximal (MVIC & dynamic max) or average (quiet & activated baseline) value was extracted from the three-trial means for each task. Participants were then instructed to perform two experimental tasks: i) body-weight squat; ii) drop-vertical jump (DVJ) three times. The experimental task signals were averaged across three trials and subsequently normalized to each discreet value from the normalization tasks. Only the rectus femoris results are presented here.

Results



Five participants have participated in this ongoing study. Activation was lower when normalized to the dynamic maximum when compared to MVIC in both experimental tasks (mean difference across signal, Squat: 5.7% ± 3.4; DVJ: 13.0% ± 7.2) (Fig. 1). Activated baseline scaled consistently to the quiet laying trial by a factor of 9 (mean factor across signal, Squat: 9.2 ± 0.2; DVJ 9.0 ± 0.4).

Discussion

The sEMG was overestimated when normalized to MVIC compared to dynamic maximum in both tasks. This observation supports the hypothesis that MVIC may not be ideal for dynamic task normalization. Although use of the MVIC optimizes comparisons between studies, groups, and conditions, it may be limited when used as a surrogate of true maximal muscle activation.

Exploratory Evaluation of Twitch-Based and Voluntary Fatigue Indicators During Sustained, Moderate-Load Isometric Contractions

Ms. Gahyun Lee, Ms. Jiwon Ryu, Mr. Cheoljae Lee, Prof. Gwanseob Shin

Ulsan National Institute of Science and Technology, Ulju-gun, Ulsan, Korea, Republic of

Introduction

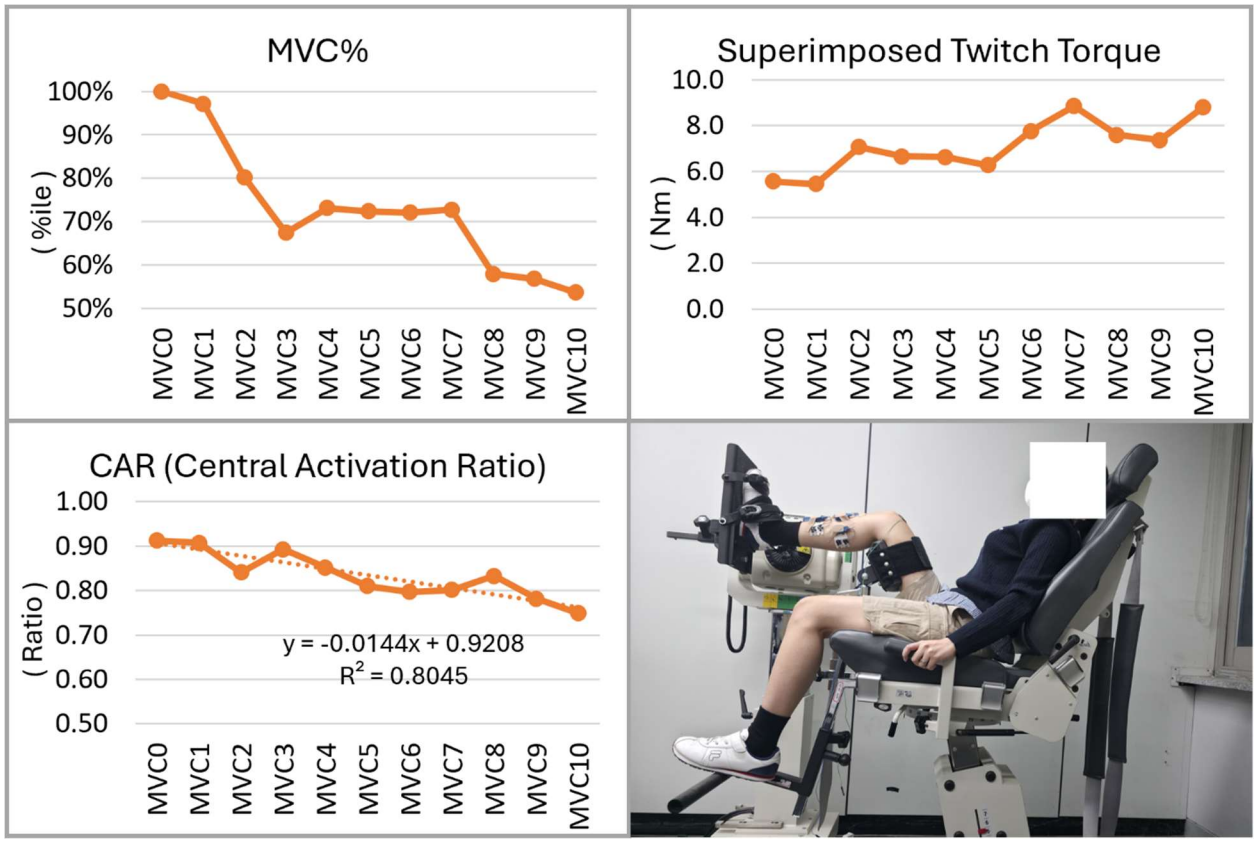
Fatigue during sustained, moderate-load tasks reflects combined central and peripheral mechanisms, yet commonly used measures—such as MVC reductions or EMG spectral shifts—mainly capture global or peripheral changes. Electrically evoked twitch-based indices, including superimposed twitch torque, the central activation ratio (CAR), voluntary activation (VA), and potentiated twitch torque, probe voluntary drive and muscle contractile properties. Their applicability under repeated, work-like loading remains insufficiently evaluated. This pilot study examined whether voluntary and twitch-based indices can detect central and peripheral fatigue during a sustained, submaximal ankle plantar-flexion task.

Methods

We evaluated fatigue-related changes across variables representing central (superimposed twitch torque, CAR, VA) and peripheral (potentiated twitch torque, EMG median frequency) mechanisms. Electrically evoked twitches were delivered to the posterior tibial nerve during MVC (superimposed twitch) and, for one participant, at rest (potentiated twitch). Surface EMG from six lower-leg muscles quantified spectral changes.

Participants first completed a baseline MVC with twitch responses. The fatiguing task consisted of repeated >40% MVC contractions inducing gradual fatigue. After each bout, twitch responses and MVC-based voluntary assessments were collected until MVC declined to ≤70% of baseline. Twitch-derived indices were analyzed only when stimulation and EMG quality met validity criteria.

Results



MVC torque progressively decreased in both participants, accompanied by reductions in EMG median frequency across most muscles. Participant A showed increasing superimposed twitch torque and decreasing CAR, indicating reduced central drive. Participant B exhibited inconsistent superimposed twitch and CAR responses due to unstable MVC during stimulation. Potentiated twitch torque, measured only in Participant

B, declined across cycles, suggesting peripheral contractile impairment. VA values for Participant B were unstable because of inconsistent twitch responses.

Discussion

Voluntary and twitch-based indices together captured distinct fatigue components during moderate-load, work-like plantar-flexion tasks. EMG spectral reductions and declining potentiated twitches reflected peripheral impairment, whereas increasing superimposed twitch torque and decreasing CAR suggested central fatigue when MVC stability was maintained. These findings highlight both the utility and challenges of twitch-based assessment under repeated submaximal loading. Maintaining stable MVC during stimulation is essential for reliable interpretation. Continued data collection is expected to improve feasibility evaluation and strengthen the robustness of twitch-derived indices in applied fatigue research.

Phantomless Calibration for the Estimation of Bone Strength in Paediatric Femora: Comparing Constant and Variable Currents

Mr George Allison[1,2], Mr Salman Almutairi[3], Professor Amaka C Offiah[3,2], Dr Xinshan Li[1,2]

[1]School of Mechanical, Aerospace & Civil Engineering, University of Sheffield, Sheffield, England, United Kingdom. [2]Insigneo Institute, University of Sheffield, Sheffield, England, United Kingdom. [3]School of Medicine and Population Health, University of Sheffield, Sheffield, England, United Kingdom

Introduction

Finite element (FE) analysis of paediatric bone based on retrospective computed tomography (CT) scans is restricted by the need for a density calibration phantom, limiting the amount of CT scans available for an under-researched population as clinical scans often use variable currents. This study aims to develop and validate a phantomless calibration technique to overcome this limitation and demonstrates its application in one child with rickets scanned with variable current.

Methods

Seventy anonymised post-mortem CT scans were obtained from Sheffield Children's Hospital, including 69 children (0-15 years old) with no known skeletal pathologies scanned with two constant currents (100kVp 60mA, 100kVp 100mA), and one 10-month-old child with rickets scanned with a variable current. Offline European Spine Phantom (ESP) calibration scans were available for all. Personalised material properties were determined based on Hounsfield units through two methodologies: (a) ESP calibration (MOD1) and (b) phantomless calibration using air, fat, and muscle peaks (MOD2) [1]. Using the PyPeCT2S pipeline, each model was subjected to four-point bending simulations, utilising two equidistant forces on the diaphysis and partially fixed ends.

Results

MOD2 calibration generally performs well against the MOD1 calibration when comparing predicted FE values as seen in Figure (1). In the infant subset of children there is negligible bias and consistent agreement at the lower predicted critical moment, while looking across the entire age range there were more pronounced differences for older cases. Many outliers trended in the negative region of the plot indicating that MOD2 generally predicted

lower bone strength estimates than MOD1. When the rickets case was predicted it saw a predicted difference of 40% with an over prediction in bone strength.

Discussion

Phantomless calibrations were comparable to phantom-based calibration, especially for younger children with no skeletal pathology scanned at a constant current. This included good performance on 6 children where the peaks were visually indistinguishable from one another. The variable current case remains an outlier. The preliminary results for constant current cases suggest that phantomless calibration could be used when no ESP calibration is present, however the inconsistencies need to be investigated further.

Estimating Ankle Plantar Flexor Muscle-Tendon Lengths Using Simplified Subject-Specific Bone Geometry

Ms. Georgia Hidson MSc Student, Dr. Lauren Welte PhD

University of Alberta, Edmonton, Alberta, Canada

Ms. Georgia Hidson

Introduction

Modelling muscle forces requires defined muscle-tendon-unit (MTU) paths on a bone model. While isometrically scaled, generic bones are commonly used due to their accessibility and affordability, subject-specific geometries derived from medical imaging are more accurate [1]. Open-source statistical shape models (SSMs) provide an accessible alternative method to generate individualized bones, but current approaches still require partial data from medical imaging or motion capture [2]. We investigated if reconstructing the tibia and fibula from one discrete measure using an SSM is sufficient to accurately model MTU lengths.

Methods

Tibia-fibula meshes (n=35, 22M, 13F), segmented from an independent set of MRI scans, were aligned and registered to the mean of an open-source SSM using Coherent Point Drift and Procrustes analysis [1,2]. Discrete measures were investigated for a linear correlation with the first principal component (PC) of the SSM (84% variation); the identified relationship between the tibia-fibula complex length and PC1 was used to score and reconstruct the sample meshes. Soleus, tibialis posterior, peroneus longus, and peroneus brevis MTU insertions were manually selected on the SSM mean. Corresponding points on the original and reconstructed bones mapped the MTU paths using an established wrapping algorithm [3]. The Jaccard index assessed volumetric similarity between original and reconstructed meshes. Paired t-tests evaluated differences in axial bone and MTU lengths.

Results

PC1 and the tibia-fibula complex length had a strong linear correlation (r^2=0.99, $p<0.05$). The average Jaccard index (mean±1sd) for the tibia and fibula was 0.72±0.06 and

0.48±0.11, respectively. The bone lengths between the original and reconstructed complex were not significantly different ($p>0.05$), whereas MTU length was significantly different for only the soleus and peroneus brevis fibres ($p<0.05$) (Figure 1).

Discussion

Agreement between the original and reconstructed bones lengths suggests that linear-regression-based reconstructions are suitable for creating subject-specific tibia-fibula bone models. However, geometric differences affect the soleus and peroneus brevis fibres that wrap closely along the bone. Therefore, improving volumetric similarity by reconstructing from multiple PCs that describe variation for the tibia and fibula individually may improve their MTU length estimations.

Estimating individual muscle forces during load sharing through an elastography-driven model

Dr. Gustavo Grinspan[1,2], Dr. Liliam Fernandes de Oliveira[3], Dr. Maria Clara Branda[3], Dr. Nicolás Benech[2]

[1]Biophysics and Systems Biology Section, Faculty of Sciences, University of the Republic, Montevideo, Montevideo, Uruguay. [2]Ultrasonic Acoustics Laboratory, Faculty of Sciences, University of the Republic, Montevideo, Montevideo, Uruguay. [3]Laboratory of Neurophysiology and Muscle Mechanics, Biomedical Engineering Program, Federal University of Rio de Janeiro, Rio de Janeiro, Rio de Janeiro, Brazil

Introduction

Estimating individual muscle forces is a long-standing problem in muscle biomechanics. In recent years, elastography has been proposed as a good alternative for such a purpose. By measuring the longitudinal shear elastic modulus (μ_L) at different joint torque (τ) levels, the relative longitudinal shortening (Δl) of individual muscles can be characterized by $C(\tau) = 1-(\mu_L(0)/\mu_L(\tau))$, being $C \propto \Delta l$ and $C \in [0, 1]$ [1]. Thus, this work proposes a model that, based on the $C(\tau)$ coefficients, allows the calculation of the individual muscle forces of the biceps brachii (BB), brachioradialis (BR), and brachialis (BA) muscles during their synergistic action.

Methods

We employed the $C_i(\tau)$ values reported in [1], derived from $\mu_{Li}(\tau)$ measurements in thirteen healthy volunteers using an Aixplorer ultrasonic scanner in SSI mode (i = BB, BR, BA). The protocol consisted of linear isometric elbow-flexion ramps from rest to 30% MVC over 15 s, with the elbow at 90° and the wrist supinated. The $C_i(\tau)$ coefficients were used to obtain input values for an optimization algorithm, which retrieves the corresponding $F_i(\tau)$ forces required to establish the static equilibrium across the elbow joint. Likewise, as $C_{BB}(\tau)$ described a sigmoidal curve, we calculate its inflection point ($C_{BB}^{\sim}$) through the Hill cooperative model [2].

Results

The $F_i(\tau)$ values ranged from 0 – 290.65 ± 52.99 N, 0 – 204.66 ± 37.42 N, and 0 – 211.40 ± 82.45 N, for BB, BR, and BA, respectively. These values stabilize the external elbow torque, yielding a net torque of zero. The $C_{BB}^{\sim}$ was found at 10.90 ± 4.92 % MVC.

Discussion

We found that for ~0-15% MVC, torque production is mainly due to the BA and BR, whereas for 10-30% MVC, it is mainly due to the BB. Thus, the C_{BB}~ ~10% MVC appears to be a load-sharing breakpoint between these muscles. This is in good agreement with previous studies [3], suggesting the present model can retrieve plausible $F_i(\tau)$ values regarding the load-sharing behavior between synergistic muscles.

Impact of Helical Fibres on Soft Bodied Animals: A Computational Model

Mr Harshil Pathak, Dr. Nilima Nigam, Dr. James Wakeling

Simon Fraser University, Burnaby, British Columbia, Canada

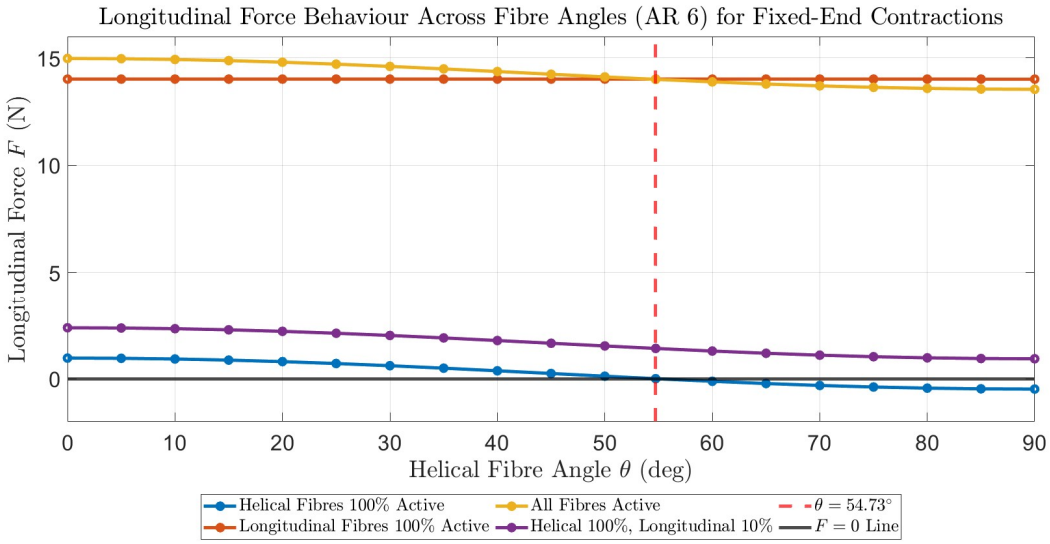
Introduction

Skeletal muscles can undergo large deformations over short timescales, driven by the nonlinear activation of muscle fibres. In many soft-bodied organisms, such as worms, these fibres are arranged in longitudinal, circular, and cross-linked helical patterns. Understanding how these architectures influence deformation motivates the development of computational tools that can represent realistic fibre configurations.

Methods

We use a three-dimensional finite element model to simulate elastic deformations in skeletal muscle. The model was implemented in our open source **Flexodeal** code [1], a finite element framework based on the Hill-type muscle model, capable of simulating both dynamic and quasi-static muscle contractions. We extend **Flexodeal** to incorporate spatially varying fibre orientations and nonuniform activation patterns, allowing us to represent helical and circular architectures. All simulations were carried out using a fully dynamic formulation that includes inertial effects and each simulation ramps the activation of fibres from 0% to 100%. We run four simulations: helical fibres 100% active; longitudinal fibres 100% active; both helical and longitudinal fibres 100% active; and helical fibres 100% active with longitudinal fibres 10% active. Each case is evaluated for helical angles ranging from 0° to 90°. We also use the 3D model to examine how strain energy varies with fibre angle.

Results



The results were insensitive to the aspect ratio (AR), defined as the ratio of cylinder length to radius. The longitudinal forces depended on the helical fibre angle ($\theta = 54.73^\circ$), and we observed a critical angle at which the longitudinal force dropped to zero for fixed-end contractions (shown in Figure).

Discussion

The numerical experiments reproduce deformation patterns that are consistent with physiological expectations for longitudinal, circular, and helical fibre arrangements. We found that the quantities we report are insensitive to aspect ratio, in contrast to the findings of Ellers et al. [2]. We also recover the same critical helical angle ($\theta = 54.73^\circ$), despite using

a nonlinear model with realistic muscle properties, consistent with the geometrical prediction of Clarke and Cowey [3].

Validation of an Innovative Kinematic Model for the Analysis of Spinal Deformations Considered as a Single Deformable Body (Case of Receiving a Right Knee Strike in Muay Thai)

Dr. Hassen LE SAGE HAKIM[1,2], Dr. Olivier NOCENT[2]

[1]ILEPS, Higher School of Sports and Teaching Professions; CY Cergy Paris University, Cergy, Île-de-France, France. [2]Performance Health Metrology Society laboratory (PSMS EA 7507), University of Reims Champagne-Ardenne, Reims, Champagne-Ardenne, France

Introduction

***Introduction*:** The aim of this study was to establish an experimental methodology to 3D movements analysis of the spine, which will be considered as a single deformable body. These analyses focus to study its local mechanical load during an impact.

Methods

***Methods*:** Two professional Nak-Muay of international level participated in this study. The receiver of the knee strike (P2) was equipped with markers placed: at the vertex, on the sixth cervical vertebra (C6), at the thoracic level (T1, T3, T5, T6, T7, T8) and at the lumbar level (L1, L3, L5). Markers were positioned on the anterior and posterior superior iliac spines to create a local landmark. A 16-camera optoelectronic system (Flex13, Optitrack; Motive Body software) was used to perform motion capture and analysis.

The most realistic polynomial reproducing the spine as a whole, from the origin of the local landmark to the vertex, is of degree 5. The plotting of the profile of the range of maximum voluntary amplitudes (MVA), describing the evolution of the so-called normal spinal curvatures, made it possible to scroll through all the curves of the curvatures of the polynomials representing the deformations of the spine following the knee strike.

Results

***Results*:** No overshoot in the cervical region. The curvatures were between K=1.3 and K=-2.4 for a range of MVA curvatures between Kmax≈5 and Kmin≈-7.5.

At the thoracic spine level, the maximum curvature obtained following the impact (K=8.13) exceeds the MVA (K=4.03) between T7 and T8.

The deformation of the lumbar region evolves outside the range of the MVA to reach its maximum value of K=22, compared to the corresponding point on the MVA, at the level of L5, K=3.74 (Fig.1a). The spine spends a total of 0.425 seconds outside its comfort zone.

Discussion

***Discussion*:** Our study allowed us to validate the biomechanical model of Ranavolo et al., (2013), representing the spine in its natural shape using a reduced number of markers. This validation enabled us to develop our own geometric reconstruction method dedicated to the three-dimensional monitoring of the entire spine as a single deformable body in order to determine its possible lesion behaviors.

Images (Optional)

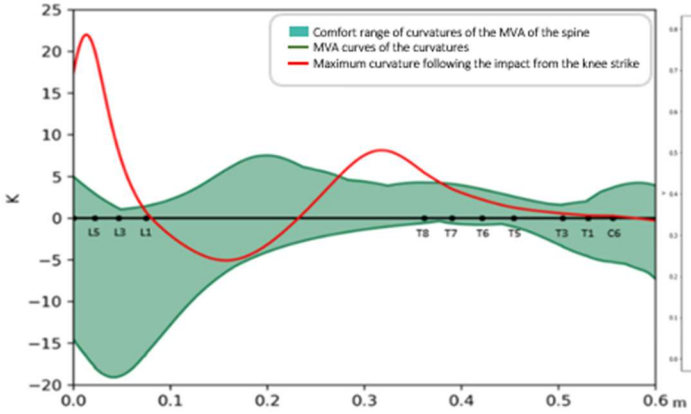

Fig1a: Maximum curvatures of the lumbar and thoracic rachis due to knee strike impact exceeding the range of MVA of movements in the sagittal plane expressed in local curvatures (K) calculated every millimeter over the different polynomials.

Impact of Viewing Volume Width on Gait Kinematics Captured With Markerless Motion Capture

Ms. Heather Li Yam Nam, Ms. Alyson Colpitts MASc, Dr. Elise Laende PhD

University of Waterloo, Waterloo, Ontario, Canada

Introduction

Markerless motion capture offers a simple and cost-effective solution to collect human kinematic data and opens up the possibility of performing motion capture in non-traditional, out-of-lab environments that may offer increased access to populations of interest but may have space limitations (e.g., narrow hallways). Site-specific differences in gait kinematics from markerless motion capture have been shown in previous work [1], but the effect of viewing volume width specifically has not been previously investigated. The objective of our study was to compare gait kinematics from two markerless motion capture configurations (narrow and wide) collected simultaneously to investigate the impact of viewing volume width on joint angles.

Methods

Two 8-camera (Sony RXOII) markerless configurations were set up to represent a narrow hallway (2.4 m wide) and wide space (7.7 m wide) in a single larger volume to permit concurrent data collections by both systems. Overground walking trials of 1 minute were collected and processed for 49 healthy participants using markerless motion software (Theia3D, version 2024.1.19). Kinematic event detection was performed in Visual3D and data were exported to R for further analysis. Mean joint waveforms were plotted for both configurations and root mean square differences (RMSD) across waveforms were calculated for all planes.

Results

Group mean knee joint angle waveforms in all planes generally show good agreement, but offsets in the sagittal plane between the narrow and wide configurations (Figure 1). RMSD values were 6.4 degrees in the sagittal plane, 3.2 degrees in the frontal plane, and 3.0 degrees in the transverse plane for the knee joint angles.

Discussion

Our results compare favourably to previously reported values for marker-based motion capture (mean offsets between multiple marker-based motion capture sites of 11 degrees in the sagittal plane and 4 degrees in the frontal plane [2]). Future work will investigate intermediate widths to identify viewing volume limits and investigate mitigation measures, such as adding additional cameras. We anticipate future outcomes will further advance the standardization of data collection protocols and reporting to facilitate high quality data for multi-centre research.

A Multimodal View on Chronic Low Back Pain: Integrating Structure, Movement and Mechanics Across Disciplines

Prof. Dr. Hendrik Schmidt[1], Prof. Dr. Sara Checa[2], Prof. Dr. Matthias Pumberger[1], Dr. Ulrike Grittner[1], Prof. Dr. Adamantios Arampatzis[3], Prof. Dr. Lena Fleig[4], Dr. Özgür Celik[1], Prof. Dr. Georg Duda[1], Dr. Sandra Reitmaier[1]

[1]Charite-Universitaetsmedizin Berlin, Berlin, Berlin, Germany. [2]Hamburg University of Technology, Hamburg, Hamburg, Germany. [3]Humboldt-Universität zu Berlin, Berlin, Berlin, Germany. [4]Medical School Berlin, Berlin, Berlin, Germany

Introduction

Chronic low back pain (cLBP) remains one of the most prevalent and costly musculoskeletal disorders, yet its underlying drivers are incompletely understood, limiting the development of targeted diagnostics and individualized treatments. To address this, our Research Unit, bringing together biomechanists, human and veterinary clinicians, biologists, psychologists, computational engineers and data scientists, investigated how structural alterations, movement behavior and mechanical loading interact in cLBP onset and persistence.

Methods

Here, we summarize key insights from the first four years of coordinated research.

Results

Population-based multimodal investigations on 2,500 individuals with and without cLBP revealed consistent associations between lumbar disc degeneration, particularly at L5/S1, paraspinal muscle degeneration, reduced functional and constrained multi-planar lumbar mobility. Individuals with cLBP exhibited fewer distinct habitual postures during daily life, reduced lumbar lordosis, smaller segmental excursions and diminished movement variability, reflecting protective or pain-avoidant motor patterns. These adaptations often extended beyond the lumbar region into thoracic and pelvic regions. Psychosocial factors, including kinesiophobia and reduced physical/mental well-being, further shaped these structural–functional patterns, while inactivity amplified pain and disability. The consortium applied diverse methodologies, including linear mixed models, PCA-based movement analyses, machine learning, finite-element simulations, and controlled animal experiments, yielding heterogeneous statistical bases. Specific numerical results are omitted for clarity; detailed quantitative outcomes will be presented at the WCB. Still, two overarching trends emerged: (i) diagnostic models based solely on routine clinical

assessments achieved ~60% accuracy, whereas (ii) inclusion of dynamic measures of muscle activity, real-life motion profiles, and segmental loading increased accuracy to ~70%, highlighting the value of functional and mechanical information.

Mechanistic studies supported this interpretation. In a controlled sheep model, nucleotomy induced early hypomobility and increased neuromuscular stabilization rather than hypermobility; finite-element simulations confirmed rapid restoration of segmental stiffness under complex loading. Mouse tail-loading demonstrated that mechanical overload triggers bone and marrow remodeling and alters inflammation-related receptor patterns.

Discussion

Taken together, these four-year findings advocate a shift from predominantly structure-focused evaluation toward a dynamic, biopsychosocial understanding of cLBP. Our findings emphasize the need for diagnostic strategies that integrate muscular function, compensatory movement behavior and psychosocial variables to prevent chronification and improve clinical outcomes.

An Optimized Hinge Joint Approximates the 3D Motion of the Walker Knee

Mr. Jacob Foster MS BIOE, Dr. Reed Gurchiek PhD

Clemson University, Clemson, South Carolina, United States

Introduction

The Walker knee model is commonly used in gait analysis for its ability to capture 3D knee motions (flexion, valgus, and internal rotation). However, only the flexion angle parameterizes joint configuration wherein knee valgus and internal rotation follow a prescribed relationship with flexion. Such a motion could result from rotation about a single axis. In this study, we aimed to identify said axis toward a hinge joint approximation to the Walker knee. This would reduce computational cost by removing the need to calculate knee valgus and internal rotation.

Methods

We simulated flexion of the Walker knee (1-120 degrees) using the RajagopalLaiUhlrich2023 OpenSim model. To determine the single axis of rotation which best approximated the 3D motions of the Walker knee across all configurations, we solved a constrained optimization problem. The three components of the axis and the rotation about said axis for each configuration were the decision variables and the axis was subject to a unit-length constraint. The cost function quantified the angle of the error rotation matrix. We quantified error in this approximation using the average angle of the error rotation matrix and the root mean square error (RMSE) of the flexion, valgus, and internal rotation angles.

Results

The optimal axis was slightly anterior and superior to the Walker knee flexion axis in the neutral configuration. Modeling the knee as a hinge joint using this axis approximated the 3D motion of the Walker knee to within 2.67 degrees (average rotation angle of the error matrix) and 0.49, 1.59, and 2.49 degrees RMSE for flexion, valgus, and internal rotation angles, respectively. This approximation was superior to a naïve approximation based on the flexion axis of the Walker knee in the neutral configuration which yielded over 15 degrees RMSE for the internal rotation angle.

Discussion

Our results demonstrate the feasibility of approximating the 3D motions of the Walker knee model with a hinge joint given an optimized hinge joint axis. A better approximation for gait models could be made by optimizing over a reduced knee range of motion (e.g., 90 instead of 120 degrees). Future work should assess effects on relevant muscle moment arms.

Influence of the Residuum–Socket Interface on Hip Joint Loading in Individuals with Transfemoral Amputation

Ms. Jacqueline Sammel, Mr. Mitchell Ekdahl, Dr. Brecca Gaffney

University if Colorado Denver, Denver, CO, United States

Introduction

Individuals with transfemoral amputations (TFA) have an increased risk of hip osteoarthritis (OA), commonly attributed to asymmetric joint loading. Standard methods for quantifying dynamic joint loading commonly use rigid body link-segments models. However, previously developed TFA models assume the residuum-socket interface (RSI) as rigid, ignoring soft-tissue compliance and potentially altering calculated joint loading. Recent work introduced and validated the kinematics within a musculoskeletal model permitting six degrees of freedom (6-DOF) at the RSI for individuals with transtibial amputations, but the RSI's effect on estimated muscle-driven joint reaction forces (JRFs) during walking remain unknown. Our objective was to determine the influence of modeling the RSI joint on hip JRFs in individuals with TFA during walking.

Methods

Motion capture data was collected from 13 adults with unilateral TFA (6M/7F, Age: 54±15.9 yr, BMI: 28.3±4.6 kg/m^2) during overground walking. For each participant, two subject-specific models were created: (1) a model with a 6-DOF custom femur-socket joint allowing for RSI motion and (2) a rigid model with no RSI motion. Muscle forces were computed via static optimization and used to estimate hip JRFs (normalized to bodyweight (BW)) during the stance period. Temporal comparisons of hip JRFs were made between models via one-dimensional statistical parametric mapping. Discrete comparisons of peaks and impulse JRFs (positive and negative) were compared using paired t-tests (α=0.05).

Results

There were no temporal differences for hip JRFs between model types throughout the stance phase (Figure 1). Maximum medial JRF was larger in the rigid model than the RSI model ($p<0.017$, RSI:0.78 ±0.38 xBW ; Rigid:0.82 ±0.40 xBW).

Discussion

Allowing RSI motion did not significantly influence amputated limb hip JRFs compared to the rigid model, suggesting that small interface motions at the residual limb do not alter

time-continuous hip JRFs estimated from link-segment models during level walking. These results are relevant when considering how to account for soft-tissue compliance dependent upon suspension type. For example, when examining joint loading differences with a rigid fixation prosthesis (e.g., bone-anchored limb) and a socket-prosthesis, incorporating motion at the residuum-socket interface is negligible.

Images (Optional)

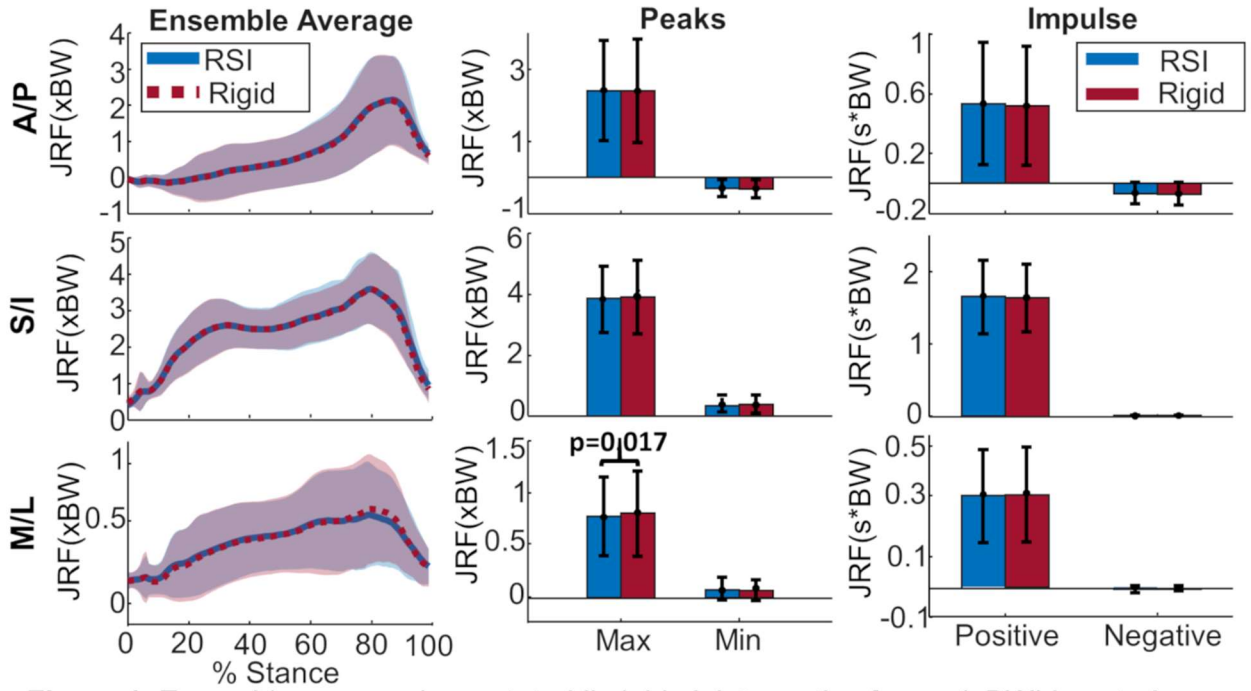

Figure 1. Ensemble-averaged amputated-limb hip joint reaction forces (×BW) in anterior–posterior (A/P), superior–inferior (S/I), and medial–lateral (M/L) directions comparing RSI (blue) and rigid (red) models during stance, with corresponding group mean (±SD) peaks and positive/negative impulses.

Finite Element Models of the Proximal Tibia Accurately Predict Internal Bone Displacements and Reaction Forces

Mr Dylan Zaluski MSc, Dr Saija Kontulainen PhD, Dr James (J.D.) Johnston PhD

University of Saskatchewan, Saskatoon, Saskatchewan, Canada

Introduction

Subject-specific finite element (FE) models of bones, with geometry and material properties measured via quantitative computed tomography (QCT), are a valuable tool for studying the role played by bone mechanics in joint diseases like osteoarthritis. Previous QCT-based FE models (QCT-FEMs) of the human tibia have been validated for surface phenomena (strain, stiffness); however, the validity of these models for internal bone deformation has not yet been reported. The objective of this study was to validate QCT-FEMs of the proximal tibia against both internal bone displacements and external reaction forces.

Methods

Five embalmed human tibiae were mechanically tested inside a high-resolution peripheral QCT (HR-pQCT) scanner during imaging (0.041mm isotropic voxel). Compressive loads were applied to individual medial and lateral tibial compartments using a Zwick electro-mechanical testing system in steps of 0.5, 1.0 and 1.5mm (max load: 10kN). Internal displacement fields were measured using LaVision digital volume correlation (DVC) software. HR-pQCT scans were down-sampled to simulate clinical CT (0.5mm voxel), segmented and meshed to create QCT-FEMs with linear hexahedral elements. Each element was assigned elastic moduli (E) (isotropic and anisotropic) proportional to its bone-mineral density (BMD) using various sets of trabecular and cortical density-modulus relationships (E-BMD) from the literature. Displacement boundary conditions were applied to the loaded surfaces by interpolating DVC measurements. A custom element-by-element solver was used to predict nodal displacements and reaction forces. Root-mean-square error (RMSE) was used to quantify the accuracy of FE-predicted compared to experimentally-measured internal bone displacements (~280,000 measures) and global reaction forces (30 measures).

Results

The accuracy of predictions of internal bone displacements was relatively insensitive to the selected E-BMD relationships (Table 1 includes a sample of min/max results). External reaction forces exhibited considerably greater variability with selected E-BMD.

Discussion

Predictions of internal bone displacements were acceptably accurate for all tested E-BMD (RMSE less than 4.3%). FE-predicted reaction forces had greater variability, with the Nazemi et al approach offering the lowest error (11.8%). The results presented here expand upon previous QCT-FE validation studies of the proximal tibia by validating predictions of internal bone mechanics, finding these models to be suitably accurate for modeling proximal tibial mechanical behavior.

Kinematic Coupling Constraints Create Physiological Motions for OpenSim Musculoskeletal Models but Change Muscle Moment Arms Which Compromise Muscle Forces and Joint Loads

Dr. Jeffrey Reinbolt Ph.D.[1], Dr. Anita Vasavada Ph.D.[2]

[1]University of Tennessee-Knoxville, Knoxville, TN, United States. [2]Washington State University, Pullman, WA, United States

Introduction

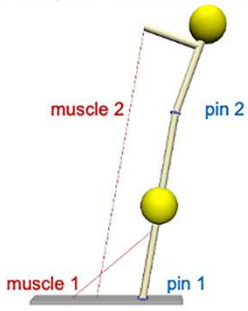
Musculoskeletal models require physiological kinematics of multiple bodies, many of which cannot be tracked directly. Kinematic couplings between bodies (*e.g.*, "spinal rhythm" for vertebral kinematics) are implemented in OpenSim using CoordinateCouplerConstraints to effectively apply non-physiological loads constraining the kinematics to follow physiologically-based mathematical relationships. We evaluated two models, a simple double pendulum and complex cervical spine (Figure a), to determine how kinematic constraints affect computed muscle forces and joint loads.

Methods

Both models had unconstrained and constrained versions created, simulated, and analyzed in OpenSim 4.3. The double pendulum had 2 joints and 2 muscle-tendon units (uniarticular and biarticular). The cervical spine had 9 joints and 82 muscle-tendon units (uniarticular and multiarticular). For kinematic constraints, a generalized coordinate represented the overall flexion-extension angle, and each joint angle was constrained to a defined percentage of the overall angle. The coupler constraint acts as a gear ratio defining relative motion of the bodies (Figure b). The effects of kinematic constraints were compared across: net joint moments from inverse dynamics, muscle forces from static optimizations, muscle moment arms from muscle analyses, joint loads from joint reaction analyses, and constraint loads from force reporter analyses.

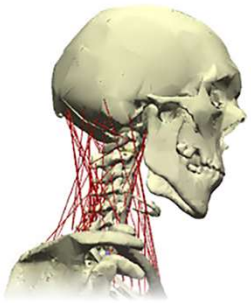
Results

Without constraints, joint and muscle moments were equal with uniarticular muscle forces contributing the most (Figure c). With constraints, muscle moments using geometric moment arms changed in different directions because the forces decreased in the uniarticular muscles but increased in multiarticular muscles. The moment changes were perfectly offset by their respective constraint loads so that their sum matched the net joint moments. However, muscle moments using muscle analysis moment arms increased due to greater moment arms for all muscles because of kinematic constraints, and the sum



with constraint loads no longer matched the net joint moments. Including constraints changed the joint loads.

Discussion



Muscle forces, moments, and joint loads changed when kinematic constraints were included in models. Constraints led to higher forces in multiarticular muscles because of kinematic couplings. These couplings increased moment arms when calculated by the "effective torque" method used in OpenSim. Kinematic constraints should only be used to define physiological motion, not when computing loads.

Comparing Pose Estimation Models for Reconstructing Three-Dimensional Joint Centre and Anatomical Landmark Positions in Markerless Gait Analysis

MR. Wenfeng Zhang[1], MR. Jeng-Heng Lin[1], MS. Tsai-Ling Lin[1], MR. Cheng-Hao Yu[1], Prof. Ting-Ming Wang[2], Prof. Tung-Wu Lu[1]

[1]National Taiwan University, Taipei, Taiwan, Taiwan. [2]National Taiwan University Hospital, Taipei, Taiwan, Taiwan

Introduction

Traditionally, gait analysis requires placing infrared retroreflective markers on anatomical landmarks and tracking their three-dimensional (3D) trajectories using stereophotogrammetry. Although this approach can accurately reconstruct the motions of body segments during walking, the requirement for markers restricts its use to laboratory settings and often alters natural movement patterns. With recent advances in human pose estimation (HPE) techniques, tracking anatomical landmarks from RGB videos offers a promising alternative, but their accuracy remains unclear. This study aims to compare different HPE models for reconstructing 3D joint centre and anatomical landmark positions during gait by evaluating their accuracy against the data obtained using a marker-based motion capture system.

Methods

Twelve participants walked while their movements were recorded using eight synchronised RGB cameras. Three HPE models (i.e., Mediapipe, MMPose, and OpenPose) were used to extract two-dimensional locations of lower-limb joints from videos, and the corresponding 3D joint centre positions were reconstructed using the direct linear transformation algorithm. The 3D positions of anatomical landmarks for each lower-limb segment were then estimated using a recurrent neural network [1] based on the predicted joint centre positions. The reconstruction accuracy was quantified using the root-mean-square error relative to ground truth obtained from a marker-based stereophotogrammetry system. A Kruskal-Wallis test was conducted to compare reconstruction errors across models and body parts, with Friedman tests used for post-hoc comparison.

Results

OpenPose and MMPose showed significantly lower reconstruction errors on the joint centre than MediaPipe, with the hip joints exhibiting significantly larger errors than the other lower-limb joints (Table 1). Compared to MMPose, OpenPose showed significantly lower reconstruction errors for anatomical landmarks on the pelvis, shank, and foot, with

those on the pelcis segment exhibiting significantly larger errors than those on the other segments (Table 1).

Discussion

This study provides a systematic evaluation of the accuracy of HPE models in reconstructing 3D positions of joint centres and anatomical landmarks during gait. The OpenPose models yielded reconstruction errors lower than those of MediaPipe and MMPose, but all remained at the centimetre level, indicating a continued need for more accurate HPE models for markerless gait analysis.

[3]Roth McFarlane Hand and Upper Limb Centre, London, Ontario, Canada. [4]Department of Mechanical and Materials Engineering, Western University, London, Ontario, Canada

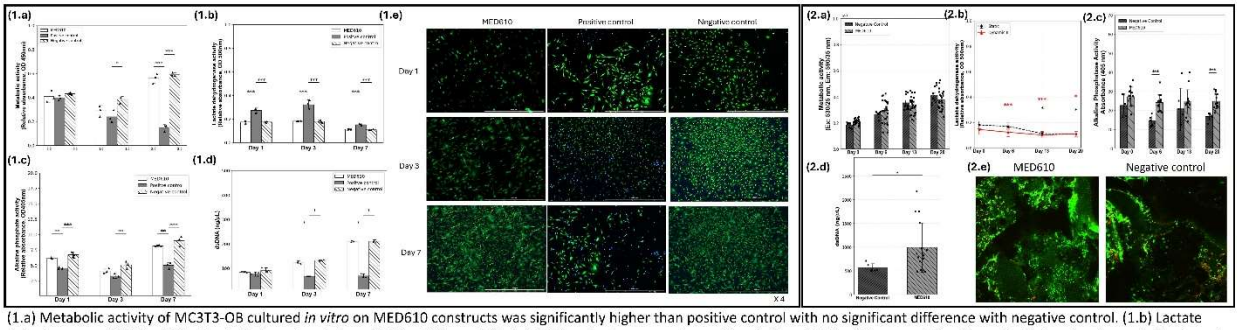
Introduction

3D printing enables fabrication of highly customized, patient-specific biomedical devices [1]. MED610, a biocompatible photopolymer, may pose cytotoxic risks from residual printing materials, limiting its use in cell and tissue culture [2]. This study evaluated the cytocompatibility of 3D-printed MED610 constructs for in vitro and ex vivo applications.

Methods

Disks (n=18,Ø15×2mm) and custom bioreactor components were 3D-printed using MED610. Differentiated osteoblasts (MC3T3-OB) were seeded at 20,000 cells/mL on MED610 disks, with negative (NEG, untreated) and positive controls (POS, 2%ethanol) under osteogenic condition [2]. Human osteoarthritic trabecular bone cores (Ø9.15±0.14 × 9.5±2.0 mm, n=16) from four arthroplasty patients were cultured in bioreactors for 21 days, with negative controls cultured in 6-well plates (NEG, n=6). Osteogenic, metabolic, and genomic activity (dsDNA), along with lactate dehydrogenase (LDH) levels, were assessed to quantify differentiation, viability, proliferation and cytotoxicity of bone cells *in vitro* (Days 1, 3, 7) and *ex vivo* (Days 0, 6, 13, 21).

Results



Metabolic activity of MC3T3-OB on MED610 was significantly higher than in the POS (85%viability) and lower LDH level indicating 15% cytotoxicity(fig.1.a-e). Osteogenic activity, measured via alkaline phosphatase (ALP), was significantly higher on MED610 and the NEG compared to the POS. Total dsDNA content also increased significantly on MED610 relative to the POS. Perfused bone tissue in the bioreactor exhibited a significant increase in metabolic activity over the 21-day culture period, comparable to NEG (fig.2.a-

d). ALP levels were elevated in perfused tissue, while LDH levels decreased over time and were similar to the NEG. dsDNA content was significantly higher in perfused tissue.

Discussion

These preliminary results indicate that MED610 is a cytocompatible material. MC3T3-OB cells cultured on MED610 showed enhanced metabolic and osteogenic activity as evidenced by higher ALP activity and increased dsDNA. Perfused bone tissue also showed increased viability over the 21-day of culture, supporting the biocompatibility of MED610 for tissue culture application. Future work will assess osteoclast activity and characterize the material properties of MED610 constructs to further optimize their design for cell culture applications.

Images (Optional)

(1.a) Metabolic activity of MC3T3-OB cultured *in vitro* on MED610 constructs was significantly higher than positive control with no significant difference with negative control. (1.b) Lactate dehydrogenase (LDH) activity, (1.c) alkaline phosphatase (ALP) activity, and (1.d) dsDNA content measured over Days 1, 3, and 7. (1.e) Representative live cell staining showing cell attachment, viability and proliferation of cells cultured on MED610 (Calcein AM, green: live cells; DAPI, blue: nuclei of dead cells).
(2a-e) Human trabecular bone cores *ex vivo* cultured in 3D-printable MED610 bioreactors for 21 days. Measurements of (2.a) metabolic activity, (2.b) LDH level, (2.c) ALP activity, (2.d) dsDNA content, and (2.e) representative confocal images of live (Calcein AM, green) and dead (Deep Red, Red) staining indicate that MED610 supports bone tissue viability, proliferation, and osteogenic function. Data are presented as mean ± SD. *p < 0.05, **p < 0.01, ***p < 0.001.

The Influence of Soleus Architecture on Muscle Efficiency During Running

Professor JOHN H Challis, Ms Axelle M Wasiak

Penn State University, University Park, PA, United States

Introduction

The Achilles tendon is a major site of elastic energy storage and return during human locomotion, and its behavior can influence the energetic cost of movement. Variations in muscle-tendon complex architecture can alter how the Achilles tendon modulates the energetic cost of force production by the triceps surae. Two key features of soleus architecture were identified for investigation: the ratio of tendon slack length to optimal fascicle length, and the ratio of tendon cross-sectional area to muscle cross-sectional area. The purpose of this study was to determine how these architectural parameters affect the efficiency of soleus force production during running. We hypothesized that there exists a combination of soleus architectural parameters that minimizes the muscle's energetic requirements during running.

Methods

Soleus muscle–tendon properties were measured in 13 participants (6 M 7 F) using dynamometry and ultrasound imaging to characterize a physiologically realistic range of architectural values.. Data were collected on seven healthy runners (3M 4F) who ran barefoot at 3.1 m/s while force plate and motion data were captured. From these data the mean kinematics and kinetics of the stance phase were determined. A muscle model driven by these experimental inputs estimated soleus behavior during stance. From model outputs - active state, fascicle length and velocity - the energetic cost of the muscle was calculated.

Results

Soleus energy cost was greatest when the ratio of tendon slack length to optimal fascicle length was low, corresponding to a relatively short tendon and long fascicles. Energy cost was also elevated when the ratio of tendon cross-sectional area to muscle cross-sectional area was high. In contrast, energy cost was minimized when participants exhibited a relatively long tendon (high tendon slack length to fascicle length ratio) and a more compliant tendon (low tendon cross-sectional area to muscle cross-sectional area ratio).

Discussion

This study demonstrates that soleus muscle architecture strongly influences the energetic efficiency of force production during running. It highlighted the value of having a long Achilles tendon relative to the optimal fascicle length and a compliant tendon on minimizing the energetic cost for the soleus during the support phase of running.

Repeatability of Segmental Symmetry Metrics using Self-Placed IMUs for Telemedicine Amputee Mobility Assessment

Mr. Joseph Redmond, Mr. Colin Kennedy, Mr. William Nash, Mr. Gregory Flynn, Prof. Corey Pew

Montana State University, Bozeman, MT, United States

Introduction

Amputees experience gait asymmetries, impacting mobility and quality of life. Clinicians currently assess amputees using Observational Gait Analysis, a subjective measure relying on clinician skill and in-person appointments. For remote populations, assessments can be infrequent and inaccessible. Inertial Measurement Units (IMUs) can provide objective metrics of gait symmetry using segmental metrics of the thigh and shank [1]. Measurements may lose accuracy if IMUs are self-placed in Telemedicine visits. This study aims to evaluate IMU measures of segmental symmetry when sensors are placed by the patient. We hypothesize that self-placed IMUs can produce reliable and repeatable segmental symmetry analysis.

Methods

Four IMUs with an alignment pin were developed to aid participants in self-placement on the anterior thighs and shanks. Participants were observed walking on a treadmill at three speeds relative to a two-minute walk test. Optical motion capture (MoCap) generated a control dataset, and markers applied to IMUs quantified misalignment. Sagittal angular velocity measurements were normalized and used to create asymmetry scores for each segment pair, computed by the mean Euclidian difference between paired gait cycles on the left and right [1]. Self-placement was done twice to assess measurement repeatability. Between MoCap and IMU generated scores, a paired t-test evaluated score changes, while a Pitman-Morgan test evaluated intertrial variance.

Results

Shank asymmetry metrics on 9 Healthy Controls (6F; 53±19yrs.) were found to be greater using self-placed IMUs compared to MoCap (11.85 vs 11.12, $p=0.021$) and showed higher variance under with sensor reapplication (Ratio=3.7, $p=0.001$). Net axial misalignment between the left and right sensors correlated with higher asymmetry scores ($\beta=0.09$ pts/deg, $R^2=0.19$, $p=0.001$; Misalignment=11.6±8.1º). Under repeated conditions, motion

capture established a minimal detectable change (MDC=2.55) that 29% of IMU score pairings exceeded.

Discussion

While score bias can be calibrated, IMU noise reduces repeatability of asymmetry measurements. Sensor alignment impacted scores, and differences between placements increased variability. Comparison of scores to clinician-placed IMUs could vary and lead to misclassification of gait changes in telemedicine translation. Future work will discuss consistency metrics, incorporate thigh scoring, evaluate amputee populations, and consider noise regression.

Investigating Biomechanical Factors that Influence Power Generation in Functional Neuromuscular Stimulation Cycling via Musculoskeletal Modeling

Ms. Kanthi Karumbunathan[1,2], Dr. Musa Audu[1,2], Dr. Ronald Triolo[1,2]

[1]Case Western Reserve University, Cleveland, OH, United States. [2]Louis Stokes Cleveland VA Medical Center, Cleveland, OH, United States

Introduction

For individuals with spinal cord injury (SCI), functional neuromuscular stimulation (FNS) is an invaluable intervention used to mitigate muscle atrophy, cardiovascular deconditioning, and bone demineralization while simultaneously supporting psychological well-being through restoration of lost function. By delivering coordinated, low-level electrical pulses to motor neurons, FNS elicits muscle contractions to produce functional motion such as cycling. Despite its widespread use, FNS cycling faces two primary limitations: minimal power output and rapid-onset muscle fatigue. Understanding how biomechanical configurations influence cycling performance is critical in developing more effective therapies. This study evaluates the effect of hip height on upright, FNS cycling efficiency using musculoskeletal modeling in OpenSim with a secondary aim of identifying significant correlations between hip-height-dependent biomechanical parameters and cycling efficiency.

Methods

For each seat-height configuration, iterative forward-dynamics-based optimizations identified muscle excitation patterns required to reproduce a target pedaling motion at 35 RPM. Mechanical power output, obtained through inverse dynamics, and metabolic power consumption, determined via the Umberger muscle energetics model, were used to characterize efficiency trends.

Results

Results demonstrate a distinct optimal hip-height range, approximately 0.51–0.57 m above the crank, that maximizes efficiency, with a peak at ~0.54 m (Fig. 1). Muscle fiber lengths and contraction velocities for the gluteus maximus, vasti, and rectus femoris were extracted from the simulated muscle states as secondary effects of seat height. Among these variables, mean gluteus maximus fiber velocity squared demonstrated a significant negative correlation with gross efficiency ($p = 0.006$), characterizing it as a primary

biomechanical predictor of performance under the set conditions. Lorentzian peak analysis of instantaneous-efficiency profiles (all $R^2 > 0.89$) revealed five conserved peak clusters across seat heights; peak behavior significantly associated with gross efficiency also aligned with regions of minimized square gluteus maximus velocity, cross-validating the gluteus maximus fiber-velocity-squared–gross-efficiency relationship.

Discussion

These findings highlight the impact of hip biomechanics on FNS cycling efficiency and identify gluteus maximus fiber-velocity dynamics as a key determinant. Ongoing work includes translating this methodology into a recumbent cycling model and validating resulting correlations clinically. This study ultimately provides a potential framework for pre-clinical optimization of biomechanical variables to enhance therapeutic outcomes of FNS cycling.

Effects of Fixed and Adaptive Filtering Methods on Joint Work During Countermovement Jumping After ACL Reconstruction

Ms. Katelyn Campbell MS[1], Dr. Eric Dugan PhD[1,2]

[1]Texas Children's Hospital, The Woodlands, Texas, United States. [2]Baylor College of Medicine, Houston, Texas, United States

Introduction

Joint mechanics during dynamic tasks are sensitive to signal processing choices, yet cutoff selection is rarely standardized in return-to-sport evaluation. Fixed-cutoff filters may oversuppress impact-related frequencies and alter estimates of joint loading and energy absorption used to assess readiness for sport after ACL reconstruction. Augustus et al. introduced a time-varying cutoff profile that preserves these features. This study evaluated whether filtering strategy influences joint work during countermovement jumping and whether any differences are clinically meaningful.

Methods

Twenty-two adolescents, 6 to 12 months after ACL reconstruction, completed three countermovement jump trials. Marker and ground reaction force data were filtered using three matched approaches: 10 Hz, 15 Hz, and an adaptive 10 to 50 Hz method applied identically to kinematic and GRF signals. Joint work was computed for the braking, propulsive, and landing phases. Linear mixed-effects models tested effects of Filter Type, Limb Status, and their interaction. Pairwise equivalence testing evaluated whether filters produced clinically equivalent values using bounds of plus or minus 5 percent of mean absolute work.

Results

Filtering method did not affect ankle or knee work in any phase, and it did not affect hip braking or hip propulsive work. Hip landing work was the only variable that differed across filtering methods ($p = 0.008$). Limb Status effects were significant for most joints, although there were no Filter by Limb interactions, indicating that filtering did not alter injury-related asymmetry patterns. Equivalence testing showed that joint work estimates were clinically equivalent across filters for eight of the nine joint and phase combinations. Hip landing work was the only measure that did not meet equivalence criteria.

Discussion

Most joint work variables used in return-to-sport evaluations were unaffected by filtering choices, indicating consistent interpretation across preprocessing methods. Hip landing work was the only measure sensitive to filter design. The adaptive filter produced the most negative values, the 10 Hz filter produced intermediate values, and the 15 Hz filter produced the least. Because hip landing work reflects impact attenuation after ACL reconstruction, these differences may influence interpretation in landing-focused assessments, although overall filtering effects were limited.

Multiscale Modeling Reveals That Offsetting the Stepping Foot During Sit-to-Walk Generates Greater and More Heterogeneous Positive Net Work by Soleus Muscle Fascicles

Dr. Katherine Knaus, Mr. Haozhixiang Li, Mr. Michael Miller, Dr. Anne Silverman

Colorado School of Mines, Golden, CO, United States

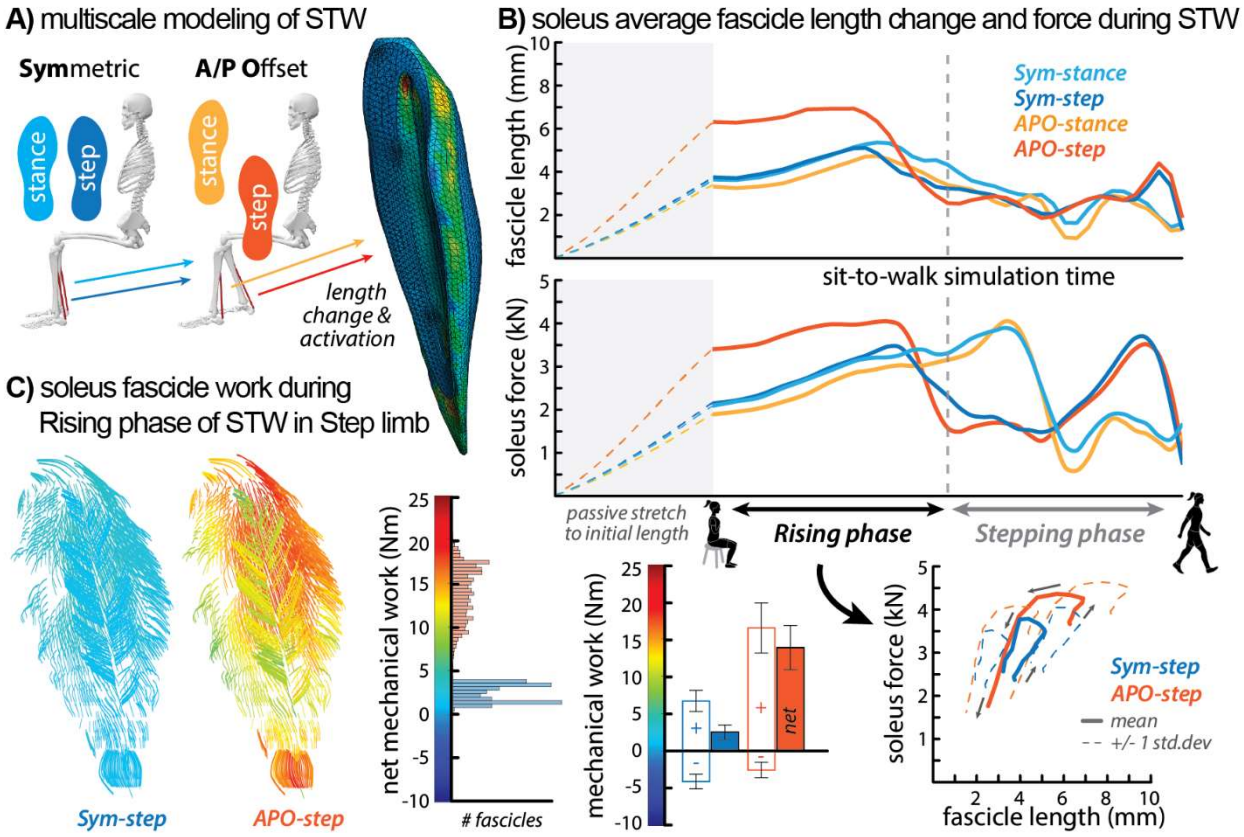
Introduction

Muscle work required for activities of daily living like sit-to-walk (STW) can be affected by selected movement strategy [1]. Multiscale modeling can reveal underlying nonuniform muscle mechanics during whole body movement. We characterized soleus muscle work in STW with different initial foot placements to determine how fascicle work varies throughout the muscle with movement strategy.

Methods

Whole-body kinematics and electromyography (EMG) were measured in young adults performing STW [1] with feet initially positioned symmetrically (**Sym**) or with anterior-posterior offset (APO). Soleus musculotendon lengths computed from musculoskeletal model [2] simulations of STW and average soleus EMG [1] prescribed varying activation and length inputs to a 3D finite element model (FEM) [3] for the **Step** and Stance limb soleus muscle in **Sym** and APO conditions. FEM explicitly defined fascicle architecture [3] to compute individual fascicle lengths and forces, which were used to calculate soleus work described by each fascicle [Figure 1].

Results



Multiscale modeling predicted nonuniform fascicle dynamics in both **Step** and Stance limb soleus during STW performed with **Sym** and APO foot placements. During **Rising**, Step limb soleus fascicles performed 140% more net work in **APO** than Sym with 85% more positive and 45% less negative work [Figure 1]. Distribution of work by **Step** limb soleus fascicles during Rising was greater in **APO** (5.4-20.5kN*m) than Sym (0.7-4.1N*m).

Discussion

Step limb soleus stores more energy (negative work) in **APO** before starting STW as the foot offsets posteriorly, allowing the muscle to perform more work to propel the body during Rising. Differences in soleus fascicle mechanics between **APO** and **Sym** persist in both

limbs into **Stepping** following initial differences in work during **Rising**. While soleus work during **Rising** is greater in **APO**, nonuniformity in fascicle work leads to a range of differences between foot placements depending on which fascicle is measured (29-188% difference). Variability in fascicle mechanics should be considered when assessing muscle work required in different strategies for movements like STW based on measurements of a specific region of muscle, like with ultrasound.

Toward the Development of a Thumb Musculoskeletal Model With a Translational degree of Freedom at the Carpometacarpal Joint: A Preliminary Modeling Study

Mr. Keith Brennan[1], Dr. Joseph Towles PhD[2]

[1]Case Western Reserve University, Cleveland, OH, United States. [2]Swarthmore College, Swarthmore, PA, United States

Introduction

Neurological injuries result in loss of grasp function, significantly impacting activities of daily living. Biomechanical models are increasingly used to plan thumb reconstruction surgeries by predicting how tendon transfers affect thumb-tip forces in the context of restoring grasping ability [1]. Current thumb models do not replicate well the endpoint forces that thumb muscles produce [2]. We believe that the absence of a translational degree of freedom (DOF) at the carpometacarpal (CMC) joint currently limits their predictive accuracy. The goal of this work was to enhance thumb model realism by incorporating a translational DOF at the CMC joint and to evaluate its effect on individual muscle endpoint force predictions by the model.

Methods

A published, open-source upper extremity model [2] was modified in both extended and flexed thumb postures by adding a translational DOF at the CMC joint. To simulate muscle endpoint force production, we welded the thumb-tip to the environment in the postures of interest and applied 10 N of force to each of the 9 thumb muscles.

Results

In 12 of 18 instances, the discrepancy between the model-predicted and cadaver-measured thumb-tip force directions was reduced. In the extended thumb posture, endpoint force directional discrepancies were reduced in all 9 thumb muscles. In FPL, the reduction was 38° (Fig. 1), in EPL 42°, in EPB 15°, in APL 55°, in FPBr 19°, in APB 35°, in FPBu 23°, in ADP 6°, and in OPP 57°. In the flexed thumb posture, endpoint force directional

discrepancies were reduced in 3 muscles only. In FPL, the reduction was 18°, in EPL 1°, and in EPB 68°.

Discussion

The observation that the modified CMC joint had positive effects on the model's ability to replicate measured muscle endpoint force direction in multiple thumb postures speaks to the potential importance of representing translational kinematic properties in future thumb models. This work challenges long-standing approaches to model the thumb with rotational joints only.

Cervical Disc Loads During Isometric Flexion, Extension and Lateral Bending

Dr Kodjo Moglo, Mr. Rizwan Arshad

Royal Military College of Canada, Kingston, Ontario, Canada

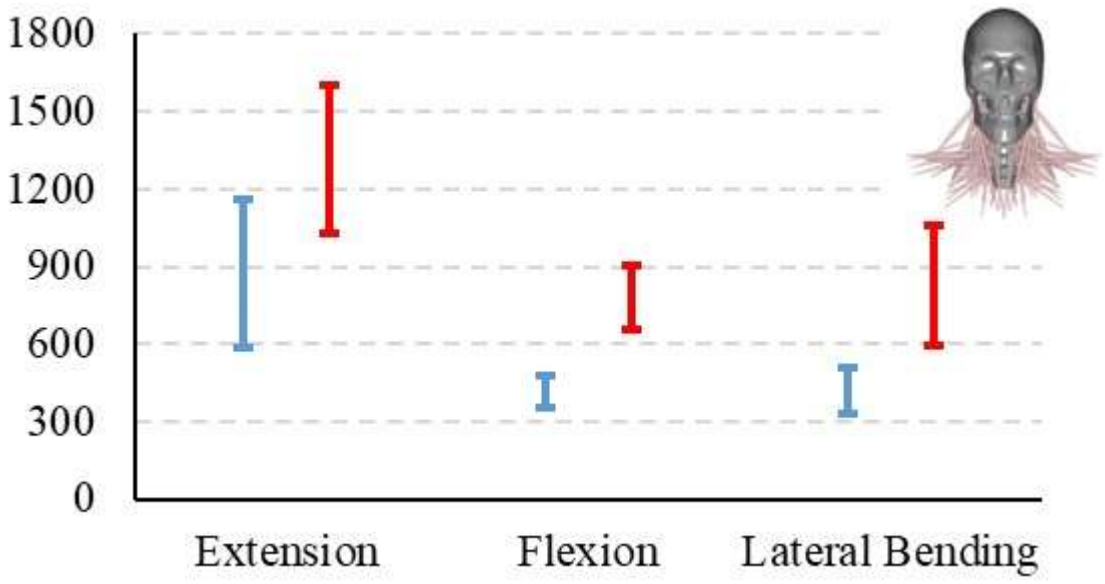
Introduction

Cervical disc loads under isometric loading conditions could vary largely due to varying muscle strengths [1]. This study investigates the variation in compressive disc load with the difference in specific muscle strength

Methods

A 50th percentile head and neck musculoskeletal model (C0-T1) was used to estimate C4C5 compressive load [2]. The cadaveric neck muscle volume was scaled up according to Zheng et al [3]. The joints considered 6 DoF (3 rotations, 3 translations). Two values (30 and 60 N/cm^2) of specific muscle strengths were considered. In total 8 simulations were performed for each direction by varying applied loads and disc compressive and shear stiffness at two levels. Ensuring that maximum muscle activity condition was achieved in one or more muscle groups, various external load in extension (Ex), flexion (Fl) and lateral bending (Lb) was applied.

Results



Under isometric loading conditions in extension, flexion and lateral bending, the estimated compressive loads at C4-C5 level showed large variation due to specific muscle strength (Fig. 1). The highest loads were found during extension, followed by lateral bending and flexion. For specific strength of 30 and 60 N/cm^2, the compressive loads at C4-C5 during isometric extension were between 584-1156N and 1025 to 1605N. For lateral bending, loads were between 331-506 and 591-1057N, whereas for isometric flexion, estimated loads were between 354-481N and 653-901N. Figure 1 shows C4-C5 disc loads under isometric conditions with specific muscle strength: 30 N/cm^2 (Blue) and 60 N/cm^2 (Red).

Discussion

Cervical spine loading during isometric loading conditions remains poorly understood. Many biomechanical parameters can affect the disc loads. However, neck muscle strength is key factor determining the range of maximum loads that can be endured by the cervical joints. The specific muscle strength can differ between neck flexors and extensors due to

fiber type composition and physiological demands. These estimated loads provide insights into load bearing capacity of healthy populations whose varying neck muscle strength can be measured in vivo.

Active Muscular-Contraction-Induced Knee Flexion of an Anatomically Faithful Lower Limb

Dr. Anup Pant, Dr. Lance Frazer, Dr. Daniel Nicolella

Southwest Research Institute, San Antonio, TX, United States

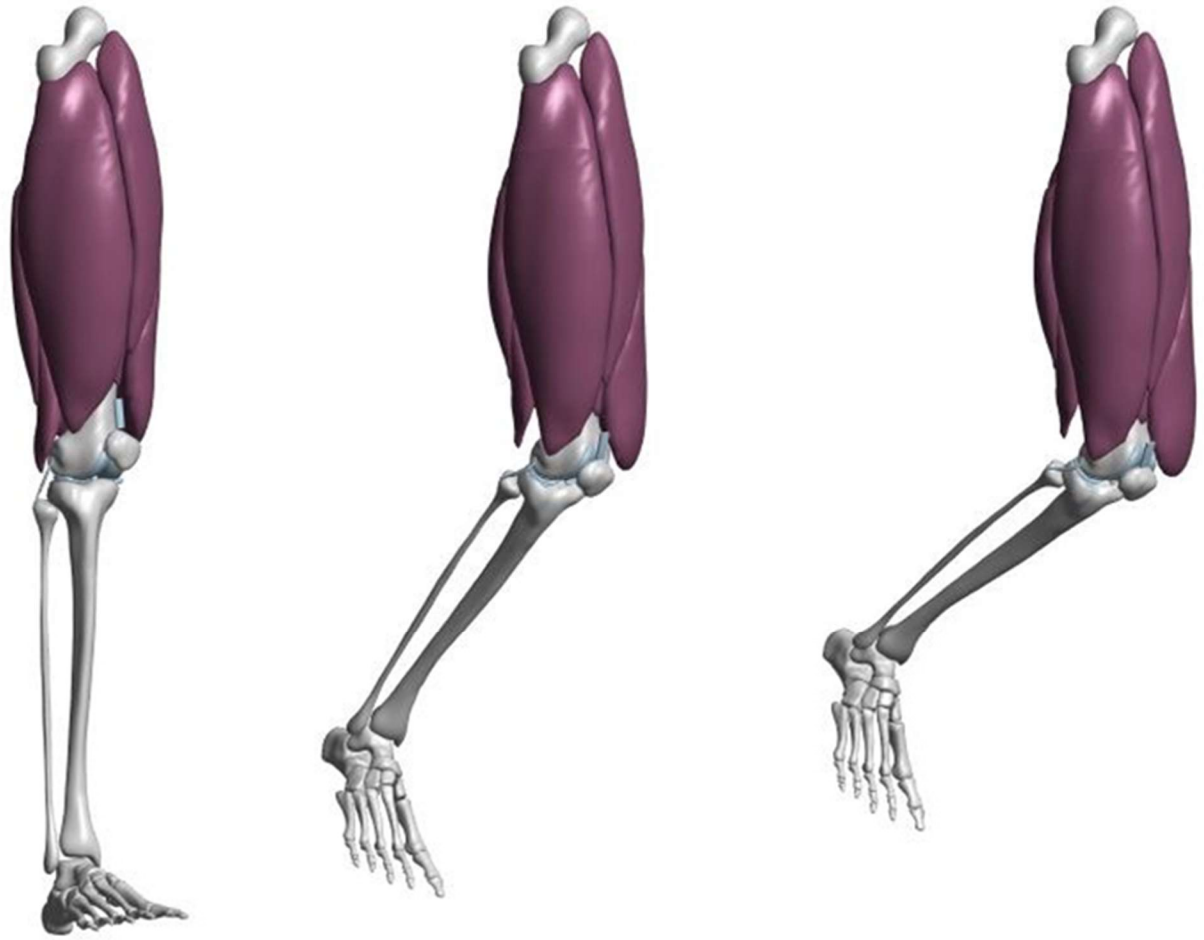
Introduction

Personalized Finite Element (FE) models provide unique insight into subjects' tissue mechanics [1]. Typical workflows for estimating tissue strains from physiological movement use rigid-body musculoskeletal (MSK) tools to estimate joint loads and muscle forces, which are then applied as FE boundary conditions. However, this approach requires limiting assumptions, such as mismatched geometries between the rigid-body and FE models and missing physics (internal contact, soft tissue, etc.). Direct FE modeling of the human model driven by observed motion can bypass rigid-body models and more accurately capture tissue responses. In this work, we demonstrate direct FE modeling of movement using contractile 3D musculature.

Methods

A right lower-limb FE model was generated from MRI-based bone and muscle geometry of a 21-year-old male. The MRI data lacked high fidelity soft tissue of the knee, so a height-weight matched Open Knee joint (subject 009) was blended into the model [2]. Bones were treated as rigid, muscles as Ogden rubber with active contraction, and ligaments as springs. A quasi-static FE analysis [3] was performed where hamstring activation drove knee flexion. Using an inverse-dynamics-approach, knee-flexion was prescribed, muscle activations were optimized to minimize the resulting knee moment [4], and the activations were reapplied to verify reproduction of the knee-flexion.

Results



The model successfully reproduced 60° knee-flexion (Figure 1) via forward simulation. Knee contact was preserved through the full motion.

Discussion

Direct FE modeling from motion removes the need for separate rigid-body musculoskeletal analyses. Paired with motion capture data, more accurate predictions of tissues mechanics are achievable compared to using rigid-body modeling as an intermediary.

Higher fidelity FE modeling of motion can provide actionable biomechanics insights, such as identifying high-risk loading patterns, tracking rehabilitation progress, or guiding performance optimization.

Spring-Damper Titin Model to Improve the Estimation of Muscle Forces and Metabolic Costs

Ms Lena Kloock[1], Ms Myriam de Graaf[1,2,3], Dr. Kim Boström[1], Prof. Dr. Heiko Wagner[1,2,3]

[1]Dept. of Movement Science, Institute of Sport Sciences, University of Münster, Münster, North Rhine-Westphalia, Germany. [2]Otto Creutzfeldt Center for Cognitive and Behavioral Neuroscience, University of Münster, Münster, North Rhine-Westphalia, Germany. [3]Center for Data Science and Complexity (CDSC), University of Münster, Münster, North Rhine-Westphalia, Germany

Introduction

Hill-type muscle models are a key component of large-scale inverse dynamic models, that calculate muscle activation, joint contact forces, and, when used in conjunction with energy expenditure models, metabolic costs. However, models without the molecular spring titin [1] do not accurately reproduce relevant characteristics of eccentric movements, such as force-enhancement or metabolic costs [2]. Here, we add a spring-damper titin model to a Hill-type muscle model and evaluate the accuracy of resulting model predictions. In a next step, we will determine if the enhanced model also improves the estimation of muscle metabolic costs during eccentric phases.

Methods

We added a spring-damper module to represent titin's elastic and viscoelastic behavior to a Hill-type muscle model with force-length and force-velocity relationships. For validation, we compared the predictions of the standard and the titin model to reference data from force-enhancement experiments [3]. We used the relative root-mean-square-error (rRMSE) as performance indicator, and a repeated measures ANOVA to check for significant performance improvements.

In a later phase, muscle metabolic costs will be calculated using an inverse-dynamic musculoskeletal model (Computed MyoGraphie®, Predimo GmbH, Münster, Germany) [4] enhanced with a metabolic energy model. Titin will be added to the muscles of the inverse-dynamics model. Measuring nine subjects during walking, we used movement kinematics (XSens MVN Link, Movella, Enschede, Netherlands) as input data, and energy expenditure (MetaMax 3B, Cortex Biophysik GmbH, Leipzig, Germany) as validation data.

Results

The model with titin predicts force-enhancement significantly better than titin-less model (see Figure 1). Results of the metabolic energy prediction are not yet available.

Discussion

Adding a spring-damper titin model to a Hill-type muscle model improves muscle force prediction during force-enhancement experiments. Though being less complex than other titin models, the proposed model accurately predicts measured muscle forces. Due to its simplicity, the model can efficiently be incorporated into large-scale inverse-dynamics models used to predict metabolic cost. We expect the inclusion of titin will also improve metabolic cost predictions.

Static and Fatigue Strength of Tibiotalocalcaneal (TTC) Nail: In-silico Method Development, Verification & Validation

Dr. Lin Wang[1], Mr. Stanley Kmiec Jr.[2], Dr. Dana Coombs[2]

[1]DePuy Synthes, Leeds, West Yorkshire, United Kingdom. [2]DePuy Synthes, West Chester, Pennsylvania, United States

Introduction

Tibiotalocalcaneal (TTC) arthrodesis is a commonly used medical procedure to treat severe arthritis, deformities, and trauma in the hindfoot, by fusing the ankle and subtalar joints with an intramedullary (IM) nail. As such, the nail must withstand complex biomechanical loads and preclinical investigation of its mechanical integrity is critical. This study aims to develop an efficient and effective in-silico (computational) modelling method to answer the question of interest whether proposed TTC nails meet static and fatigue strength requirements.

Methods

A 10x150mm DePuy Synthes EXPERT™ Hindfoot Arthrodesis Nail (EX-HAN) was used for model development, and model credibility was accessed as per ASME V&V40 framework (Figure 1a). Finite Element Analysis (FEA) would be employed to simulate the benchtop testing of the TTC nails under offset bending loads (Context-of-Use), then the predicted yielding load and max. principal stress (Quantities-of-Interest) would be used for design benchmarking (Figure 1b). Based on the model influence and decision consequence, model risk was determined to be medium. Force and displacement controls were applied to the hole of the proximal block for static and fatigue analyses (with modified Goodman method) respectively, while the ball bearing near the distal block was simplified with relevant remote boundary conditions. All interactions were modelled with friction contacts except for the bonded screw-block pairs. Metallic components were modelled as elastic-plastic while Delrin blocks as elastic material.

Results

Code and Calculation activities are completed as part of the verification efforts and resulted in adequate credibility (e.g. grid discretization error < 3%). When validating the static FEA with corresponding benchtop comparator, the difference of yielding load is only 2% (Figure 1c), demonstrating sufficient credibility of this in-silico approach. Furthermore, the fatigue FEA estimates that the peak max. principal stress occurs at the middle (distal) hole, which correlates with the crack location of the testing samples (Figure 1d).

Discussion

An in-silico method has been successfully developed to evaluate the static and fatigue strength of TTC nails, offering an alternative to the traditional, costly, and iterative design-prototyping-testing. Moreover, it provides an ideal platform to benchmark TTC nail design changes/concepts exclusively, without any variability from experimental, patient, or surgical factors.

A Parametric CAD Model Generator for the Thoracolumbar Spine: Integration of the Muscular Architecture

Ms Linda Carpenedo, Mr Alessandro Carini, Mr Davide Joseph Pedretti, Prof. Luigi La Barbera

LaBS, Dept. of Chemistry, Materials and Chemical Engineering, Politecnico di Milano, Milan, Italy, Italy

Introduction

Spine models are essential for studying biomechanics and guiding clinical decisions. In general, both the reference morphology and the definition of loading conditions are determined by the specific goals of each study. Here, a fully parametric thoracolumbar spine CAD generator, recently extended to include pelvis and sacrum [1], is further expanded to incorporate detailed thoracolumbar musculature while preserving full parametric control for adaptable morphology and loading definitions.

Methods

A literature review identified the 11 thoracolumbar muscle groups involved in flexion–extension [2], which are implemented by discretizing each muscle into fascicles anchored to vertebral and pelvic/sacral landmarks (Figure 1a). Model reliability is assessed by comparing normalized fascicle lengths with published data and by validating insertion sites and lever arms against an external dataset [3].

Results

24 lumbar and 82 thoracic muscle fascicles per side are included in the model in a symmetric muscular architecture (Figure 1a). As all the fascicles attach to anatomical landmarks, the muscular architecture properly follows the model updates. Muscular modelling choices result in normalised muscle lengths that always match those reported by other *in vivo* and *in silico* references (median difference on 106 fascicles of 9%, with a maximal one of 90% measured for the *external oblique*) [4]. Moreover, medio-lateral and antero-posterior distances for the attachments and the lever arms are always coherent with those of an external dataset [3] (Figure 1b).

Discussion

This work developed a reliable parametric musculoskeletal model of the thoracolumbar spine. The muscular architecture is coherent with anatomical data [2,3,4]. Some discrepancies can be justified by the approximations introduced by other models and by

specific muscle configurations; for example, the oblique muscles are broad and flat, whereas we represent them as discrete fascicles. The parametric features allow tuning the model to patient-specific characteristics, and the tool may be used for further biomechanical finite element analyses. Future developments include extending the muscular architecture to muscle groups involved in other tasks (i.e., lateral bending and torsion).

Fit Is a Safety Factor: Biomechanical Evidence Challenging One-Size-Fits-All Medical Gowns

Dr. Jingeng Li PhD[1], Professor Li-Shan Chou PhD[2]

[1]Iowa State University, Ames, Iowa, United States. [2]Purdue University, West Lafayette, Indiana, United States

Introduction

Self-contamination during medical gown doffing remains a persistent threat to healthcare worker safety, yet the influence of gown tightness on biomechanical performance and contamination risk is poorly understood. Although universal-sized gowns are widely used for cost and logistical convenience, improper fit, whether excessively tight or oversized, may alter movement patterns, increase hand–gown contact, and compromise the safety of doffing. This study investigated how three gown tightness conditions (Tight, Fit, Oversize) affect contamination risk, upper-limb kinematics, movement smoothness, and hand–gown interactions during standardized medical gown removal.

Methods

Forty healthy adults (12 Tight, 15 Fit, and 13 Oversized) performed CDC-recommended gown-doffing procedures while instrumented with five inertial measurement units (SageMotion, USA) and a marker-based optical motion capture system. Each participant doffed gowns sprayed with fluorescent solution to simulate contamination. Upper-limb range of motion, normalized zero-crossing (NZC) of angular velocity, hand-to-gown distance, and hand-gown contact time were computed. Group differences were assessed using either one-way ANOVA or the Kruskal–Wallis test, depending on whether the normality assumptions were met. Stepwise regression identified biomechanical predictors of contamination risk.

Results

Tight and Oversize gowns resulted in significantly higher contamination counts on the dominant hand and whole body compared with Fit gowns ($p \leq .015$). Range of motion was largely unaffected by gown tightness, whereas NZC values, reflecting reduced movement smoothness, were consistently higher in Oversize gowns across multiple joints ($p < .05$). Tight gowns produced significantly shorter hand-to-gown distances ($p \leq .016$), indicating forced proximity to contaminated surfaces. Stepwise regression identified elbow flexion/extension NZC as the strongest single predictor of contamination ($R^2 = 0.157$),

indicating that a decrease in motor control due to wearing an unmatched gown could be a key risk factor for contamination.

Discussion

Improper gown tightness significantly increases contamination risk by disrupting movement smoothness and altering hand–gown interactions, even when removal procedures are standardized. Both excessively tight and oversized gowns introduce biomechanical disadvantages that elevate exposure risk. These findings provide quantitative evidence supporting the need for properly fitted medical gowns and indicate that movement smoothness may be a critical biomechanical factor in explaining contamination during PPE doffing.

Validation of OpenCap-Based Estimates of Peak Knee Abduction Moments during a Drop Vertical Jump

Mr. Lucas Gaston, Ms. Sophia Stemler, Dr. Scott Monfort, Ms. Alexandra Lynch, Ms. Fatemeh Aflatounian

Montana State University, Bozeman, MT, United States

Introduction

Peak external knee abduction moments (pKAbM) have been linked to anterior cruciate ligament (ACL) injury risk.[1] However, monitoring knee kinetics using motion capture (MoCap) requires expensive equipment and is often impractical in clinical settings. OpenCap offers an affordable and easy-to-use alternative, requiring only iOS devices to collect motion data, making it more feasible for clinicians.[2] However, OpenCap-based estimates of pKAbM have scarcely been validated against MoCap data. This study aims to address this gap by simultaneously collecting MoCap and OpenCap data during the clinically significant double limb drop vertical jump (DLDJ). We hypothesized that OpenCap-based pKAbM would strongly correlate with MoCap-based pKAbM, supporting potential suitability for clinical implementation.

Methods

Eight participants (4F/4M; 22.5 ± 3.5 yrs; 1.72 ± 0.08 m; 69.5 ± 14 kg; Tegner: 4.57 ± 1.27; Marx: 6.25 ± 3.69) completed five DLDJ trials. Three iOS devices running OpenCap and the 8-camera hybrid Qualisys MoCap system recorded data. MoCap data was processed in Theia3D, and OpenCap kinetics were estimated using torque-driven OpenSim algorithmic differentiation simulations. Right leg pKAbM during the first 100ms after landing were estimated and normalized by height and weight. Eight trials were removed due to simulations not converging. Pearson correlations were found between the OpenCap and MoCap values.

Results

OpenCap and MoCap pKAbM values demonstrated a weak, nonsignificant correlation ($r = 0.245$; $p = 0.177$; Fig.1).

Discussion

The weak, nonsignificant relationship between OpenCap and MoCap estimates of pKAbM highlights the difficulty of estimating frontal plane kinetics. Ongoing data collection efforts will help to adequately power the detection of this relationship; however, the upper bound

of the 95% confidence interval of the correlation coefficient for the current sample (i.e., r = 0.55) suggests that the relationship may not reach a strong magnitude. Ongoing data collection will also include a marker-based MoCap comparison, which will provide a benchmark against 'gold-standard' MoCap.

Effect of Posterior Elements Removal on the Mechanical Behaviour of Thoracic and Lumbar Human Spine Segments Tested in Compression

Miss Margherita Pasini[1], Miss Gaia Youssef[1], Prof Enrico Dall'Ara[2], Prof Luca Cristofolini[1], Dr Marco Palanca[1]

[1]University of Bologna, Bologna, Italy, Italy. [2]University of Sheffield, Sheffield, United Kingdom, United Kingdom

Introduction

In-situ mechanical testing with microCT and DVC has provided unprecedented insights into spinal biomechanics [1]. However, due to the limited size of the microCT chamber, removal of the posterior elements is often required. Because thoracic and lumbar regions differ in morphology, the biomechanical effect of the posterior-element removal may also differ, jeopardising comparisons across spinal levels. This study aimed to investigate whether, and to what extent, posterior elements removal affects the biomechanics of thoracic and lumbar spine segments.

Methods

Six thoracic and five lumbar four-vertebrae segments were tested in the elastic regime using a spine simulator (MIB4.0-MAS2-S) equipped with a 6-axis load cell. Vertebral strain fields were measured with a four-camera 3D-DIC system (Aramis Adjustable 12M, Zeiss).

Each specimen was axially compressed until an average minimum principal strain (Eps_min) of 2000microstrains on the anterior vertebral surface was reached [2].

Posterior elements were removed, cutting the pedicles. The same protocol was then repeated.

The following parameters were calculated and compared (paired t-Test) before and after posterior element removal, separately for thoracis and lumbar vertebrae: 1) target load as the load required to induce Eps_min=2000microstrain on the anterior vertebral surface, 2) stiffness as the slope of the load-displacement curve between 20%-80% of the target load, 3) strain variability as the standard deviation of the maximum (Eps_max) and minimum (Eps_min) principal strains on vertebral surface.

Results

Posterior element removal did not affect the mechanical properties of the thoracic specimens (Figure 1, p>0.05). Lumbar specimens showed smaller target load (-40%, p=0.0096) and stiffness (-23%, p=0.027) together with a significantly increased Eps_max variability (+34%, p=0.004).

Discussion

Posterior element removal introduces significant mechanical alterations in lumbar specimens. The physiological lumbar lordosis, indeed, stresses the posterior elements when the spine is loaded in compression. Once removed, the segment becomes less stable. By contrast, the kyphotic curvature of the thoracic spine reduces the contribution of posterior elements under compression, making thoracic segments less sensitive to their removal. In conclusion, lumbar specimens should be tested with intact posterior elements, whereas thoracic specimens can yield reliable results even after posterior elements removal.

Toward a 8DOF Multisegment Musculoskeletal Modeling Framework for planning personalised exercise protocol for Diabetic Foot Prevention

Ms. Maria Dalle Vacche, Mr. Giulio Rigoni, Ms. Annamaria Guiotto, Ms. Fabiola Spolaor, Prof. Zimi Sawacha

University of Padova, Padova, Veneto, Italy

Introduction

Diabetes affects 537 million people worldwide, with up to 46% developing diabetic foot (DF) leading to ulcers and amputations [1]. In DF individuals, lumbrical and interosseous muscles often show atrophy and weakness, contributing to biomechanical alterations associated with plantar ulcers. Despite guidelines suggesting the adoption of customized orthoses, 34% of DF individuals develop ulcers, highlighting the need for complementary treatments such as exercise protocols targeting lumbrical and interosseous muscles [1]. However quantitative individual muscle force measurement is often unavailable in routine clinical settings. This paper aims to address this through the adoption of a 8-degree-of-freedom (DOF) EMG-informed multisegment musculoskeletal (MSM) foot model [2] in OpenSim.

Methods

The gait of 20 subjects (mean age and BMI: 55.4 ± 11.4 years, 25 ± 4.1 kg/m^2) was assessed (9 controls, 6 diabetic, 5 neuropathic subjects) through 6 BTS cameras, synchronized with two Bertec force platforms , a 12-channel surface-EMG (sEMG) system, 2 Imago Ortesi plantar pressure systems (150 Hz). The foot Padova model was adopted [3] and the sEMG activity of 6 lower limb muscles recorded bilaterally. Muscle activations and forces were estimated either through a modified version of [2] which includes an EMG-informed approach [4] and via static optimization. Activation results were compared with sEMG envelopes for validity assessment [5]. Statistical Parametric Mapping (SPM) analysis [6] was conducted to compare different subject groups.

Results

Figure 1 shows the proposed framework. Preliminary muscle activation estimates obtained through Static Optimization indicate that diabetic participants exhibit higher activation levels than both controls and neuropathic subjects, likely due to the increased stiffness of the plantar fascia.

Discussion

The proposed model allows identifying specific foot muscle impairments associated with diabetes. This methodology could be used for planning specific selective foot muscles strengthening protocols, and assessing the effect of the interventions.

Images (Optional)

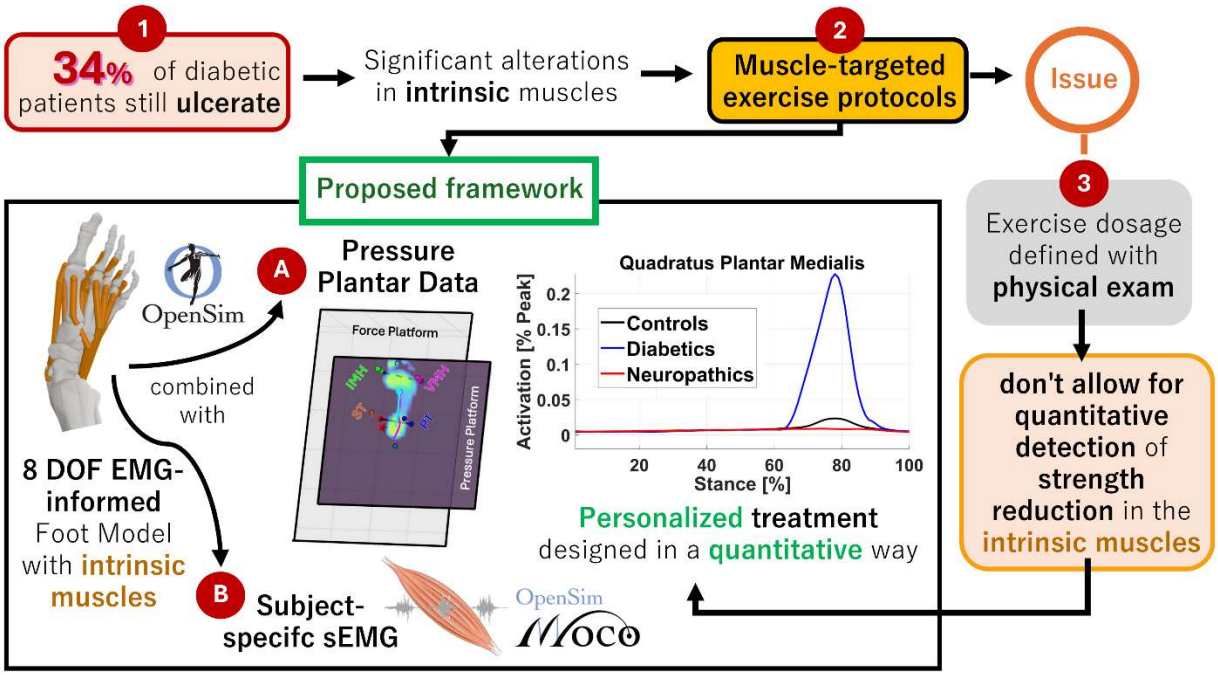

Figure 1: *Proposed Musculoskeletal Modeling Framework*. Simulations to estimate muscle activations and forces were performed in OpenSim. A) Ground reaction forces were partitioned into rearfoot, midfoot, and forefoot contributions by integrating plantar pressure data. B) Experimental sEMG signals were incorporated into Moco to perform EMG-informed simulations.

Impact of Patient-Specific Anatomy on Muscle Parameter Calibration and Muscle Forces Estimations in Children with Cerebral Palsy

MSc Markus Astl, MSc Elias Wallnöfer, PhD Willi Koller, PhD Basilio Goncalves, Assoz. Prof. Mag. Hans Kainz

University of Vienna, Vienna, Vienna, Austria

Introduction

The importance of electromyography-assisted approaches and imaging-based musculoskeletal models for neuromuscular simulations in children with cerebral palsy (CP) has been shown [1,2]. Muscle parameter calibration represents a further step in personalization. CEINMS [3] and the Muscle Redundancy Solver (MuReSo) [4] incorporate such calibrations and have been used in CP studies [2,5]. This study evaluated how these two EMG-informed frameworks alter muscle properties and forces in generic-scaled and MRI-based models.

Methods

Retrospective data [1], including 3D motion capture, ground reaction forces, electromyography (EMG), and both a generic-scaled model [6] (GSM) and an MRI-based model [7] (MBM) of four children with CP, were analyzed. EMG from eight lower-limb muscles was normalized to maximum activations obtained by static optimization in OpenSim [8]. Muscle parameter calibration and force estimation were performed with CEINMS and MuReSo. Shared parameters were matched across tools, while tool-specific settings were optimized for validation. Calibration of optimal fibre length and tendon slack length was limited to ±5%.

Results

Preliminary results for one child showed that CEINMS and MuReSo adjusted optimal fibre lengths (OFL) in the same direction for 57% of muscles in the GSM and 61% in the MBM. Tendon slack lengths (TSL) showed higher agreement (61% and 73%) between approaches. Calibration reduced OFL and TSL differences between GSM and MBM for 39% and 68% of muscles respectively. Mean root-mean-square-differences of muscle forces between models was 14% and 7% body weight for CEINMS and MuReSo respectively.

Discussion

Limited agreement in calibration direction and muscle forces highlights that CEINMS and MuReSo respond differently to identical input data, likely due to tool-specific objective functions. The greater stability of MuReSo muscle forces across personalization levels indicates lower sensitivity to parameter perturbations. Analyses across all participant will evaluate the robustness of these findings.

Kinematic Variability Between a Single-Segment vs. Multi-Segment Foot Model During Treadmill Walking in Healthy Adults

Grant Schwiebert[1,2], Matthew Parrett M.Ed.[1], Mallory Rowan M.S.[1], Jessica Lewis PT, DPT[1], Dr. Sean Tabaie MD[1], Dr. Kirsten Tulchin-Francis PhD[1]

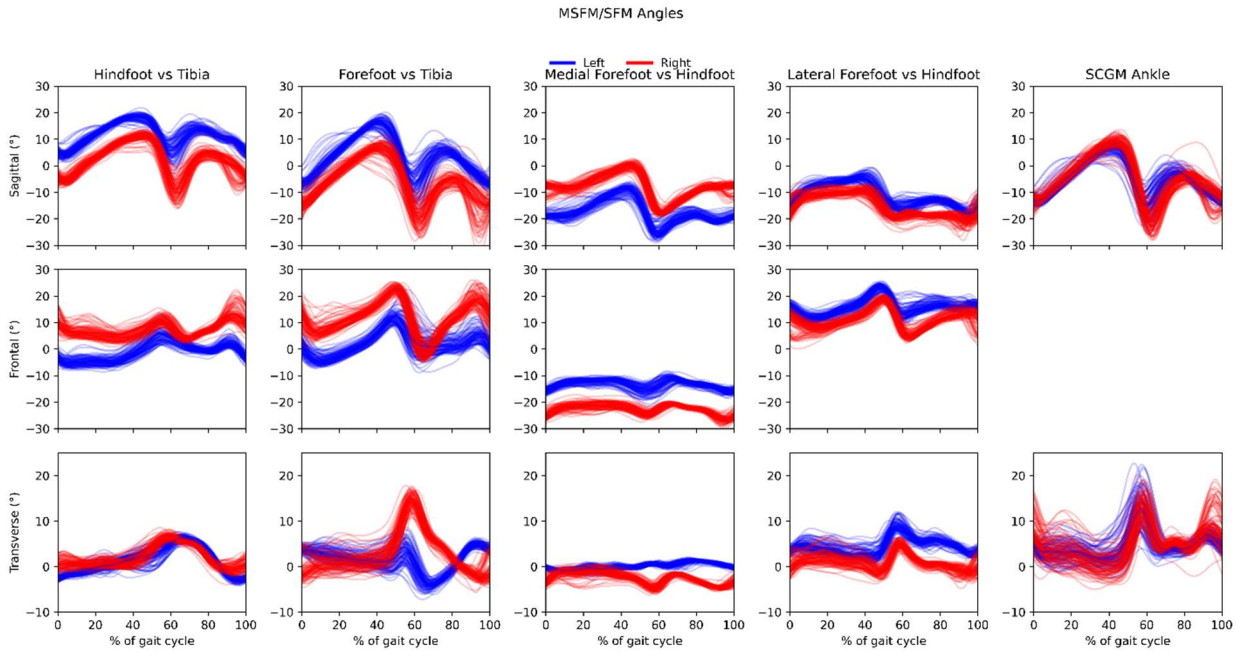
[1]Nationwide Children's Hospital, Columbus, Ohio, United States. [2]The Ohio State Unviersity, Columbis, Ohio, United States

Introduction

Single-segment foot models (SSFMs) remain common in clinical gait analysis despite bone-pin and fluoroscopic studies showing inter-segmental motion and violation of rigid-body assumptions. Existing multi-segment foot models (MSFMs) add anatomical detail but vary widely and rarely include medial-lateral forefoot or radiograph-analogous angles needed to assess deformity and loading asymmetry. The purpose of this study was to assess regional kinematics of a novel MSFM, and to quantify stride-to-stride variability, nonlinear dynamic stability, and waveform reliability relative to a SSFM.

Methods

Seven healthy adults (6M, 24.1±3.9yrs, 77.0±9.8kg, 175.8±7.6cm) walked barefoot on a treadmill at 2.5 mph for 90 seconds while 3D motion capture data were collected using the Shriners Children's Gait Model (SCGM) and a novel MSFM simultaneously. The MSFM included intersegment Euler angles between the tibia, hindfoot, forefoot, and medial and lateral forefoot. Across >70 gait cycles per participant, variability metrics (standard deviation [SD], coefficient of variation [CV], range of motion [ROM], ROM-CV), and nonlinear stability metrics (short- and long-term Lyapunov exponents [SLE/LLE]) were computed. Cycle-wise waveform reliability was evaluated with ICC(2,1).



Results

The MSFM generated repeatable waveforms across all participants (Fig 1). Mean stride-to-stride ROM variability was 4.4°/1.8°/3.9° across sagittal, frontal, and transverse planes, respectively. Medial and lateral forefoot segments exhibited distinct variability signatures (1.8°/1.0°/0.7° vs 2.0°/1.3°/0.8°), demonstrating sensitivity to regional mechanics. Nonlinear MSFM stability was comparable to single-segment ankle angles (SLE: 1.29 vs 1.32; LLE: 0.067 vs 0.066). Reliability was high: ICC averaged 0.79 for Euler angles and 0.79 for SCGM ankle angles.

Discussion

This preliminary evaluation demonstrates that the proposed MSFM is stable, reliable, and sensitive to clinically important medial–lateral forefoot differences often obscured by traditional models. This framework enhances the ability to analyze deformity progression, orthotic and surgical intervention outcomes, and pathological gait using repeatable, regional kinematics. Future work will include developing normative datasets, assessing the model with a probabilistic marker-placement error and soft-tissue artifact analysis to strengthen clinical translation, and evaluating its performance in pathological feet. The intra-foot mechanics with segment-specific fidelity of this MSFM provides a strong foundation for improved diagnosis, treatment planning, and longitudinal monitoring.

Inter-Site Reliability of Ankle Kinematics from Biplanar Videoradiography

Dr David Williams[1], Miss Katherine Prentice[1], Miss Lauren Swain[1], Dr Michael Rainbow[2]

[1]Cardiff University, Cardiff, Wales, United Kingdom. [2]Queen's University, Kingston, Ontario, Canada

Introduction

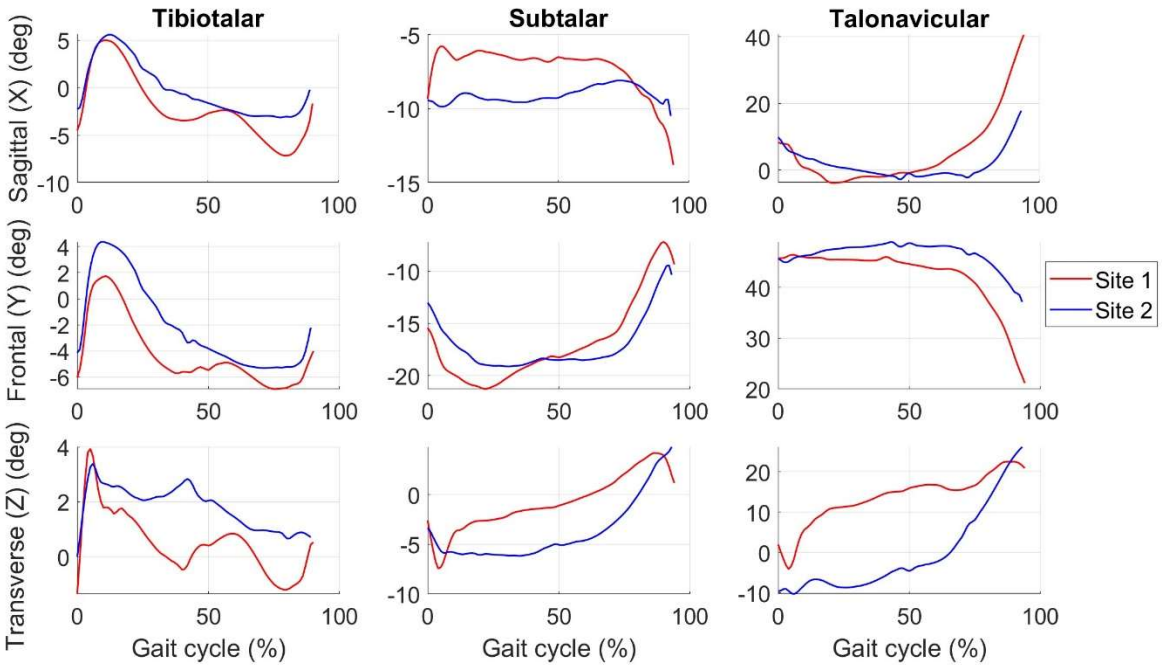
Accurate measurement of kinematics is essential for advancing clinical and fundamental biomechanical understanding of the foot and ankle; however, the small sample sizes typical of biplanar videoradiography (BVR) studies potentially limit the power of this accurate analysis. Multisite data collection offers a route to increase participant numbers, but only if comparable biomechanical signals can be obtained across laboratories operating separate imaging systems and processing workflows. This study presents a foundational inter-site comparison designed to inform a larger multisite initiative.

Methods

One volunteer who had previously received tantalum bead implants: five in the distal tibia, four in the talus, three in the calcaneus and four in the navicular [1] performed barefoot level walking at two separate laboratories, each using a BVR system with matched X-ray geometry parameters. CT images were captured (Resolution: 0.441 mm x 0.441 mm x 0.625 mm) and segmented to generate bone surface models and define bead location. Bone poses from each site were determined by digitising bead positions in XMALab. Kinematics were derived for the talocrural (tibia–talus), subtalar (talus–calcaneus), and talonavicular (talus–navicular) joints using anatomically aligned coordinate systems. Joint angles were time-normalised to the gait cycle and compared across sites.

Results

Hindfoot kinematics showed close inter-site agreement (Figure 1). Differences across the gait cycle were 3 ± 2°, 3 ± 1°, and 2 ± 1° for tibia–talus rotations, and −2 ± 4°, −2 ± 2°, and −6 ± 3° for talus–calcaneus rotations (Sagittal, Frontal, Transverse respectively). Larger discrepancies were observed at the talonavicular joint (−5 ± 11°, 6 ± 6°, −21 ± 5°).



Discussion

While it is unclear whether the differences we observe are due to inter-day variation in movement patterns or to systematic differences between labs, these findings demonstrate that comparable hindfoot kinematics can be obtained across independent BVR laboratories. Biplanar videoradiography lends itself well to multi-site studies because

traditional sources of inter-lab variation [2] such as user-defined anatomical coordinate systems, replicating camera setups, and soft tissue artifact are eliminated. Future work will expand this comparison to other joints in the foot and ankle complex.

Superior and Inferior Endplate Deflection in Response to Physiologic Loading Scenarios

Mr. Michael Watson MSc[1], Dr. Jackie Zehr PhD[2], Dr. Jack Callaghan PhD[1]

[1]University of Waterloo, Waterloo, ON, Canada. [2]University of Toronto, Toronto, ON, Canada

Introduction

Within a spinal joint, the vertebral endplate transmits compression force between adjacent intervertebral discs and vertebrae. Prior literature has attributed the inferior endplate's (IE) higher incidence of failure to its greater tendency to deflect compared to the superior endplate (SE) [1]. However, existing endplate deflection measures are confounded by techniques that either rely on prolonged static loading or damage the vertebral structure. This study introduces a novel method that avoids these limitations and enables the change in endplate deflection to be measured under cyclic loading conditions, providing a more physiologically relevant deflection metric.

Methods

Eighteen porcine cervical functional units (C3C4, C4C5, C5C6; N = 6 per level) were dissected into 36 vertebrae. High-resolution laser profilometry captured cranial and caudal endplate topography to enable the fabrication of custom 3D-printed indenters that both conformed to and contacted exclusively the nuclear region of the endplate. Specimens were positioned neutrally and loaded with a custom cyclic waveform ranging from 0.3 kN to 30% of predicted ultimate strength. Endplate deflection was assessed after 0, 1000, 3000, and 5000 cycles by recording indenter displacement under brief static loads of 0.3, 1, and 3 kN, totalling 12 measurements per vertebra. Linear mixed-effects models tested the effects of load magnitude, cycle count, endplate level, and the nucleus occupying proportion of endplate area on deflection.

Results

Greater IE deflection was observed across all measures with IEs of C4C5 and C5C6 joints demonstrating a significant increase in deflection rate during the first 1000 cycles. C4C5 joints exhibited the largest difference in SE and IE deflection, followed by C5C6 and C3C4 joints. Endplate deflection was not influenced by the proportion of the nucleus occupying endplate area at any spinal level.

Discussion

This study demonstrates the utility of a novel method for measuring SE and IE deflection under cyclic loading conditions. The results indicate that inferior–superior compliance differences vary by spinal level, reflecting anatomical and structural factors that influence injury susceptibility. The absence of an effect from the nucleus occupying area further supports deflection being driven primarily by localized structural weaknesses.

During 3D Center-Out Reaching Movement of the Mouse Forelimb, Fascicular Velocities Are Greatly Affected by Target Location and Can at Times Exhibit Both Eccentric and Concentric Contractions Within a Movement

Ms. Shuting Chen, Mr. Minghuan Gu, Ms. Nancy Shao, Ms. Anisa Torres, Dr. Francisco Valero-Cuevas

University of Southern California, Los Angeles, CA, United States

Introduction

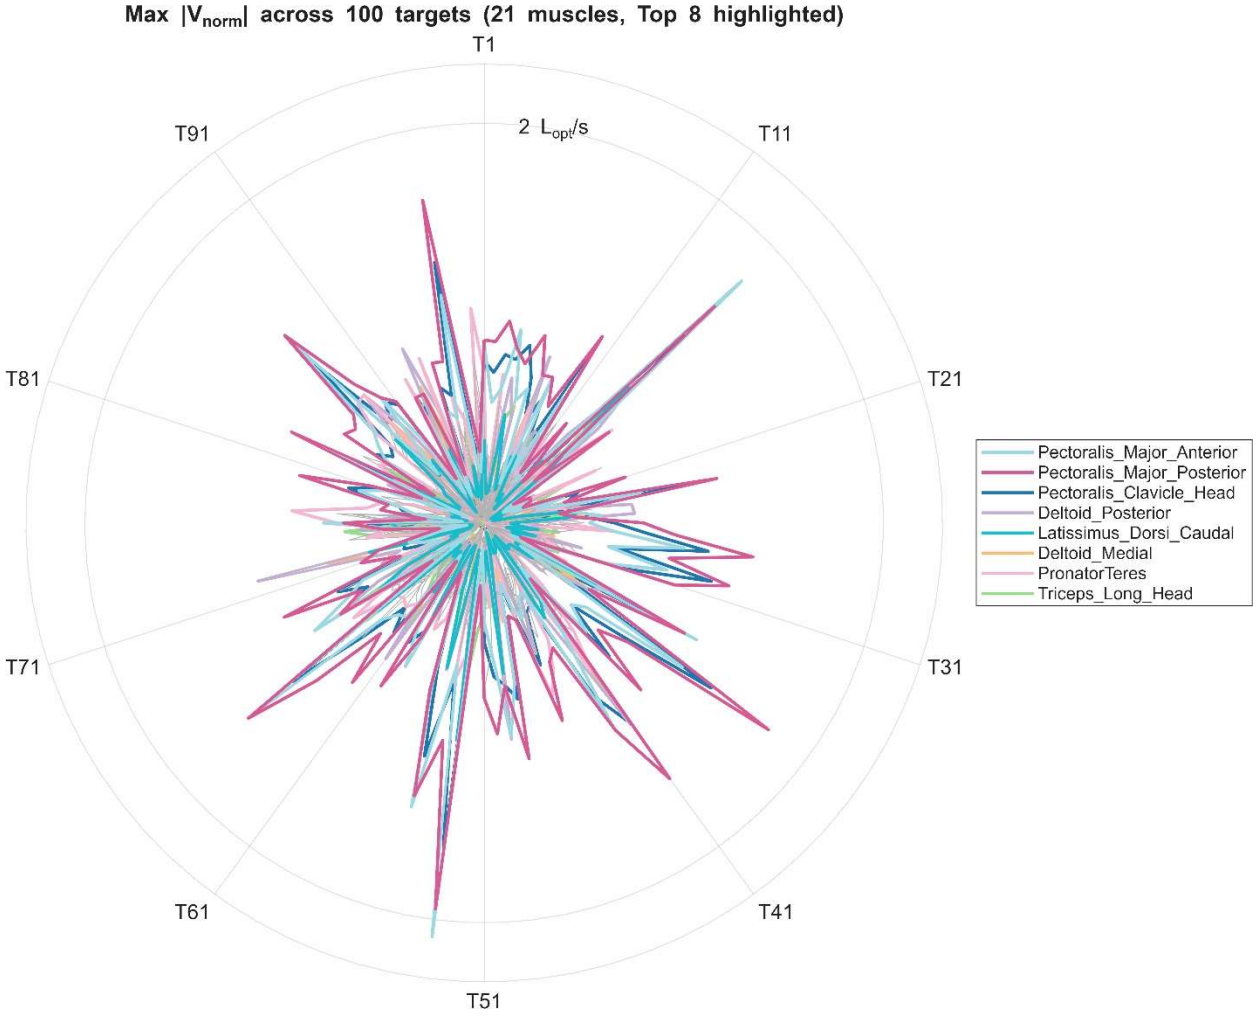
The fusimotor system is critical for limb movement[3]. Murine models help understand mismodulation of stretch reflexes relevant to spasticity in neurological conditions such as stroke[1]. Therefore, there is a need to quantify fascicular velocities for the mouse forelimb to inform experimental protocols for muscle mechanics[2].

Methods

Our computational model of the murine forelimb quantifies fascicular velocities for 3D center-out movements. We extended a 3D, 6-DOF, 21-muscle forelimb model[2] by adding wrist flexion-extension and radio-ulnar deviation in OpenSim 4.5, and reading out fascicular velocities via the Java API in MATLAB. 100 Monte Carlo simulations of 500-ms center-out movements spanned the 3-D workspace via quintic minimum-jerk S-curve trajectories from reference to target. Fascicular velocities were normalized to each muscles' optimal fiber length L_0. Additionally, we randomly perturbed each S-curve and L_0 by ±10%.

Results

Most simulated peak fascicle velocities across all muscles and targets were within ±1 L_0/s, and only 5 muscles surpassed 1 L_0/s. The fastest fascicle velocities consistently occurred within *Pectoralis Major, Latissimus Dorsi, Medial Deltoid,* and Flexor Carpi Radialis.



Our Monte Carlo analysis showed that <10% of perturbed trajectories exceeded 1 L_0/s. Varying L_0 by ±10% yielded modest variability in peak velocities (coefficients of variation ~6-7% for most sensitive muscles) suggesting our predictions are robust to muscle architecture.

Most importantly, we find that even center-out movements induce some muscles to have fascicular velocities that switch between eccentric and concentric velocities, as has also been predicted in humans and non-human primates[3].

Discussion

Murine experimental paradigms to understand fusimotor regulation of reflexes in the forelimb must identify both movement targets to use, and muscles to record from. Our study identifies both, and also shows that fascicular velocities are relatively slow for 500 ms movements. We also confirm predictions that 3D forelimb movements induce target-dependent complex fascicular velocities that are useful to study the fusimotor system.

Scaling Knee Kinematics: Beyond Sex and Size—Toward Shape-Based Insights

Dr. Morgan J. Dalman Ph.D.[1], Dr. Emily M. McCain Ph.D.[2], Mr. Brendan S. Shea[1], Ms. Emma R. Swartz[1], Dr. Silvia S. Blemker Ph.D.[1,2]

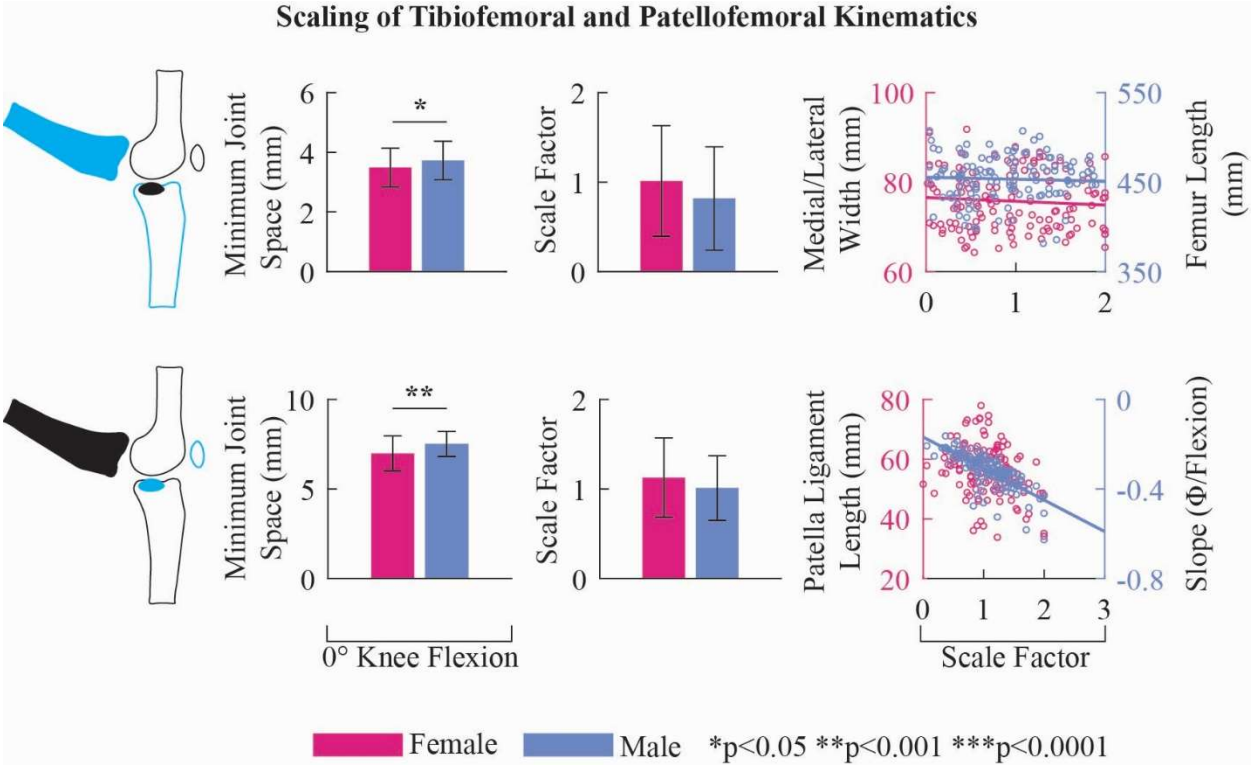
[1]University of Virginia, Charlottesville, VA, United States. [2]Springbok Analytics, Charlottesville, VA, United States

Introduction

Musculoskeletal models typically rely on standardized assumptions for joint positioning, limiting subject-specific accuracy. Current scaling techniques are size-based, assuming larger bones require proportionally larger shifts in positioning. Because bone size often differs by sex, these methods impose sex-related differences without accounting for actual kinematic variation. For example, tibiofemoral (TF) kinematics defined by Walker et al. (1988)[1] were derived from 23 cadaveric knees of unknown sex, while patellofemoral (PF) kinematics from Van Eijden et al. (1986)[2] were based on 10 male cadaver knees. This study investigates whether scaling factors for knee kinematics differ by sex and if they relate to size-based metrics commonly used in musculoskeletal modeling.

Methods

Subject-specific knee models (N = 69; 38F/31M; 27.5 ± 7.3 years) were generated for both limbs from three-point Dixon Sequence MRI scans. Scans were processed using an AI-based segmentation pipeline with manual validation (Springbok Analytics, Charlottesville, VA). Models incorporated Walker's tibiofemoral coordinate system and Van Eijden's patella model, which relate patella position to the angle (ϕ) between the tibial axis and patella ligament. Segmented TF and PF joint spaces were calculated at 0° flexion, and optimized scaling factors minimizing joint space differences between 0° and 120° flexion were applied to translations and ϕ_{120}, respectively. Sex differences and correlations with size-based metrics were analyzed.



Results

Initial joint spacing differed significantly between sexes (TF: $p < 0.05$; PF: $p < 0.001$), but scaling factors did not (TF: $p = 0.06$; PF: $p = 0.09$). TF scaling factors showed no correlation with size-based metrics such as medial-lateral width ($R^2 = 0.00$; $p = 0.37$) and femur length ($R^2 = 0.00$; $p = 0.55$). PF scaling factors were weakly related to patella ligament length ($R^2 = 0.09$; $p < 0.001$), but strongly influenced by the slope of ϕ versus knee angle ($R^2 = 0.57$; $p < 0.0001$).

Discussion

These findings demonstrate that current-sized based scaling assumptions do not solely explain kinematic scaling and sex differences are not a determining factor. Instead, they highlight the need to explore shape-based drivers in future work.

Towards a Patient-Specific Finite Element Model to Simulate 3D Orthodontic Tooth Movement During Leveling Phase

Mr. Mouhamad ABOU HAMDAN [PhD Student][1], Dr. Siham TOUCHAL [Associate Professor][1], Dr. Hamdi JMAL [Associate Professor][1], Dr. Delphine WAGNER [Associate Professor][1,2,3]

[1]ICube Laboratory, UMR 7357 CNRS, Mechanics Department, University of Strasbourg, Illkirch, Grand Est, France. [2]Pôle de médecine et de chirurgie bucco-dentaire, structure interne d'orthopédie dento-faciale, Strasbourg, Grand Est, France. [3]Faculté de chirurgie dentaire, Université de Strasbourg, Strasbourg, Grand Est, France

Introduction

During leveling phase, orthodontists use a sequence of superelastic Nickel-Titanium (NiTi) archwires chosen largely by clinical expertise for their light forces that drive bone remodeling and then teeth movement.

This study develops a patient-specific 3D FE model to simulate Orthodontic Tooth Movement (OTM) during the alignment phase and quantifies the loads applied by an initial NiTi archwire on individual teeth.

Methods

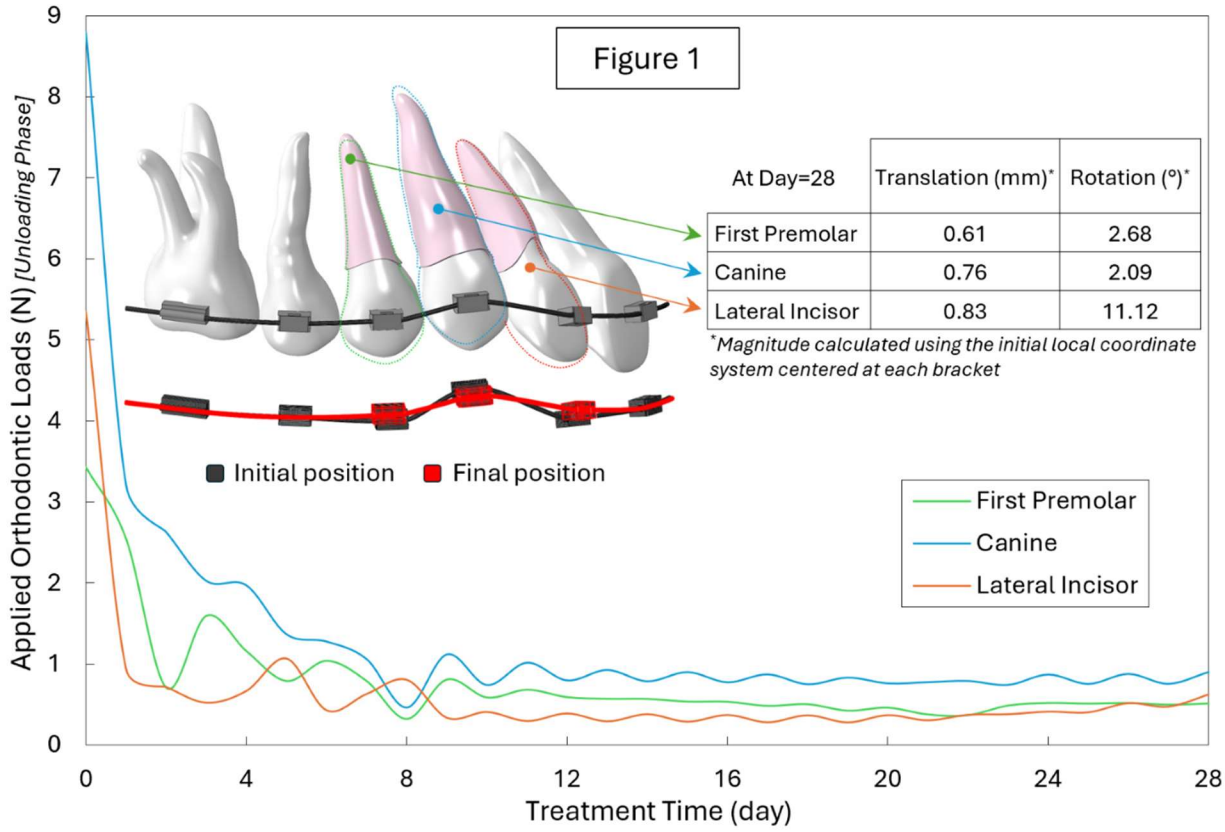
Passive self-ligating brackets and the ideal 0.016” archform were positioned on the upper right teeth reconstructed from CBCT scans. Only the lateral-incisor, canine, and first-premolar were allowed to move, while other were considered fixed. Activation was achieved by displacing the brackets already fitted in the wire to their prescribed positions on misaligned teeth, mainly characterized by 3 mm intrusion of the canine, enforcing symmetry at the wire midline.

The one-month treatment phase, automated in ABAQUS® using Python, followed two steps: first, importing the activated wire and loads to generate initial periodontal ligaments deformation within the corresponding reconstructed bone. Second, applying an external bone remodeling model [1], to update and remesh the geometry daily, repeating the process while re-importing the archwire iteratively.

Results

At treatment onset, the archwire slid through the bracket slots as the teeth began to move, resulting in a rapid decay of the initial applied forces. By around day 9, the forces reached

near stable values, remaining higher on the canine and lower but comparable on the adjacent teeth (see *Figure 1*).



As shown in *Figure 1*, these forces resulted in extrusion of the canine and intrusion of the neighboring teeth, contributing to early arch leveling, while also generating pronounced buccolingual tipping of the lateral-incisor and a milder opposite tipping in the first-premolar.

Discussion

Despite being based on patient-specific anatomy and limited to the movement of three-teeth segment, the predicted displacement magnitudes over 28-days induced by the light and stable forces align with the lower bound of clinical OTM rates reported in [2].

Future work will investigate different NiTi archwire sequences until the teeth reach almost same vertical level to optimize treatment strategies during the leveling phase.

Journey of Geometries: Variability of Knee Joint Segmentation in a Consensus Workflow

Ms Nancy Kim[1], Ms Kate Moyle[1], Ms Maryam Nazem[2], Mr Peter Laz[2], Mr Jason Halloran[3], Mr Carl Imhauser[4], Ms Snehal Chokhandre[5], Mr Ahmet Erdemir[5], Mr Thor Besier[1]

[1]Auckland Bioengineering Institute, Auckland, Auckland, New Zealand. [2]University of Denver, Denver, Colorado, United States. [3]Washington State University, Spokane, Washington, United States. [4]Hospital for Special Surgery, New York, New York, United States. [5]Cleveland Clinic, Cleveland, Ohio, United States

Introduction

Context-of-use and modelling decisions lead to variability in computational models of the knee. Our KneeHub project has shown that modelling decisions and methodological choices lead to divergent model outputs, reducing consistency and credibility for clinical use. Accurate representation of the joint tissues is a critical first step in generating a computational knee joint model, involving segmentation, smoothing, meshing, and defining anatomical coordinate systems. This study quantified variability across three independent groups at each step of constructing the geometries of the same knee, to support the development of a consensus workflow for computational knee model generation.

Methods

Three inexperienced modellers performed repeated segmentation of MR images of the same knee, each using different software. Smoothing and meshing was then performed by each group. For each processing step, intra- and inter-variability were quantified using the mean absolute distance, root-mean-square distance, Hausdorff distance, mean signed distance, and the corresponding standard deviation computed between two meshes of the same anatomy.

Results

All mean differences observed across the segmentation and meshing steps were below the twice the image resolution of 0.3125 x 0.3125 x 0.6 mm. Varying the number of image slices, performed by a single modeller, produced similar results, with an average absolute mean difference of 0.35 mm across slice-number conditions. The influence of smoothing was minimal, with mean absolute distances below 0.001 mm and a Hausdorff distance of

0.011 mm. The absolute mean difference between the raw mesh and the final mesh was 0.003 mm.

Discussion

Intra- and inter-modeller variability in knee joint segmentation remain within the expected range—below twice the image resolution[TB1] . However, some regions with larger differences may still influence downstream modelling outcomes (Figure 1). Clear documentation describing how each anatomical structure is segmented, along with information about the underlying algorithms and software tools, is essential for repeatable and accurate model generation. The values found from this study can vary depending on the algorithm and the degree of smoothing applied. Future work will quantify differences in coordinate systems and analyse their relationship to mesh-derived variability in computational knee models.

Images (Optional)

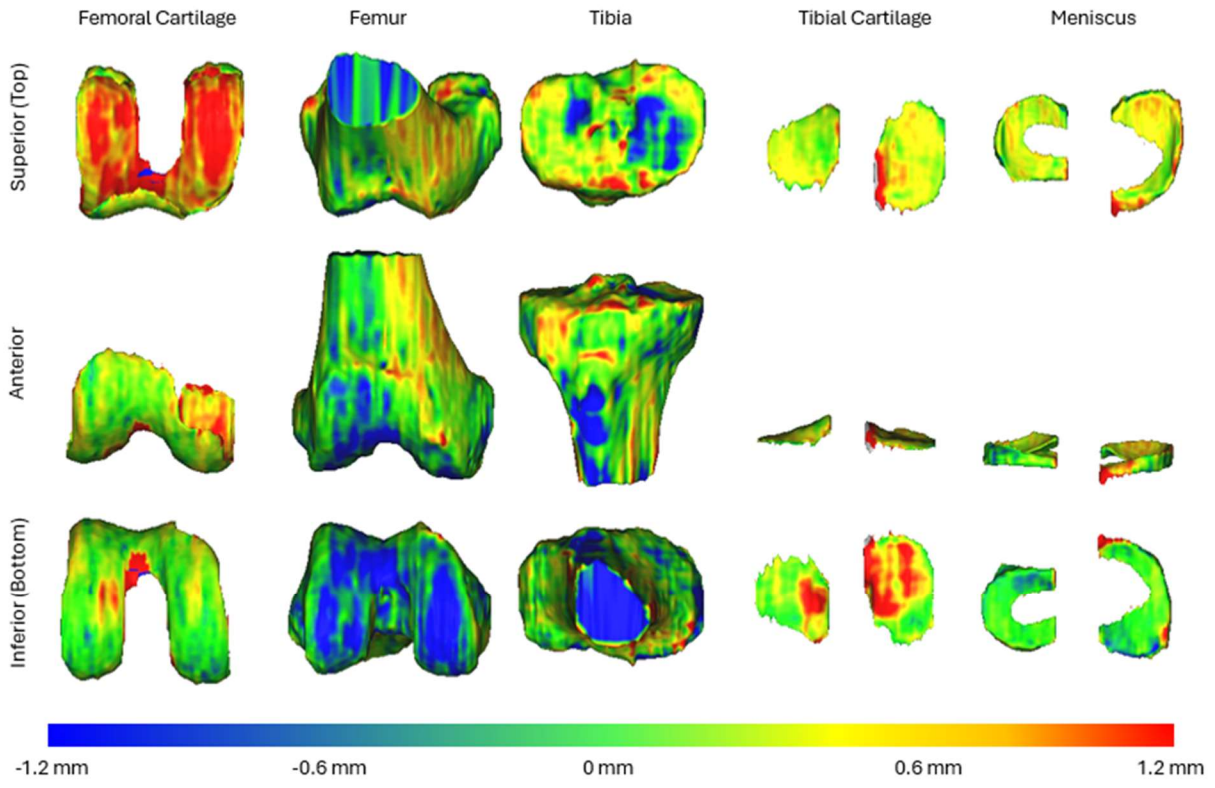

Figure 1. Signed differences between two independent knee segmentations shown across three anatomical views. Colour scale (in mm) indicates the magnitude and direction of differences, with the corresponding bar displayed at the bottom.

Within-Day Repeatability and Between-Day Reliability of Estimates of Second Metatarsal Bone Stress During Running

Ms. Naomi Frankston MS[1], Dr. Matthew Ellison PhD[2], Dr. Dominic Farris PhD[2], Dr. Hannah Rice PhD[1]

[1]Norwegian School of Sport Sciences, Oslo, Oslo, Norway. [2]University of Exeter, Exeter, Devon, United Kingdom

Introduction

Runners have a high prevalence of bone stress injuries in the foot, particularly in the second metatarsal. Quantifying internal bone stress during running is important for understanding risk of bone stress injury. Bone stress can be estimated using beam theory modeling of experimental data, but it is unclear how repeatable and reliable this approach is.

Methods

Twenty-eight female and male participants ran barefoot overground at their preferred speed while kinematics, pressure data, and ground reaction forces were recorded. At least five trials were collected at the same running speed (±5%) during laboratory visits on two different days, a mean (SD) of 21 (26) days apart (range: 1 – 139 days). Bone stress was calculated using a two-dimensional beam theory model of the second metatarsal using average bone geometries. Distances between skin-mounted metatarsal markers were calculated from static trials to allow assessment of methodological reliability independent of the reliability of running technique. Within-day trial-to-trial repeatability was assessed using an interclass correlation coefficient (ICC) and averaged over test days. Between-day reliability was assessed using ICC and standard error of measurement, defined as SD * $\sqrt{}$(1 – ICC), reported as a percentage of the mean value.

Results

Within-day between-trial repeatability was excellent (ICC > 0.9) for peak dorsal stress and peak whole body vertical ground reaction force and good (ICC: 0.75 – 0.9) for peak vertical force under the second metatarsal and second metatarsal pitch angle at the time of peak stress (Table 1). Between-day reliability was excellent for peak second metatarsal dorsal stress, peak vertical force under the second metatarsal, peak whole body vertical force, and second metatarsal pitch angle. Between-day reliability was moderate (ICC: 0.5 – 0.75) for second metatarsal length measured from skin-mounted markers, distance between the

first and second metatarsal head markers, and distance between the first metatarsal head and second metatarsal base markers.

Discussion

The experimentally obtained model inputs and peak second metatarsal stress output demonstrated excellent within-day repeatability and between-day reliability, despite moderate between-day marker placement reliability. Therefore, the model appears robust to repeat measurements of the same running condition but its sensitivity to detect true changes in stress between conditions may be limited.

Images (Optional)

Table 1: Within- and between-day intraclass correlation coefficients (ICC) for variables of interest and standard error measurement (SEM) as a percentage of the mean value.

Variable	Within-Day Mean ICC	Between-Day ICC	SEM (%)
Peak Second Metatarsal Dorsal Stress	0.923	0.934	6.2
Peak Vertical Force under Second Metatarsal	0.886	0.979	2.8
Peak Whole Body Vertical Force	0.980	0.980	2.5
Second Metatarsal Pitch Angle at Time of Peak Stress	0.892	0.936	3.1
Second Metatarsal Length	---	0.656	5.9
Resultant Distance between First and Second Metatarsal Head Markers	---	0.621	6.1
Resultant Distance between First Metatarsal Head and Second Metatarsal Base Markers	---	0.579	5.8

Can a Virtual Exoskeleton Reflect Real Use? A Musculoskeletal Modeling Comparison

Ms. Negar Riahi, Mr. Niromand Jasimi Zindashti, Dr. Ali Golabchi, Dr. Mahdi Tavakoli, Dr. Hossein Rouhani

University of Alberta, Edmonton, AB, Canada

Introduction

With the growing variety of industrial back-support exoskeletons, assessing their effects for specific users and tasks is essential. Musculoskeletal modeling enables such evaluation, including parameters difficult to measure experimentally. While most studies use motion collected with the device, some apply virtual exoskeletons to no-exoskeleton motion data of participants. This faster approach still requires evaluation to ensure it yields outcomes comparable to real exoskeleton use. This study examines that feasibility by comparing modeling outcomes from exoskeleton trials with those produced by applying a virtual exoskeleton to no-exoskeleton motion data.

Methods

Two participants performed lifts of 5, 10, and 15 kg from the ground to hip height under no-exoskeleton and BackX exoskeleton conditions, randomized and repeated three times. Motion was captured with nine Vicon cameras and ground reaction forces with two OR6-7 force plates. Motion modeling was performed in OpenSim to acquire joint reaction forces. Exoskeleton support was modeled as external forces on the chest and thighs (Method 3 in [1]). For the virtual-exoskeleton condition, no-exoskeleton motion data were used to simulate exoskeleton support. In both virtual-exoskeleton and exoskeleton conditions, supporting torque was computed from trunk and thigh angles. Total L5-S1 joint reaction forces were compared using Sprague and Geers curve magnitude (*M*), phase (*P*), and Comprehensive Error Factor (*C*) [2]. Peak L5-S1 loading errors during lifting and lowering were also computed and normalized to peak loading in the exoskeleton condition.

Results

As shown in Table 1, *C* ranged from 6.7 to 11.4% across loads. Normalized peak L5-S1 loading differed by 5.5–16.0% in lifting and 6.8–18.7% in lowering.

Discussion

Overall, the virtual exoskeleton showed small magnitude and phase differences relative to the real exoskeleton but consistently underestimated support, reflected by higher estimated loads (positive *M*). Agreement was lowest at 5 kg, with higher *C* values and larger normalized peak loading errors. While these initial results suggest reasonable agreement between virtual and real exoskeleton modeling (*M*/*P*/*C* values <20%), future studies should include more participants to permit statistical analysis and fully assess the feasibility of modeling a virtual back-support exoskeleton.

Images (Optional)

Table 1. Comparison of the virtual-exoskeleton and exoskeleton modeling approaches based on total L5-S1 joint reaction force. Metrics include curve magnitude (M), phase (P), and Comprehensive Error Factor (C), where 0 indicates identical curves. Peak L5-S1 loading errors during lifting and lowering phases are also shown, normalized to the peak loading in the exoskeleton condition. All values are presented as mean (SD).

Lifted weight	*M* (%)	*P* (%)	*C* (%)	Normalized Peak Load Error - Lifting (%)	Normalized Peak Load Error - Lowering (%)
5 kg	6.4 (5.2)	8.1 (4.6)	11.4 (0.3)	16.0 (0.3)	18.7 (5.5)
10 kg	7.2 (1.6)	6.7 (0.8)	9.9 (0.6)	5.6 (4.6)	6.8 (8.6)
15 kg	4.7 (1.0)	4.4 (2.4)	6.7 (0.9)	5.5 (7.2)	9.8 (0.3)

[5]Walter Reed National Military Medical Center, Bethesda, MD, United States

Introduction

Ankle-foot orthoses, such as the Intrepid Dynamic Exoskeletal Orthosis (IDEO), are commonly prescribed to overcome gait deficiencies following mild to severe lower-extremity injury. IDEO devices provide mediolateral support with rigid footplates that limit ankle range-of-motion (ROM), energy storage-and-return via posterior strut, and offload the affected limb through a proximal cuff. While physical function is restored, movement compensations are necessary while using IDEO devices. The objective of this study was to understand the biomechanical effects of altered movement strategies using an IDEO.

Methods

A baseline OpenSim model with right lower-limb musculature, reserve actuators for joints without musculature, and ground-contact was scaled to one subject. An IDEO device was additionally modeled by limiting ankle ROM and adding passive rotational stiffness to the ankle joint, defined from mechanical testing. Baseline and IDEO models tracked a running stance phase using OpenSim Moco (tracking kinematics and ground reaction forces while minimizing squared muscle activity). Kinematics and joint reaction forces (JRF) were compared from both solutions.

Results

Compared to baseline, IDEO use altered movement patterns during running stance (Figure 1a-d). Specifically, increasing hip and knee flexion, decreasing anterior pelvic tilt, and increasing forward trunk lean. The IDEO model also showed decreased resultant JRF across all joints (Figure 1e,f,h). However, mediolateral knee JRF increased using the IDEO (Figure 1g). Changes in joint loading were driven by reduced vertical JRF, no other significant JRF changes were observed.

Discussion

The simulated IDEO recreated commonly observed movement pattern adaptations, notably increasing the hip/knee flexion to act as a shock absorber due to limited ankle ROM. These preliminary results also indicate that the simulated IDEO reduced resultant joint loading in the stance limb. However, the increased mediolateral JRF could be demonstrative of increased risk for potential injury that warrants further investigation. Our future work will incorporate muscle forces, joint loading, and kinematics into a finite element modeling pipeline to determine tissue-level changes from IDEO device use during running and better understand potential deleterious effects of altered mediolateral JRF. Additionally, we will expand the IDEO model to include passive stiffness of the cuff as well as the unloading interaction between the cuff and tibia.

Quantifying the Biomechanical Effects of Muscle Strength Asymmetry during Running Using Optimal Control and Probabilistic Analyses

Dr. Nicholas Vandenberg[1], Dr. Anup Pant[1], Dr. Sarah Shaffer[1], Ms. Julia Gambill[2,3], Dr. Pawel Golyski[4,5], Dr. Lee Childers[2,4], Mr. Travis Eliason[1], Dr. Daniel Nicolella[1]

[5]Walter Reed National Military Medical Center, Bethesda, MD, United States

Introduction

Musculoskeletal overuse injuries (i.e., tibial stress fractures (TSF)) are common during military, basic training. A relationship has been observed between weak ankle plantarflexors and TSF risk, but the effects of expanded muscle strength imbalances are not well understood. The objective of this study was to determine the effects of muscle strength asymmetry on TSF risk.

Methods

A scaled musculoskeletal model with right lower-limb musculature, reserve actuators, and a ground-contact set was used for a baseline running stance solution using OpenSim Moco (tracking kinematics and ground reaction forces (GRFs) while minimizing squared muscle activity). Five asymmetry scale-factors were defined for antagonist muscle groups (hip flexor/extensors, abductor/adductors, internal/external rotators; knee flexor/extensors, and ankle plantar/dorsiflexors). 100 perturbed models were created by sampling these scale-factors using a normal distribution (mean = 1, std = 0.1) with Latin Hypercube Sampling. Perturbed models tracked the same running stance phase in Moco with 84/100 terminating normally. Variability of simulation outputs (namely: hip flexion, knee flexion, ankle angle, and knee vertical joint reaction force (JRF)) were quantified using mean ± SD trajectories and percentile envelopes, and linear regression was used to explain peak outcome variability related to asymmetry scale-factors.

Results

Knee flexion and JRF demonstrated the largest variability (Figure 1b,d). Regression analyses showed that muscle asymmetry explained 93% of knee flexion variance and 81% of knee JRF variance, which was primarily driven by asymmetry in the ankle plantar/dorsiflexor and

knee flexor/extensor musculature. Hip flexion and ankle angle were largely insensitive to muscle asymmetry (Figure 1a,c).

Discussion

Distal muscle asymmetry had the largest influence on knee kinematics and joint loading, with hip and ankle motion comparatively insensitive. These preliminary results suggest that even small functional imbalances in ankle and knee musculature can meaningfully alter knee joint loading during running, which may have implications for increased TSF risk. Future work will incorporate muscle forces from perturbed models and resulting movement and joint loading to evaluate tissue-level effects from muscle asymmetry within a finite element modeling pipeline to better understand the relationship between muscle asymmetry and risk of TSF.

Images (Optional)

Influence of Regional Thoracic Curvature on Underband Pressure in a Sports Bra

Dr Nicole Yvette Kelp PhD[1], Dr Adrian Lai PhD[2], Ms Ishi Arora[2], Ms Olga Radivojevic[2], Ms Vivian Nguyen MSc[2], Dr Michael Asmussen PhD[1]

[1]Vancouver Island University, Nanaimo, BC, Canada. [2]lululemon, Vancouver, BC, Canada

Introduction

Approximately 43–85% of women wear the wrong size bras or experience fit issues despite professional sizing [1]. This highly prevalent issue is particularly evident at the underband, where excessive or uneven pressure can cause discomfort, chafing, digging, and breathing restrictions [2,3]. Limited fit education, reliance on online sizing tools, and the assumption that the torso can be described solely by circumference, likely contributes to these persistent fit issues as female thoracic morphology is highly variable [2,4]. A mismatch exists between body geometry, bra structure, and traditional sizing metrics. This study aimed to determine how three-dimensional underbust morphology influences underband pressure distribution.

Methods

Twelve female participants (sizes 32B–34D/36C) wore a professionally sized compression sports bra with an elastic underband. Mean curvature (m-1) at fourteen standardized regions around the underbust was calculated with a neighborhood radius of 0.03 m from segmented three-dimensional body scans (Figure 1). Underband pressure (Kikuhime) was measured at peak inhalation in the same underbust regions.

Results

Using linear mixed effects models, mean curvature and underbust region were strong predictors of maximum underband pressure, with no interactions. Higher local curvature was associated with significantly greater inhalation pressure ($\beta = 0.92$ mmHg per 1 m^{-1}, $p < 0.001$), indicating that more curved regions of the ribcage experienced consistently higher loading. Pressures were highest in the lateral and posterolateral regions and lowest at anterior sites, with notable asymmetry on the anterior ribcage. Across participants, pressures varied by 8–12 mmHg depending on location, demonstrating substantial individual and regional variability.

Discussion

Curvature-driven pressure differences underscore the importance of thoracic morphology in determining underband pressure. Quantifying regional curvature adds an objective measure of shape that complements traditional size and circumference metrics and helps to explain observed differences in fit and comfort among same-size wearers [2]. Future work should include more diverse bra styles, body size, and bra regions to enhance its applicability.

Images (Optional)

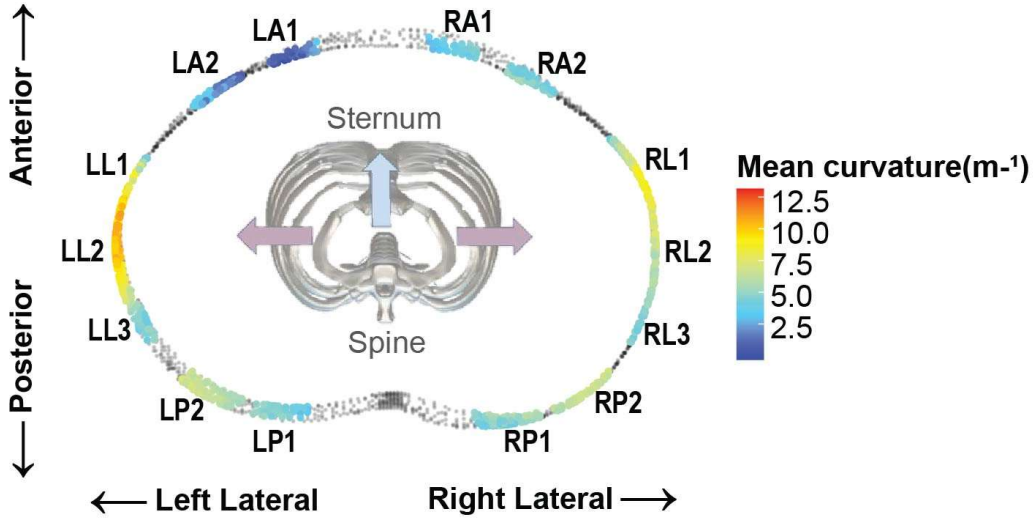

Figure 1. Superior view of a thoracic cross-section derived from 3D body scans. Scalar-field colormaps illustrate regional mean curvature across the fourteen underbust regions: left/right anterior (LA1–2, RA1–2), left/right lateral (LL1–3, RL1–3), and left/right posterior (LP1–2, RP1–2). Example shown for Subject 1.

Beyond Anthropometric Scaling: Improving Spinal Load Prediction via Machine Learning-Derived Muscle Parameters

Mr Nima Ashjaee, Dr. Sidney Fels, Dr. John Street, Dr. Thomas Oxland

University of British Columbia, Vancouver, BC, Canada

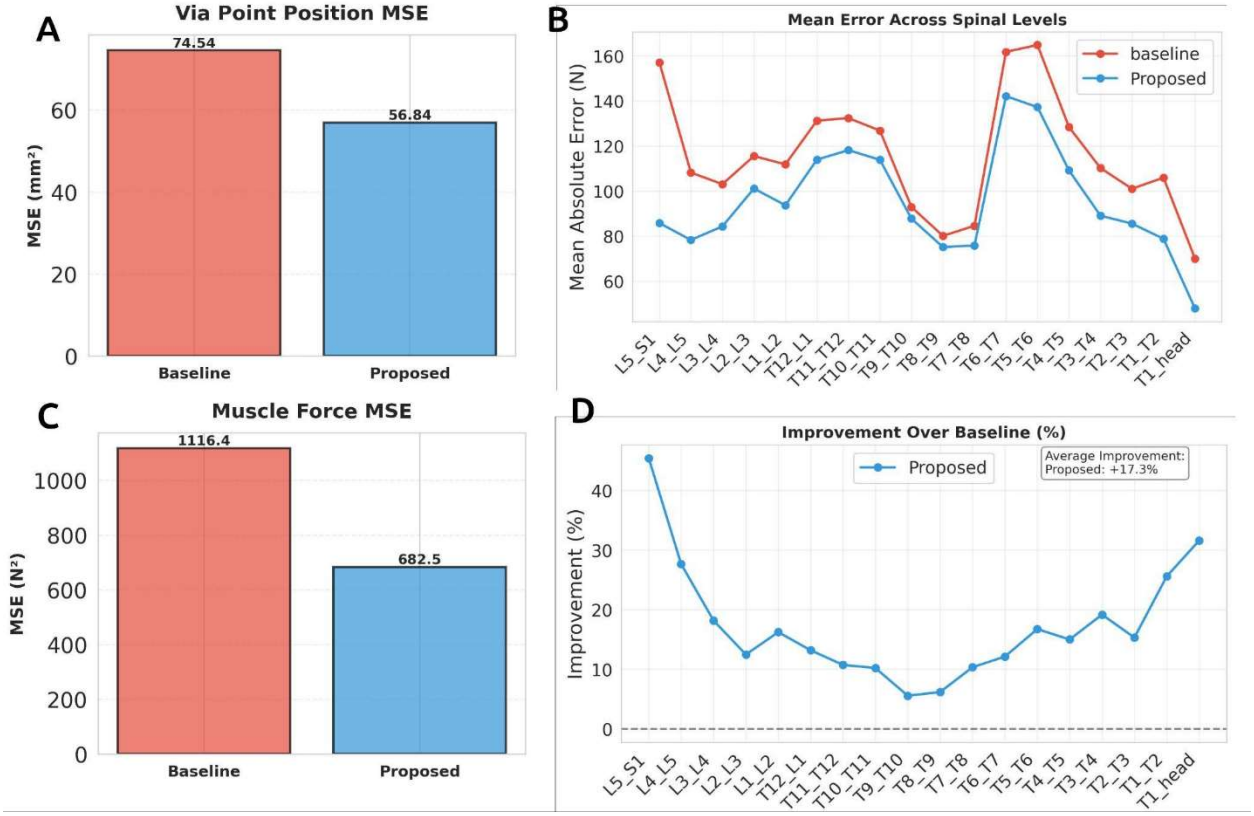
Introduction

Subject-specific musculoskeletal (MSK) models are increasingly used to study spinal biomechanics and adult spinal deformity [1]. However, clinical adoption is limited by the difficulty of obtaining individualized soft-tissue properties. Vertebral geometry can be obtained from biplanar radiography, but muscle geometry or force capacity typically require CT/MRI. Current practice scales generic models using height and mass, which introduces substantial error [1,2]. Here, we show that machine-learning models can predict subject-specific muscle geometry and force capacity from readily available spinal geometry and demographic features, improving downstream MSK load prediction by 17%.

Methods

We used 250 subject-specific thoracolumbar models [3] in OpenSim following established research [1]. Inputs included age, sex, height, weight, and 3D coordinates of 17 vertebrae. Two muscle parameters most influencing loading [2] were targets: maximum-isometric-force (575 muscles) and geometry-path (4008 points). Two data-conditioning strategies were evaluated: a Native-Data workflow (inputs used directly) and an Anthropometrically-Normalized workflow (inputs normalized by height/weight). Within each workflow we evaluated Random Forests, Multi-Layer Perceptrons, and a Hierarchical Autoencoder. The best models were then used to generate pseudo-subject-specific MSK models. For every subject, three variants were simulated: (i) Ground-Truth (CT-derived), (ii) Baseline height/weight scaling, and (iii) our Proposed model. Ten static postures were simulated and intervertebral compression was computed with Static Optimization.

Results



A hybrid approach performed best: Random Forests (Native-Data) for maximum-isometric-force and the Autoencoder (Normalized) for geometry-path. Compared to conventional scaling, the Proposed method reduced Mean-Square-Error in via-point positions (56.84 vs. 74.54 mm^2; Fig 1a) and maximum-isometric-force (682 vs. 1116 N^2; Fig1b). These improvements yielded more realistic spinal loads: the Proposed model reduced compressive-force error at all spinal levels (Fig 1c) and improved accuracy by 17% on

average. The largest gains occurred at the cranial and caudal extremities, with smaller but consistent benefits in the mid-thoracic spine (Fig 1d).

Discussion

Predicting subject-specific muscle geometry and force capacity from available imaging improves anatomical fidelity and downstream load prediction. This approach may enable subject-specific MSK modeling in settings where soft-tissue imaging is unavailable.

Sensitivity of Hill-Type Muscle Parameters to Joint-Moment Capacity During Walking, Running, and Sprinting

Student Nozomu Tanaka MSc[1], Associate Professor Stacey Meardon PhD[2], Professor Timothy Derrick PhD[1]

[1]Iowa State University, Ames, Iowa, United States. [2]East Carolina University, Greenville, North Carolina, United States

Introduction

Musculoskeletal models with Hill-type muscles are widely used to estimate muscle forces during human movement. These models work well for walking, but several studies have noted that some muscle parameters must be adjusted to generate sufficient force for running activities. Although such modifications can reduce apparent moment deficits, the sensitivity of each parameter remains unclear. This study investigated the impact of maximum isometric force (F_{iso}), maximum contraction velocity (v_{max}), and tendon compliance (ε^{T}_{o}) on joint-moment capacity during walking, running, and sprinting.

Methods

Thirteen healthy adults performed overground walking, running, and sprinting at target speeds of 1.5, 3.5, and 5.5 $m \cdot s^{-1}$. Three-dimensional kinematics were captured using an eight-camera Qualisys system, and ground-reaction forces were recorded with six Bertec force plates embedded in the floor. Joint-moment capacities were the maximum torque a joint can produce in a given direction. They were estimated using OpenSim Gait2392 with the Thelen2003 muscle model by summing moments about the joint axes from each crossing muscle's maximum force (based on muscle length and contraction velocity) and its moment arm, assuming maximal agonist activation and no cocontractions. Functional Demand (FD) was defined as the ratio of the experimental joint moment to the modeled moment capacity. Sensitivity analyses were performed by scaling F_{iso} (1×, 2×, 6×), increasing v_{max} (10, 15, 20 $l_0 \cdot s^{-1}$), and modifying ε^{T}_{o} (1×, 2×, 3×).

Results

During walking, joint-moment capacities estimated with default parameters exceeded actual joint moments (FD < 1). During running and sprinting, the model underestimated capacity, with the largest deficit seen for ankle plantarflexion during sprinting at push-off (FD ≈ 5.5). Increasing F_{iso} reduced FD proportionally, yet achieving FD ≤ 1 at push-off required roughly a six-fold increase. Increasing v_{max} to 20 $l_0 \cdot s^{-1}$ reduced FD to about 1.7 but did not resolve the plantarflexion deficit. Changes in ε^{T}_{o} had a minimal effect at push-off.

Discussion

Sensitivity analysis revealed that parameter tuning enhanced joint-moment capacities; however, the effects were limited and often required parameter values outside physiological ranges. These results indicate that tuning alone cannot fully address the moment deficits observed during high-speed locomotion. Additional factors beyond simple parameter adjustments may need consideration to improve model performance.

Quantitative Determination of the Sample Size Required for Modeling Anatomical Variation of the Human Knee Joint in a Population

Mr. Nurkeldi Iznat, Prof. LePing Li Ph.D.

University of Calgary, Calgary, Alberta, Canada

Introduction

Statistical shape modeling (SSM) is essential for characterizing population-level variability in knee geometry, providing insights that inform joint function. In studies involving SSM, it is common to select 6–10 principal components (PCs) to form the basis for subsequent analyses. Nevertheless, no standard procedure yet exists to evaluate the stability of modes associated with PCs and determine the sample size required to adequately represent a population. The objective of this study was to determine the number of knee samples required to characterize knee joint anatomical variation within a target population.

Methods

A published method based on left-ventricle synthetic datasets [1] was adapted for our tibiofemoral joint models, incorporating all cartilages and menisci. Sample sufficiency is indicated when the number of stable modes, m, converges as the sample size grows. We started to evaluate whether 71 knee samples were sufficient to model the male population of European ancestry by determining m for n samples (n = 31, 41, 51, 61, 69). For example, given n = 31, 500 subsets were generated from the 71 samples via bootstrapping, with each subset containing 31 knees with possible replications. Stable modes were identified by comparing the PCs from each subset with that derived from the full 71-knee dataset, using a one-tailed t-test against Gaussian noise. If m does not converge by 71 samples, the procedure must be repeated with a larger sample size to determine the required sample size.

Results

Stable modes were identified for each subset using quantitative analysis. Their number, m, failed to converge (Fig. 1a), and the high-dimensional PC directions remained divergent (Fig. 1b). Therefore, 71 knee samples were not adequate to represent the target population. A speculative curve-fit indicated that 100 or more samples may be required.

Discussion

The tested method may establish a rigorous criterion for mode retention in SSM. Subsequent analyses, including finite element simulations, should rely solely on the stable

modes. We are verifying the number of subsets required to accurately identify the stable modes. Larger sample sizes will then be used to determine the number of knees required for the population.

Images (Optional)

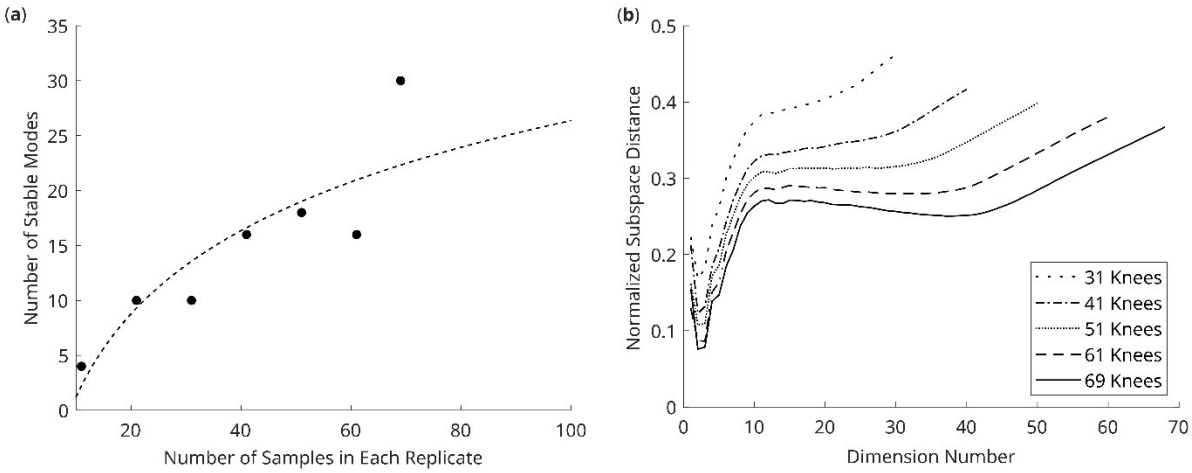

Figure 1. (**a**) Number of stable principal modes at each sample size ($p \leq 0.05$). (**b**) Average difference between the PC space of the full 71-knee dataset and the PC spaces obtained from fewer number of samples. Larger values mean the subset produces PC directions that differ more from the full dataset.

Body position and instruction paradigm independently influence measures of pelvic floor function obtained with ultrasound imaging and intravaginal dynamometry

Ms. Olena Klahsen MSc, Dr Linda McLean PhD

University of Ottawa, Ottawa, Ontario, Canada

Introduction

Symptoms of pelvic floor disorders (e.g., urine leakage) can be attributed to dysfunction of the pelvic floor muscles (PFMs), whereby they are unable to support the pelvic organs or stabilize the urethra. Assessment of PFM function is commonly conducted using ultrasound imaging (USI) and intravaginal dynamometry (IVD) during maximum-effort voluntary contractions (MVCs). Most studies report MVC outcomes recorded in a supine position, despite symptoms often being reported in upright postures. Instructions also vary among studies. We sought to determine how body position and an instruction paradigm involving contractile speed impact measures of female PFM function.

Methods

Fifty adult females were recruited and participated in a single laboratory session involving 2-dimenstional transperineal USI and IVD. For each modality, body position (standing vs. supine) and instruction paradigm (normal vs. rapid MVCs) were block-randomized with three trials performed under each condition. USI outcomes included baseline, peak and change in levator plate length and bladder neck height; IVD outcomes included baseline, maximum and relative peak (maximum – baseline) forces and rate of force development. Generalized linear mixed models were used to determine the effect of body position and instruction paradigm on each outcome (α=0.05).

Results

There was no interaction between position and instruction paradigm for any outcome. Main effects are presented in Table 1. Standing led to longer levator plate length and lower bladder neck height on USI, and higher baseline force, lower peak force and slower rate of force development on IVD. The rapid MVC instruction paradigm led to higher rate of force development on IVD but had no effect on other IVD or USI measures.

Discussion

Lower force and altered pelvic organ displacement on PFM contraction in the standing position relative to supine may contribute to symptoms being predominantly experienced where anti-gravity demands are higher. While efforts to contract the PFMs rapidly do not

impact organ displacement nor maximum force, instructions to perform the contraction as quickly as possible may be necessary to properly evaluate PFM power.

Sensitivity Study of Muscle Modelling in Rabbit Masticatory Simulations

Dr Linjie Wang[1], Dr Roger Kissane[2], Prof Karl Bates[2], Dr Graham Askew[3], Prof Michael Fagan[4], Dr Peter Watson[1]

[1]Institute of Medical and Biological Engineering, School of Mechanical Engineering, University of Leeds, Leeds, West Yorkshire, United Kingdom. [2]Department of Musculoskeletal & Ageing Science, Institute of Life Course and Medical Sciences, University of Liverpool, Liverpool, Merseyside, United Kingdom. [3]School of Biomedical Sciences, University of Leeds, Leeds, West Yorkshire, United Kingdom. [4]School of Engineering, University of Hull, Hull, East Yorkshire, United Kingdom

Introduction

Computational models assist in design/evaluation of biomedical experiments, thus supporting the principles of 3Rs of animals by reducing animal use in experiments. However, their accuracy often depends on knowledge of physiological muscle mechanics, which can create barriers for their implementation. This study investigated how 1) population variance in physiological muscle properties and 2) the level of complexity in modelling muscle dynamics, influences predicted masticatory forces in rabbits.

Methods

A subject-specific model of a rabbit was developed through combining MRI data, muscle contractile properties, and jaw movements (measured using XROMM) (Figure 1). Inverse and forward dynamics, combined with Hill-type muscle modelling, were used to simulate a maximum bite, and biting during chewing. Several iterations of the model tested the influence of: 1) population variation in muscle mechanics; 2) using literature-based muscle data (species and non-species specific); 3) complexity in muscle contractile dynamics, through sequentially reducing the input data in the muscle modelling. Models were validated by comparing the outputs to experimentally measured maximum bite force and *in vivo* muscle function.

Results

Compared to experimentally measured maximum bite forces, subject-specific modelling predicted a similar force (within 12.9%), whereas incorporating population variance resulted in larger forces (max. 24% greater). Greater differences (over 50%) occurred when using literature-based muscle contractile properties and simplified muscle modelling.

When simulating chewing, incorporating population variance predicted similar muscle activity of the superficial masseter muscle, to that of subject-specific modelling. Larger deviations were observed in other models, with predictions using literature-based muscle data activating later (max. 20ms) and for a longer duration (max. 36ms), while simplified muscle modelling predicted a greater peak activation (max. 40%) and a longer time to peak (max. 48ms).

Discussion

This study shows that modelling of the rabbit masticatory system should ideally incorporate subject-specific muscle data. While population-based data does not affect the outputs, species-specific data from the literature should only be used when more specific data are not available. Modelling using simplified muscle mechanics should be use with caution, as it overestimates muscle force and activity. In conclusion, these findings provide important considerations for developing in silico skull models for implant testing.

Images (Optional)

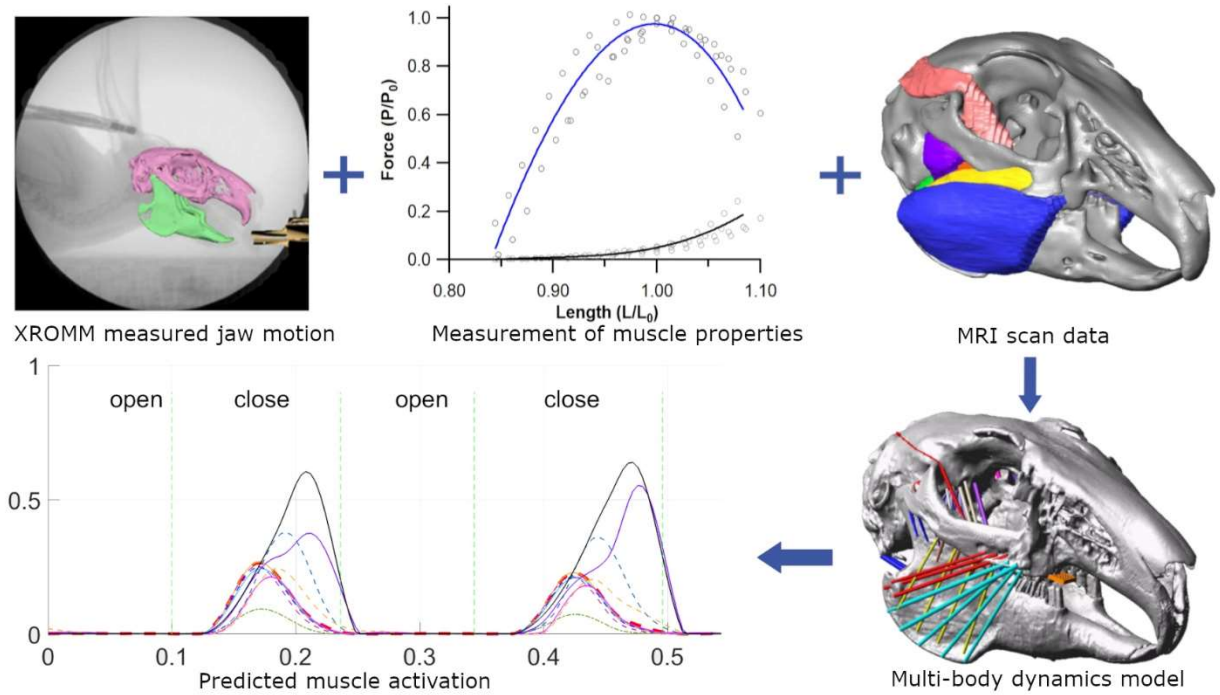

Figure 1. The experimental-computational framework used in this study: data analysis compared maximum bite forces and muscle activation profiles across several iterations of the model. The result graph shows the predicted muscle activity in model iterations, highlighting the difference in muscle activation when incorporating non-species-specific muscle contractile dynamics (dashed blue line) and when sequentially simplifying the complexity of the muscle modelling (solid purple line and solid black line).

Effects Of Changes in the Joint Center Location on Joint Biomechanics in Musculoskeletal Model Studies of Human Knee and Spine

Mr Pooya Salehi, Dr. Saeed Shirazi-Adl, Dr. Farshid Ghezelbash

Polytechnique Montreal, Montreal, Quebec, Canada

Mr Pooya Salehi

Dr. Saeed Shirazi-Adl

Introduction

Musculoskeletal (MS) model studies have emerged as viable and popular tools to estimate muscle forces and internal loads. Complex passive joints are idealized either as hinges or beams positioned at the joint geometrical center or center of rotation. The question is how sensitive are results to the joint simulation and location. We investigate the influence of changes in the joint modeling and location on detailed kinematics-kinetics and passive joint reaction moments. Both human knee and spine intervertebral joints are studied.

Methods

Finite element (FE)-MS models of the (1) lower limb, including a detailed knee and (2) trunk including deformable lumbar discs were employed. In the former, seated maximum voluntary contraction (MVIC) flexion/extension tasks at 30°, 60° and 90° knee flexion while in the latter, the trunk in the upright and flexed lifting were simulated. The position of the idealized joint was then shifted anteriorly or posteriorly to evaluate its effect on estimated muscle forces, tissue/ligament stresses, contact forces and joint passive reaction moments. In the trunk simulations, frictionless/frictional and beam idealizations were considered. Equivalent OpenSim (Gait2392) simulations were also carried out in knee MVIC extension.

Results

In all MS knee flexion/extension MVIC simulations when representing the knee with a complex FE model, passive knee (reaction) moments were highly sensitive to the location of the joint center whereas the muscle, ligament and contact forces remained unchanged

(Fig. 1). Muscle forces and internal loads, however, substantially altered at different joint centers when using an idealized joint (hinge or beam) in spine models during lifting. OpenSim also yielded high sensitivity to the joint center location (Fig. 1).

Discussion

Muscle forces and internal load distribution in knee and spine MS models substantially alter as the joint center at which moment equations are verified are altered. Results highlight the fundamental shortcomings in MS models that regularly idealize complex joints as frictionless at their center of rotation. This effect deteriorates in heavier tasks with larger reaction compression forces. As a remedy, either the joint should be represented by a detailed FE model or its passive stiffness properties be adjusted with location.

Images (Optional)

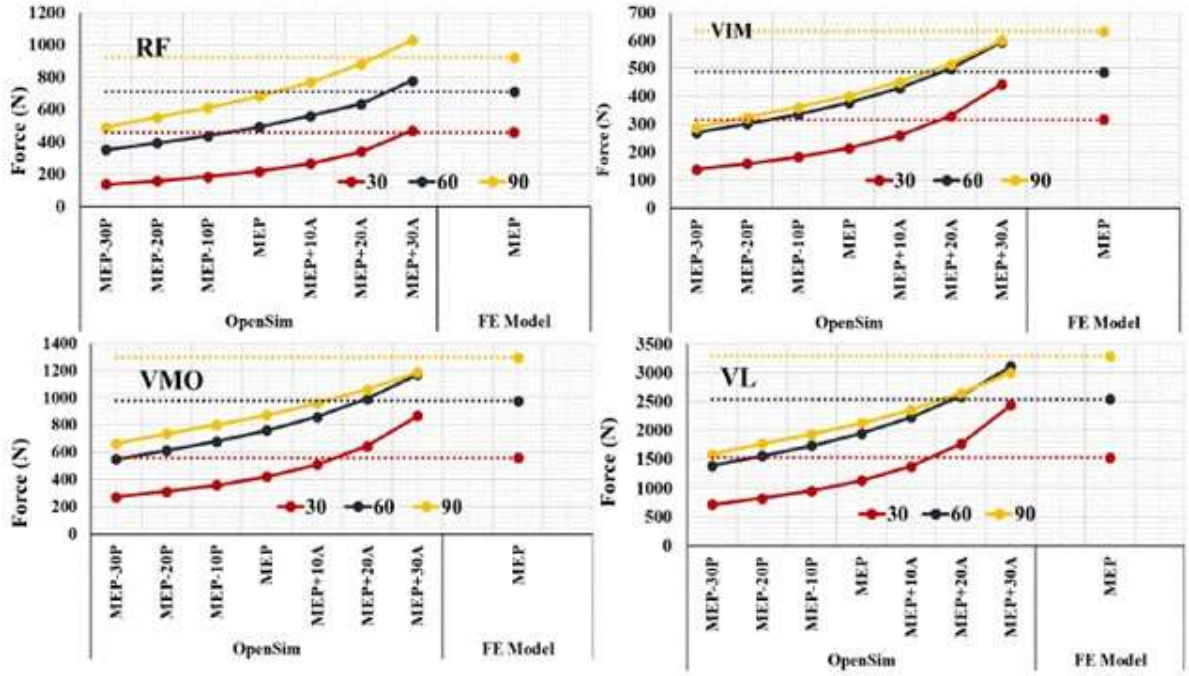

Figure 1 Comparison of quadriceps forces estimated by the OpenSim Gait 2392 model and our own FE-MS model as the joint center (placed at the mid epicondylar axis, MEP) is shifted in the anterior (A) and posterior (P) directions by up to 30 mm during MVIC extension simulations (under mean extension moments without co-activation constraints and with the resistance force applied 390 mm distal to the knee). Individual quadriceps forces in the MS-FE model remained unchanged irrespective of changes in the joint center location.

Computational biomechanics of human knee joint in maximum voluntary isometric exercises: Role of muscle coordination and resistant force lever arm

Mr. Pooya Salehi, Prof. Saeed Shirazi-Adl

Poytechnique Montreal, Montreal, Quebec, Canada

Mr. Pooya Salehi

Introduction

Knee maximum voluntary isometric contractions (MVIC) in flexion and extension are widely used to assess strength and rehabilitation programs, yet the muscle, ligament, and contact forces remain mostly unknown. A coupled finite element–musculoskeletal (FE-MS) model of the lower extremity is used to perform parametric simulations of seated MVICs at 30°, 60°, and 90° knee flexion angles.

Methods

Knee MVIC flexion and extension were simulated with a detailed FE-MS model. Under MVIC moment represented by a resistant force near the ankle, a Taguchi design considered applied moment, coactivity in antagonist muscle groups, and the resistant force lever arm as variables at 4 levels each, yielding 16 cases for every knee flexion and MVIC direction.

Results

In flexion MVIC, PCL tension rose from ~20N at 30° to ~700N at 90°. In extension MVIC, ACL force peaked to ~120N at 30° and disappeared at 90°. Flexion MVIC loaded medial hamstrings and gastrocnemii to >1kN, whereas quadriceps forces peaked to ~6.3kN at 90° in extension MVIC. Tibiofemoral (TF) contact force peaked to ~4.3BW at 30° in flexion and ~3.9BW at 60° in extension MVIC. Patellofemoral (PF) contact forces were small in flexion but very large in extension MVIC (~2.0kN at 30° to ~5.6kN at 90°, ~9BW). Sensitivity analyses demonstrated the marked effects of changes in MVIC moment, muscle coactivation, and resistant force lever arm on all results.

Discussion

In MVIC flexion, PCL force increased with knee flexion, MVIC moment, and coactivity in quads but markedly dropped with greater activity in gastrocnemii. In MVIC extension, ACL force increased at smaller knee flexion angles and larger moment and resistant force lever arm. It markedly increased in extension when loading was idealized as a pure moment. While TF contact forces were slightly larger in flexion, PF contact forces along with PT and quads forces were much larger in extension MVIC, resulting in PF cartilage contact pressures >20MPa at 90° knee flexion angle. Sensitivity analyses underscored the need to control the applied moment, knee flexion angle, and testing configuration (force lever arm) to safeguard ACL, PCL, PT, and patellar cartilage in MVIC exercises.

Images (Optional)

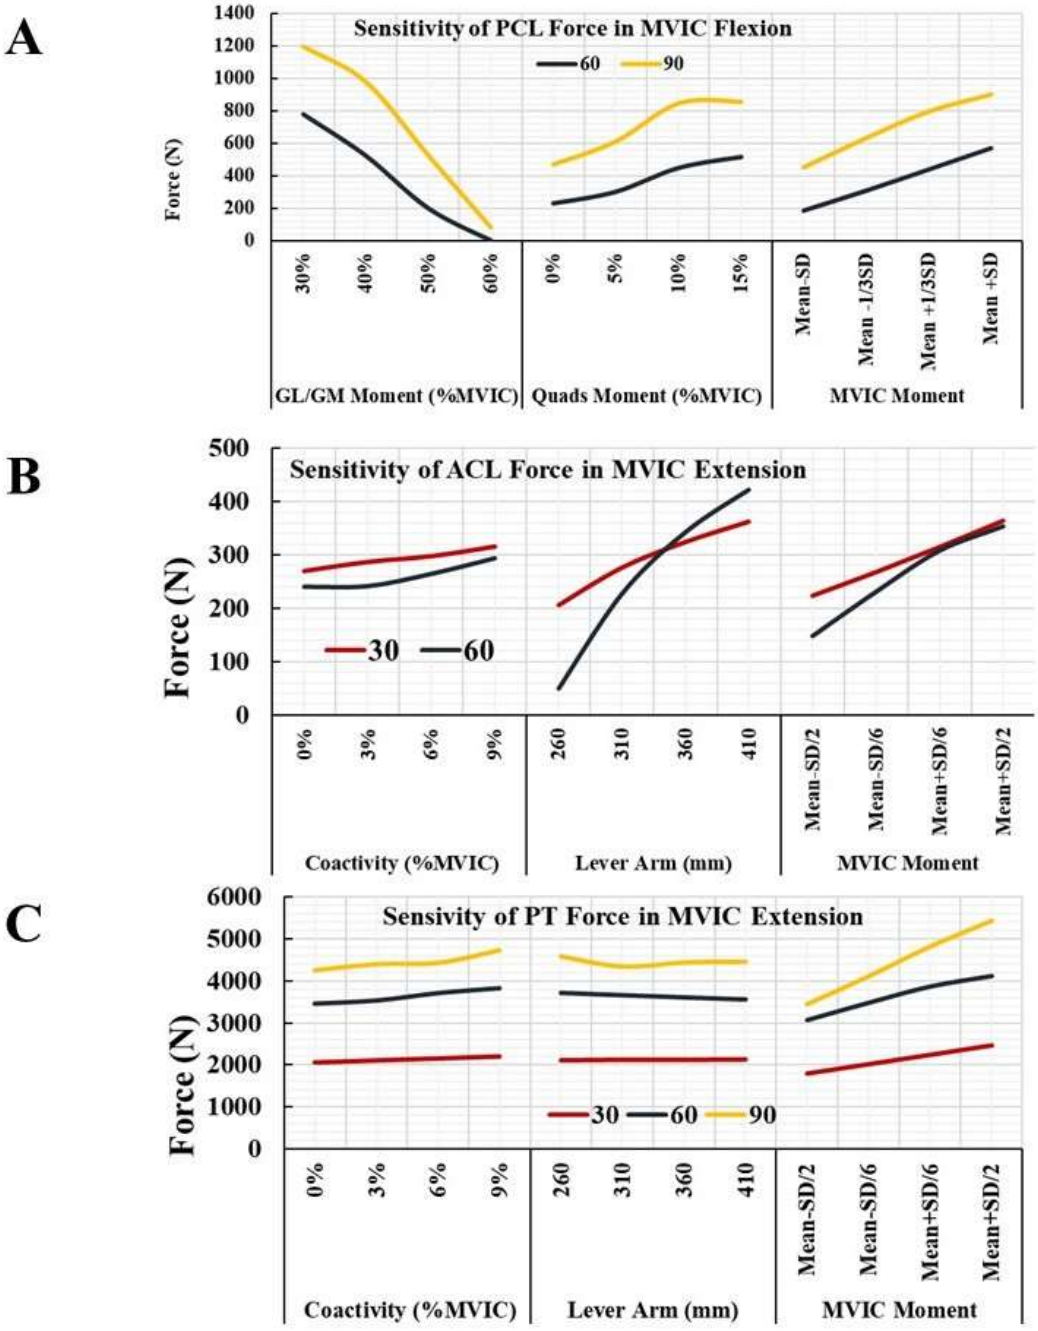

Figure 1 Sensitivity of cruciate ligaments (ACL and PCL) and patellar tendon (PT) force to various parameters each changing at 4 levels. A) PCL forces in MVIC flexion as the gastrocnemii activation level (left), quadriceps co-activation level (middle), and applied moment (right) altered. B) ACL forces and C) PT forces in MVIC extension as the co-activity in flexor muscles (left), external load lever arm (middle), and MVIC extension moment (right) altered.

Biomechanics-aware Multi-view Markerless Motion Capture Reconstruction of Complex Hand Motions and Object Interaction

Mr. Pouyan Firouzabadi[1,2], Dr. Wendy Murray[1,2], Mr. J.D. Peiffer[1,2], Mr. Kunal Shah[2], Dr. Anton Sobinov[3], Dr. Lee Miller[1,2], Dr. R. James Cotton M.D. PhD[2]

[1]Northwestern University, Chicago, IL, United States. [2]Shirely Ryan AbilityLab, Chicago, IL, United States. [3]University of Chicago, Chicago, IL, United States

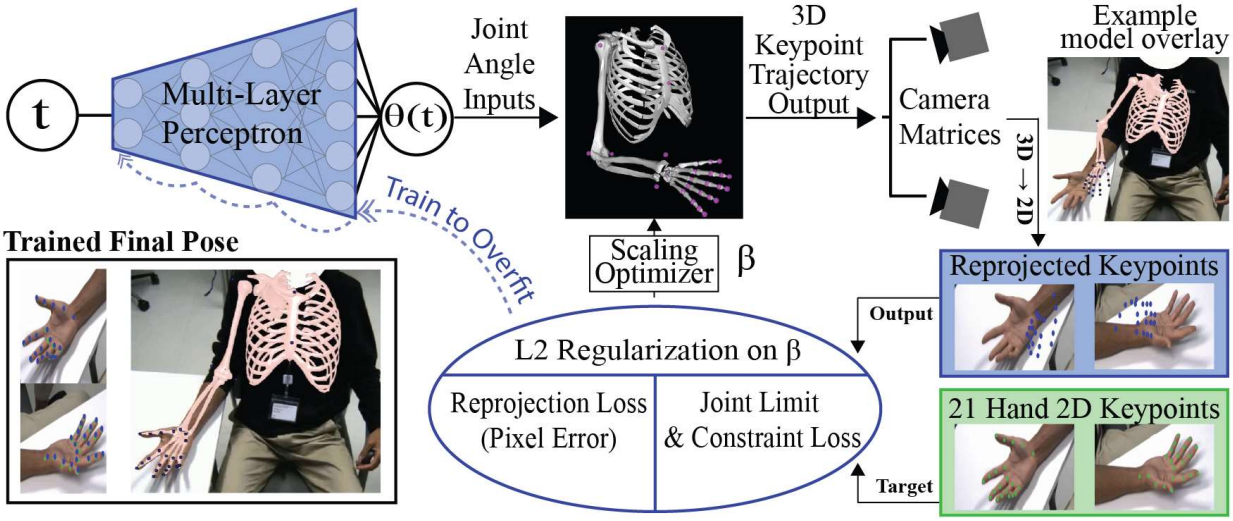
Introduction

Video-based motion capture has been sparingly applied for the biomechanical analysis of hand motion. Multi-view markerless motion capture (MMC) uses pose estimation algorithms to localize keypoints in individual 2D video frames [1]. Traditionally, 2D keypoints from all camera views are triangulated into 3D space and processed through inverse kinematics using a biomechanical model. However, frame-by-frame 2D errors propagate through the triangulation process, yielding non-physiological joint trajectories that require manual correction. We aim to demonstrate accurate 3D reconstruction of hand movements via a biomechanically constrained, end-to-end approach that eliminates the need for manual intervention [2], [3].

Methods

We used a custom 8-camera set-up to collect videos of six healthy participants performing hand postures and object interaction tasks. Videos were processed using publicly available pose estimation algorithms detecting 21 hand keypoints. A gradient-based optimization approach integrated a biomechanical model in the loop to produce plausible 3D joint kinematic trajectories. We directly compared performance of our workflow to the traditional approach that only applies biomechanical constraints after triangulation during inverse kinematics.

Results



The two methods produced different joint angle estimates. Joint angle differences averaged 12.1 ± 8.8° between methods; distal joints had the largest deviations (21.2°± 8.8°). Qualitative analysis demonstrated worse performance for the traditional method. For example, for a posture with all fingers fully extended (0° flexion), average distal joint angles were 1.7° (our method) vs. 29.9° (traditional approach). Our method also improved performance when evaluated using computer vision metrics. Specifically, alignment of our keypoints with those from pose estimation was 20% better than the traditional method. For

object interaction tasks, keypoint alignment declined by 12% further for the traditional method, but did not change relative to hand posture tasks for our approach.

Discussion

These findings demonstrate that integrating biomechanical constraints into an end-to-end pipeline improves accuracy and robustness across complex hand motions.

Images (Optional)

Our end-to-end MMC reconstruction pipeline: The multi-layer perceptron (MLP), outputs arbitrary joint angles to pose the biomechanical model, which is labeled with the 3D keypoints of interest. When the model assumes the pose, the 3D keypoints are then reprojected to each of the 8 camera's 2D planes, allowing direct comparison to the 2D keypoints identified by the pose estimation algorithm for that frame. During training, the β parameter fine-tunes the marker locations as well as the scaling of the bones specific to the participant. The MLP is trained for 40000 iterations to overfit based on the defined loss functions learning a mapping from time (t) to joint angles Θ(t) producing final poses that best represent the 2D information from all 8 camera planes

Developing A Novel Contact Modeling Framework; A Step Towards the Development of Dynamic Human Rolling Simulations

Mr. Rahmat Safdar, Ms. Mariam Jabr, Dr. Nils Hakansson

Wichita State University, Wichita, Kansas, United States

Introduction

Human rolling is a fundamental daily activity requiring coordinated motion of the trunk and extremities [1]. Rolling often occurs on compliant surfaces and involvescomplex contact mechanics. Currently, no framework exists for simulating rolling on a compliant mattress; therefore, developing a mattress contact model is essential for future investigations of rolling. Here, we investigate novel mattress contact models in two modeling programs, OpenSim and Simcenter MADYMOto create a contact model for human rolling simulations. Modeling dynamic contact is computationally expensive. OpenSim offers a simple contact model;MADYMO offers more complex computationally efficient contact modeling, but it lacks the musculoskeletal modeling capabilities of OpenSim.

Methods

Contact model parameters were derived from thirty bowling ball-drop trials recorded using high-speed motion capture (120 Hz) and ASTM D3574 indentation tests performed on a foam mattress. The OpenSim mattress surface was modeled as a Hunt-Crossley contact surface with stiffness and dissipation inputs. The MADYMO mattress surface was modeled using a planar finite-element surface with data-driven hysteretic and viscoelastic contact characteristics with loading/unloading and damping inputs. Experimental ball-drop trials were used to validate contact simulations. The simulation trajectories were assessed using RMS errors.

Results

The ball center of mass (COM) trajectories for experimental data and both simulations with summary results, including penetration and rebound distances andcoefficient of restitution (COR), are illustrated in Figure 1. The Hunt-Crossley model in OpenSim represented the initial contact and rebound behavior accurately, but MADYMO was able to replicate the overall trajectory of the ball.

Discussion

The simulations reproduced the main features of the experimental ball-drop test; the dynamics of initial impact and rebound behavior tracked the experimental average. The

results confirm Hunt-Crossley models are well-suited for quick impacts. The MADYMO model presented better energy dissipation and static behavior. Future work will pursue a modified contact model for OpenSim that combines the energy dissipative features of the MADYMO model with the Hunt-Crossley impact dynamics to provide a foundation for dynamic human rolling simulations using neuromusculoskeletal modeling approaches.

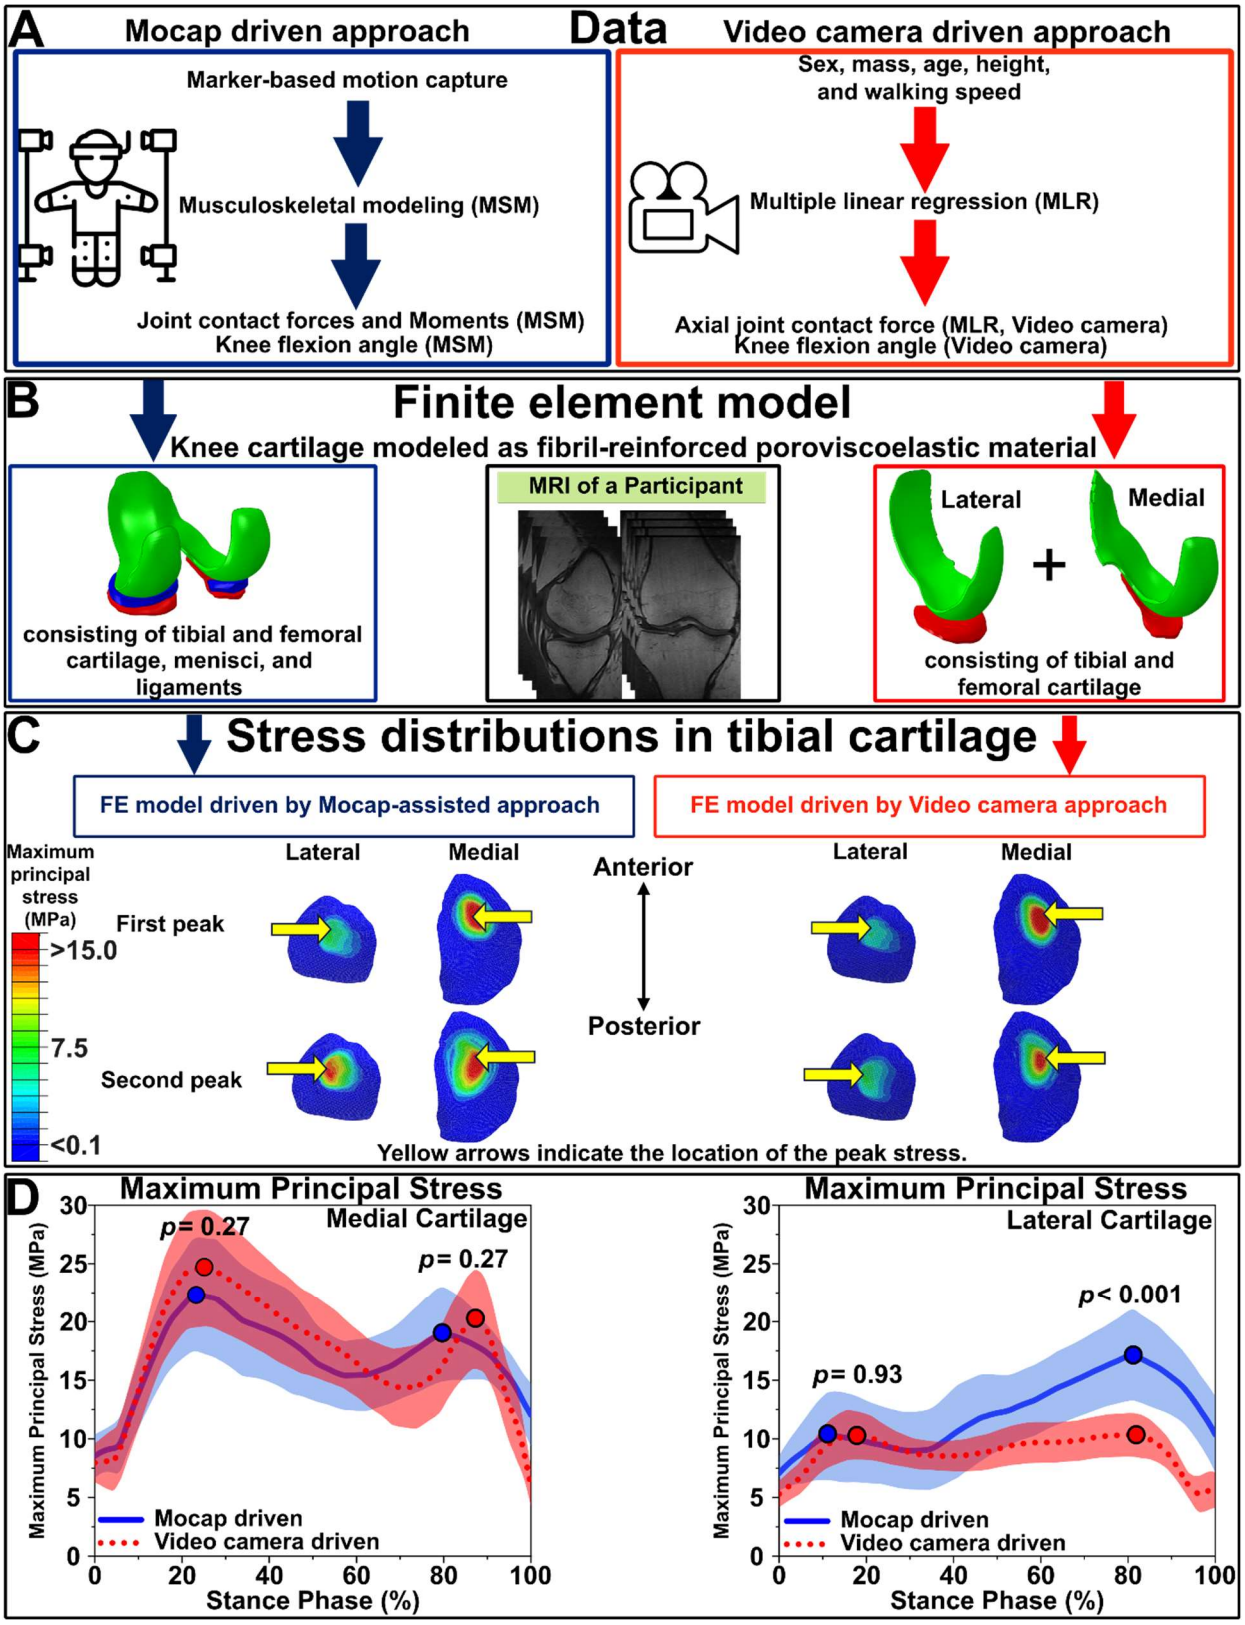
[2]Department of Internal Medicine and Rehabilitation, Helsinki University Hospital and Helsinki University, Helsinki, Helsinki, Finland. [3]Australian Centre for Precision Health and Technology (PRECISE), Griffith University, Gold Coast, Queensland, Australia

Introduction

Low-fidelity, AI-based approaches are increasingly used to estimate the kinematics and kinetics of human movement, traditionally measured by high-fidelity, marker-based motion capture (Mocap) systems [1]. However, their application to tissue-level mechanics, specifically estimating stresses and strains, remains relatively underexplored. Previously, we developed a finite element modeling (FEM) pipeline, driven by artificial neural network-based knee joint kinetics, to estimate cartilage mechanics. Here, we refined this pipeline by implementing a video camera (VC)-based method capable of extracting subject-specific knee flexion angles (KFA).

Methods

Eight healthy adults (3 females, 5 males; age 29 ± 6 years; BMI 23 ± 7 kg/m^2) were included in the study. Marker trajectories and ground reaction forces were recorded during walking in a Mocap laboratory, and magnetic resonance imaging was performed to obtain knee joint geometries. For the high-fidelity approach, Mocap data were processed in OpenSim to estimate knee joint contact forces (KJCFs) and moments (Fig. 1A), which served as inputs to a detailed FEM including cartilage, menisci, and ligaments (Fig. 1B) [2]. In the low-fidelity approach, a multiple linear regression model was used to estimate KJCF from selected subject demographic variables and knee flexion angles extracted from VC (Fig. 1A) [3,4]. The estimated KJCF and KFA from VC were applied to a simplified FEM containing cartilage layers, represented as boundary conditions (Fig. 1B).



Results

In the medial tibial cartilage, average stress values were not significantly different between the approaches ($P>0.05$, Fig. 1D). The only significant differences in peak stresses were found in the lateral tibial cartilage at about 80% of stance ($P<0.05$), likely due to varying cartilage-cartilage contact areas, necessitating further model refinement.

Discussion

We present a computational modeling method to estimate knee joint cartilage mechanics using video camera-based knee kinetic and kinematic data. This enables out-of-lab estimation of knee tissue mechanics and remodeling to support rehabilitation planning and self-management of knee degenerative diseases.

Evaluation of Parallel Mechanisms for Ankle and Knee With in Vivo Measured Running Kinematics

Mr Manuel Romeo MSc[1], Ms Anna Pedretti[1], Mr Michele Conconi PhD[1], Mr Nicola Sancisi PhD[1], Mr Raphael Dumas PhD[2]

[1]Department of Industrial Engineering, University of Bologna, Bologna, Emilia Romagna, Italy. [2]Univ Eiffel, Univ Lyon 1, LBMC UMR_T 9406, Lyon, Auvergne Rhone Alpes, France

Introduction

Multibody kinematics optimization (MKO) is essential for musculoskeletal modelling, but the resulting joint angles are highly influenced by the chosen kinematic model. The Twente Lower Extermity Model (TLEM2 [1]) is a comprehensive lower limb model that uses simple hinges for the tibiofemoral, subtalar, and talocrural joints. Parallel mechanisms, including rigid contacts and isometric ligaments, have been proposed as a more anatomically detailed alternative for modeling these joints.

The objective of this study is to preliminarily evaluate the joint angles derived from MKO when using the TLEM2 augmented with parallel mechanisms for the knee and ankle joints.

Methods

Parallel mechanisms (1 DoF) were synthesized based on the TLEM2 bone geometries [1] and predicted passive kinematics (using a congruence method [2]). They were incorporated into the musculoskeletal model to replace the hinges. The model was scaled and used to track skin marker trajectories during the stance phase of running using the dataset from [3]. This dataset also includes the trajectories of pin markers embedded in the femur, tibia, and calcaneus of 3 participants (5 trials each).

Results

The figure compares the knee and ankle angles estimated using skin markers (MKO) against the reference angles obtained from pin markers. Patterns were generally reproduced by the parallel mechanisms: R^2 between 0.92 and 0.99 for ankle and knee lexion/extension, with mean RMSE of 8.9° and 2.8°, respectively. Regarding the other DoFs, errors were limited for ankle and knee adduction/abduction, and ankle inversion/eversion (< 5.8°), while higher for knee internal/external rotation (< 13.2°). Values were comparable with hinges.

Discussion

The errors in the joint angles come from both the soft tissue (and shoe) artefact and the differences between the generic models and the participants' anatomy, particularly for the knee internal/external rotation. The parallel mechanisms may ensure more biomimetic output of joint angles computed by MKO. Future evaluations will include a wider quantification of the errors (bias, limits of agreements, correlations).

Images (Optional)

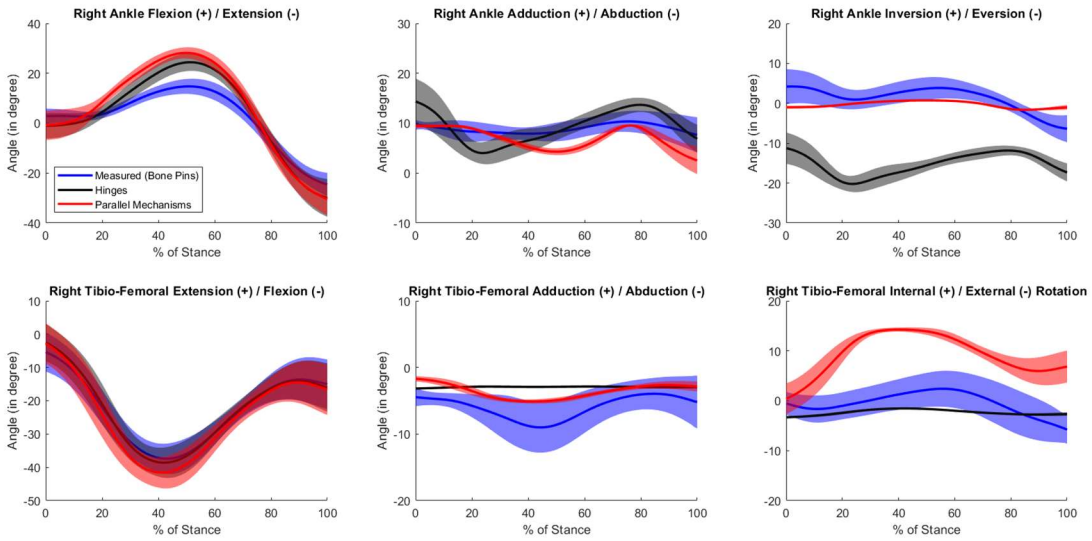

Figure: knee and ankle angles (mean and SD of all trials of the three subjects) estimated using skin markers (MKO with parallel mechanisms, in red, and with hinges, in black) and obtained from the pin markers (in blue) during the stance phase of running. ZXY and ZYX sequence of rotations are respectively used for knee and ankle.

Weakened Lumbar Multifidus Muscles Caused Altered Vertebral Mobility and Increased Lumbar Loads in Adjacent Segments Following Lumbar Interbody Fusion – Results of Muscle-Driven Simulations

Dr.-Ing. Robin Remus[1], PD Dr. med. Moritz Lodde[2], Mr. Matthias Klimek M.Sc.[2], Mr. Sascha Selkmann M.Sc.[1], Dr.-Ing. Marc Neumann[1]

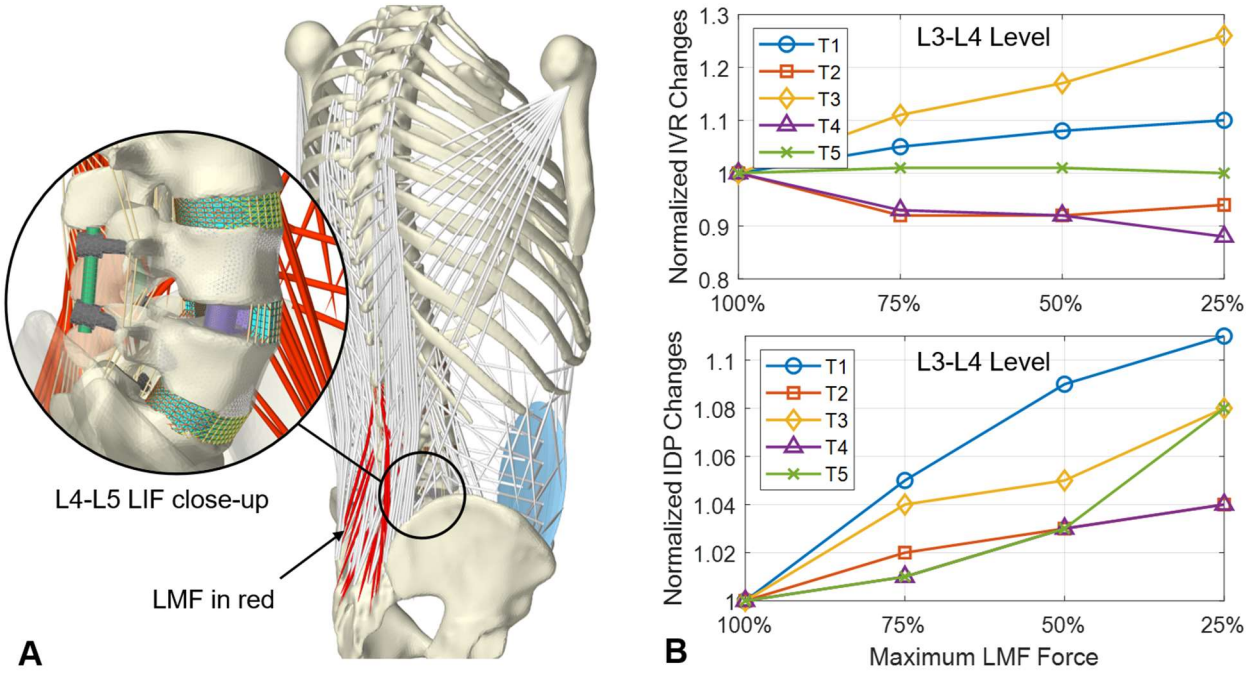
[1]Biomedical Engineering Lab, Department of Mechanical Engineering, Ruhr University Bochum, Bochum, NRW, Germany. [2]Department of Trauma, Hand and Reconstructive Surgery, University Hospital Münster, Münster, NRW, Germany

Introduction

The lumbar multifidus (LMF) is a deep trunk muscle that plays a key role in spinal stability and controlling vertebral motion. Structural or functional LMF impairments are prevalent after lumbar interbody fusion (LIF) and are associated with adjacent segment disease. This study used spinal simulations to investigate how weakened LMF muscles influence spinal kinematics and loading following LIF.

Methods

Muscle-driven simulations with varying maximum isometric forces (100%–25%) of the LMF muscle were performed using a previously validated hybrid finite element (FE)–multibody (MB) spine model [1] built in ArtiSynth (www.artisynth.org). The model consisted of rigid bones (thorax–sacrum), fiber-reinforced FE intervertebral discs, facet joints, pre-tensioned ligaments, and twelve muscle groups. Following nucleotomy and facetectomy, an expandable FE intervertebral cage and bilateral posterior FE instrumentation were used to include an L4-L5 LIF (Fig.1A). To compare the effects of LMF changes on adjacent segments, forward dynamics simulations were performed for five tasks, with all other conditions held constant: T1) standing upright, T2) holding a 20kg box, T3) 45° Roman Chair back extension exercise, T4) 10° extension, and T5) 30° flexion. The intact LMF served as reference for evaluating changes in kinematics and intradiscal pressure (IDP).



Results

Reductions in maximum LMF force resulted in altered biomechanics in adjacent segments as well as altered muscle activation patterns. Intervertebral rotations (IVR) increased cranially for T2 by up to 26% and decreased for T4 by up to -12% (Fig.1B). For all tasks, the IDP increased cranially by 1 to 11%. Caudally, IDP changes of ±2% occurred.

Discussion

This study compared the effects of reduced LMF muscle forces for different tasks using a hybrid FE-MB spine model with LIF. The results showed increased IDP and altered vertebral mobility, both of which can promote adjacent segment disease. Overall, integrating FE components into a forward-dynamics musculoskeletal model enabled simulating the interplay between muscles and passive spinal structures. This demonstrates the model's potential for investigating clinically relevant issues, such as the decision-making process for open versus minimally invasive surgical procedures, implant selection, and preoperative and postoperative physical therapy exercises for the lumbar spine.

P2-181

Validation of knee joint forces for a 3DOF ellipsoidal bi-condylar knee joint for musculoskeletal modeling

Ms Sabrina Hörmann, Dr. Nazli Tümer, Prof. Dr. Amir A. Zadpoor, Dr. Ajay Seth

Delft University of Technology, Delft, Zuid Holland, Netherlands

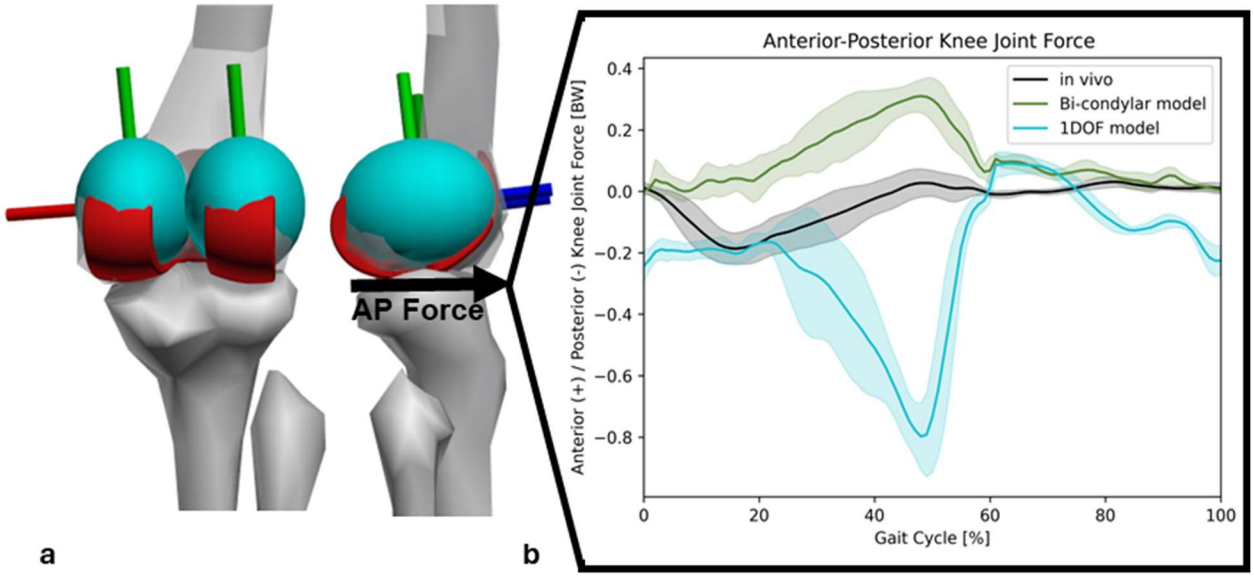
Introduction

The knee joint is typically defined as a one-degree-of-freedom (1DOF) cam-follower joint in musculoskeletal (MSK) models, allowing flexion–extension motion along cadaver-derived paths [1]. Thus, patient-specific bone geometry and its effect on joint kinematics are neglected. 6DOF models incorporating bone contact and ligaments can capture subject-specific motion but are computationally expensive and sensitive to uncertainties in tissue properties [2]. Therefore, we propose a 3DOF ellipsoidal bi-condylar knee model.

This study aims to validate the estimated knee joint forces against in vivo measurements and evaluate differences in knee joint force estimations compared to a 1DOF model.

Methods

We developed a 3DOF bi-condylar tibiofemoral joint in OpenSim [3], allowing motion in flexion-extension, internal-external, and adduction-abduction rotation. The model consists of two ellipsoidal joints representing the medial and lateral condyles, physiologically constraining internal-external and adduction-abduction rotations (Fig. part a). Experimental data to validate the model were obtained from the CAMS dataset [4]. The bi-condylar model was integrated into a full-body MSK model [5], scaled to the subject's anthropometry, and the ellipsoid radii were fitted to the knee implant geometry. Inverse kinematics and muscle redundancy were solved to estimate joint-reaction forces for one subject over eight gait cycles using both a 1DOF and a bi-condylar knee model.



Results

Preliminary results showed reduced root-mean-square errors (RMSE), averaged over the eight gait cycles, in anterior–posterior (AP) knee joint forces from 0.29 body weight (BW) for the 1DOF joint to 0.17 BW for the bi-condylar model(Fig. part b). There were only minor differences observed in the other DOFs.

Discussion

Although knee joint compressive forces are generally well estimated with the 1DOF joint model, predictions in the anterior-posterior direction remain less accurate. The results indicate that the bi-condylar model improves the estimates of anterior-posterior knee joint forces. Further work should assess these differences across more subjects and activities in the CAMS dataset.

Estimating Spine Loading of Healthcare Workers wearing Lead Aprons using Bond Graph Modelling

Mr. Samuel Brost[1], Dr. Pushparaj Pathak[2], Dr. Qingguo Li[1]

[1]Queen's University, Kingston, Ontario, Canada. [2]Indian Institute of Technology Roorkee, Roorkee, Uttarakhand, India

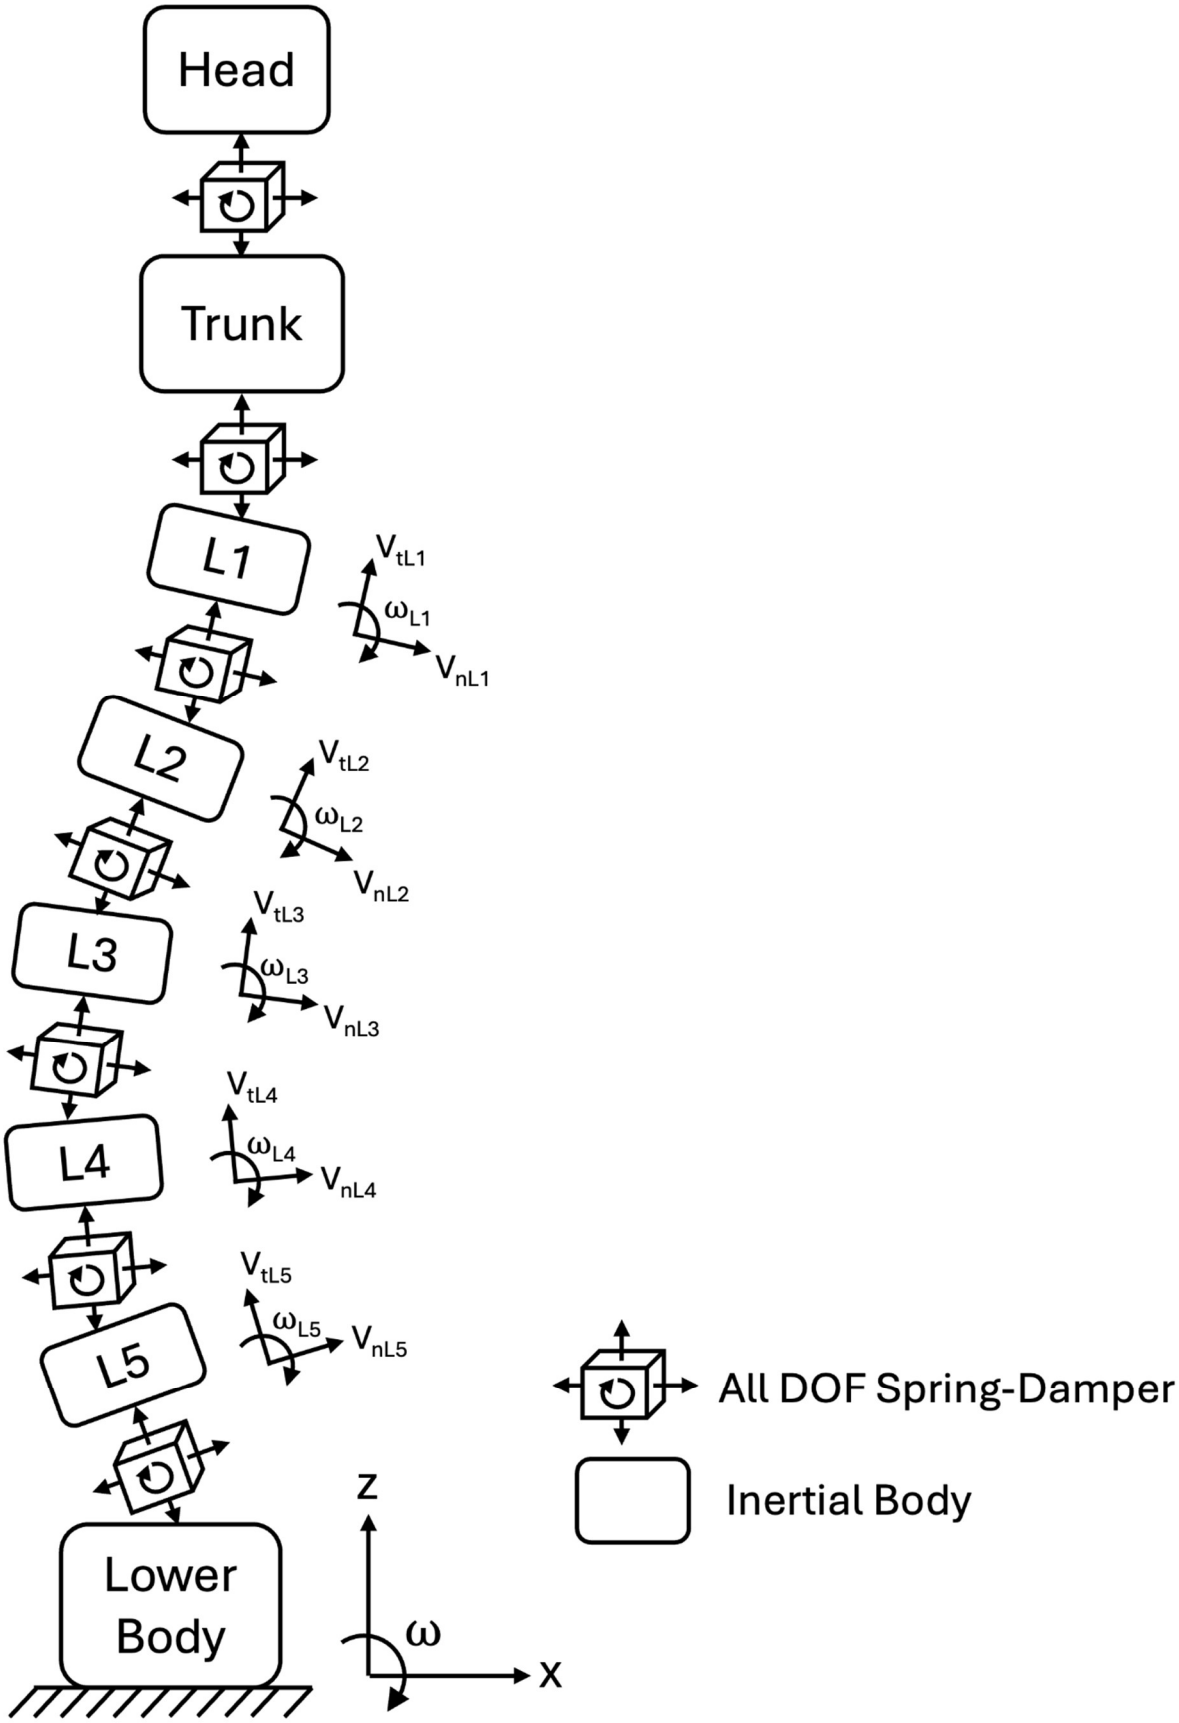
Introduction

Spinal injury is common among healthcare workers who perform X-ray-based procedures that require lead aprons and static postures [1]. Using bond graph modelling, we investigated the additional loading caused by lead aprons in these maladaptive postures to understand the dominant injury mechanism. Research on healthcare workers shows large cumulative loads, but the amount that lead aprons contribute to this issue relative to the long time spent in maladaptive postures is relatively unknown [2]. Bond graph modelling was chosen as it allows for simple multidisciplinary integration, meaning it can easily incorporate interventions such as exoskeletons within the model.

Methods

The sagittal plane spinal posture of 21 Healthcare workers at Sunnybrook Health Sciences Centre (REB #5331) was recorded using a 4 IMU system. A bond graph model, adapted from [3], was used to estimate internal loading in the lumbar spine, with the trunk and the head being modelled as inertial bodies as seen in Figure 1. The recorded neutral posture was modelled with and without the weight of a lead apron, and the displacements and loads were estimated from the bond graph model.

Results



From the population measured, the average lead apron weight was 7.55 kg. This additional load resulted in an average compression of 0.45 mm and compressional force of 97 N. This loading represents a 33 % increase over the loading without a lead apron.

Discussion

The addition of the lead vest made a noticeable contribution to the loading experienced in the lumbar spine at the neutral position. This demonstrates that the lead apron weight does have a significant role in the injuries experienced, and there is a need for interventions focused on reducing its impact. This investigation of neutral posture is a preliminary application of a model that is under development. The ongoing addition of fully modelled thoracic and cervical vertebrae and associated musculature will allow for a more detailed

investigation into the reported neck injuries and high flexion postures common in the healthcare environment.

Characterizing ACL Strain Using Only Knee Kinematics

Dr. Samuel Kwak PhD[1,2,3], Dr. Gregory Myer PhD, FACSM, CSCS*D[1,2,3,4], Dr. Christopher Riehm PhD[1,2,3]

[1]Emory Sports Performance And Research Center (SPARC), Flowery Branch, GA, United States. [2]Emory Sports Medicine Center, Atlanta, GA, United States. [3]Department of Orthopaedics, Emory University School of Medicine, Atlanta, GA, United States. [4]Wallace H. Coulter Department of Biomedical Engineering, Georgia Institute of Technology and Emory University, Atlanta, GA, United States

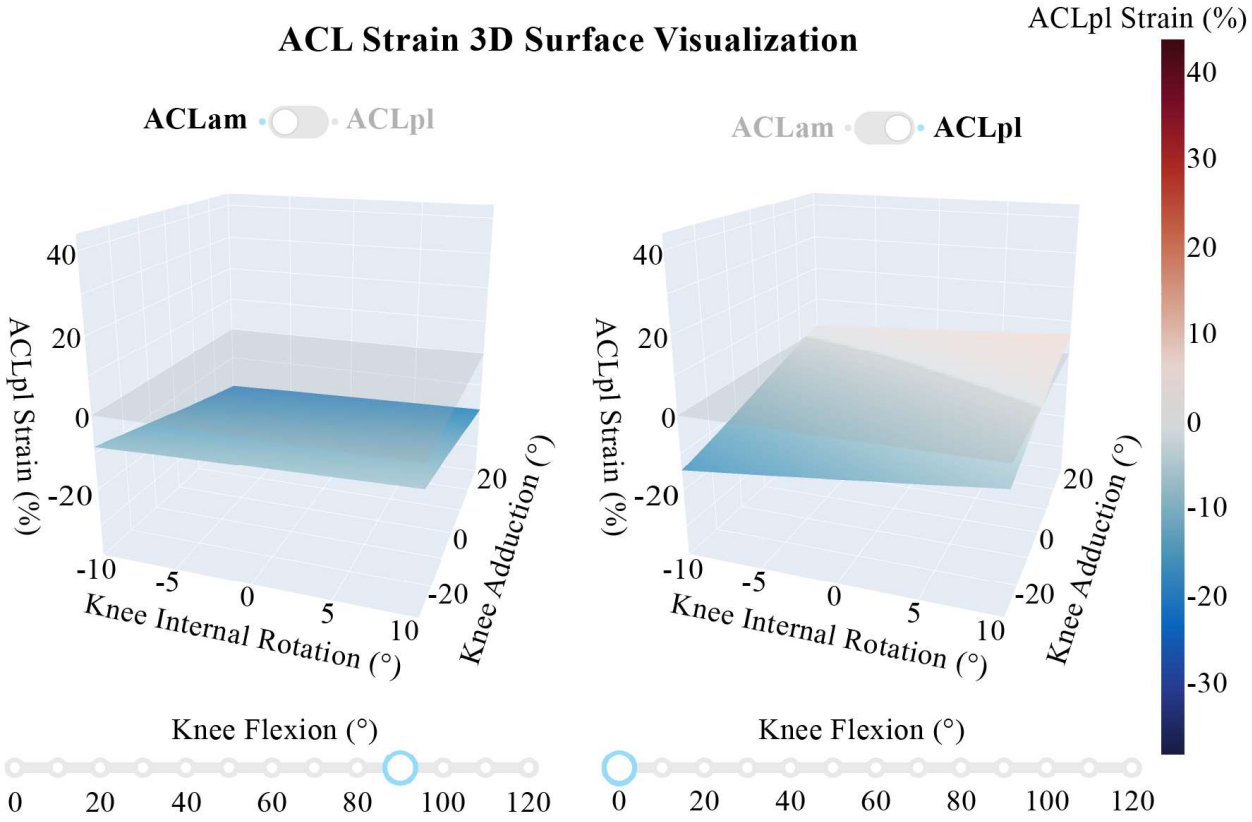
Introduction

ACL injuries are among the most studied in sports biomechanics [1]. But when considering injury risk factors, joint rotations are often used as surrogates for ACL loads [2]. However, the ACL does not deform in alignment with knee rotational axes, limiting direct inferences to ACL mechanics from measured knee kinematics. To address this limitation, we sought to develop an algebraic equation and interactive tool, derived from a knee model simulation, to quantify ACL strain in relation to 3D knee rotations.

Methods

An OpenSim knee model based on an individual's MRI-derived bone and ligament geometries [3,4], possessing an anteromedial (ACLam) and posterolateral (ACLpl) bundle with six ligament fibers each, was simulated through different knee configurations along its three rotational axes to calculate ACL strain. Using a machine learning-based symbolic regressor, PySR [5], a modeling equation was created that derives ACL strain from knee joint kinematics. We evaluated the performance of the equation using R^2 and mean absolute error (MAE). The OpenSim-based data was also used to create an interactive ACL strain tool in Render using custom Python code.

Results



The equation estimating ACLam strain was: $\varepsilon_{ACLam} = 0.206\theta_{add} - 10.4 - (5.79*10^{-5}\theta_{flex}^2\theta_{add} + 0.135\theta_{flex} + \theta_{int} + 1.65) / (8.30*10^{-5}\theta_{flex}^2 + [245 / (\theta_{flex} - 35.1)])$. ε is percent ligament strain and θ_{flex}, θ_{add}, and θ_{int}, represent knee flexion, adduction, and internal rotation, respectively, in degrees. Relative to the simulation, this equation yielded an R^2 of 0.9986 and MAE of 0.09% strain. For ACLpl strain, the equation was: $\varepsilon_{ACLpl} = (\theta_{flex} - 0.393\theta_{flex}\theta_{int} - 2.38\theta_{add}\theta_{int} + 3.69\theta_{int}) * (1.05*10^{-5}\theta_{flex}^2 - 0.184) - 0.430\theta_{int} - 3.58$. Relative to the simulation, this equation

yielded an R^2 of 0.9943 and MAE of 0.36% strain. The interactive tool can be found here: lenhart-2015-acl-strain-plot.onrender.com.

Discussion

The proposed modeling equations and interactive tool allow for quantitative characterization of the complex interaction between knee rotation and ACL strain. Future work will include knee translation to enhance methods for kinematic derived quantification of ACL loading.

P2-184

Development of an Artificial Musculoskeletal Replica of the Knee Joint: Comparison of repeatability and passive joint kinematics with cadaveric data

Mr Sanjib Dutta, Mr R. Yogeshwar Rao, Dr Darshan S Shah

BiOME Lab, Department of Mechanical Engineering, Indian Institute of Technology Bombay, India, Mumbai, Maharashtra, India

Introduction

In vitro cadaveric biomechanical testing overcomes shortcomings of *in vivo* and *in silico* testing arising from invasive measurements and tissue site trueness, respectively. However, due to the limited availability, maintenance and ethical issues surrounding cadaveric specimens, artificial joint models are a more practical alternative for *in vitro* orthopaedic biomechanics research. Current artificial models typically only replicate one of the anatomical, functional or material aspects of the joint; however, all aforementioned aspects need to be replicated to accurately mimic a cadaveric joint. This study aimed to develop a biomechanically accurate and repeatable artificial musculoskeletal replica of the knee joint.

Methods

11 artificial joints were assembled using 3D-printed femur and tibia, based on synthetic bone models (Synbone, Switzerland), aligned as per standard hip-knee-ankle and lower-limb-torsional alignment. Custom artificial menisci and composite collateral and cruciate ligaments were developed to replicate the morphology, insertion sites and mechanical properties of the native tissues.[1,2] Following assembly of the aforementioned anatomical tissues, each specimen underwent three cycles of passive flexion-extension (FE), while a six-camera optical motion capture system (Qualisys, Sweden) tracked clusters of retroreflective markers rigidly affixed to the bones to provide tibiofemoral kinematics. Root mean square error (RMSE) of internal-external rotation (IErot) during FE across specimens was compared with cadaveric studies in the literature.[4,5] Bootstrap resampling confidence intervals (CI), based on root mean square (RMS) for each specimen, were calculated to assess repeatability.

Results

Mean RMSE across specimens was 5.56°, while comparisons with literature showed an RMSE of 1.54° (Fig. 1). Mean RMS across specimens was 4.08±2.93° with CI = [2.85°, 5.65°].

Discussion

The developed artificial model successfully replicated the musculoskeletal anatomy of the joint, the mechanical properties of soft tissues, and the passive coupling of knee FE and IErot.[3] Specimens exhibited moderate repeatability based on the CI, possibly owing to variable joint laxity and tissue pre-straining across specimens. Further development will focus on optimizing and standardising tissue pre-straining for a more robust and reliable artificial model.

Automated Ligament Insertion Definition with Template Mapping via Geodesic-based Bayesian Coherent Point Drift

Dr. Scott Sibole[1], Ms. Maryam Nazem[2], Ms. Kate Moyle[3], Ms. Nancy Kim[3], Dr. Jason Halloran[1]

[1]Washington State University, Spokane, WA, United States. [2]University of Denver, Denver, CO, United States. [3]University of Auckland, Auckland, Auckland, New Zealand

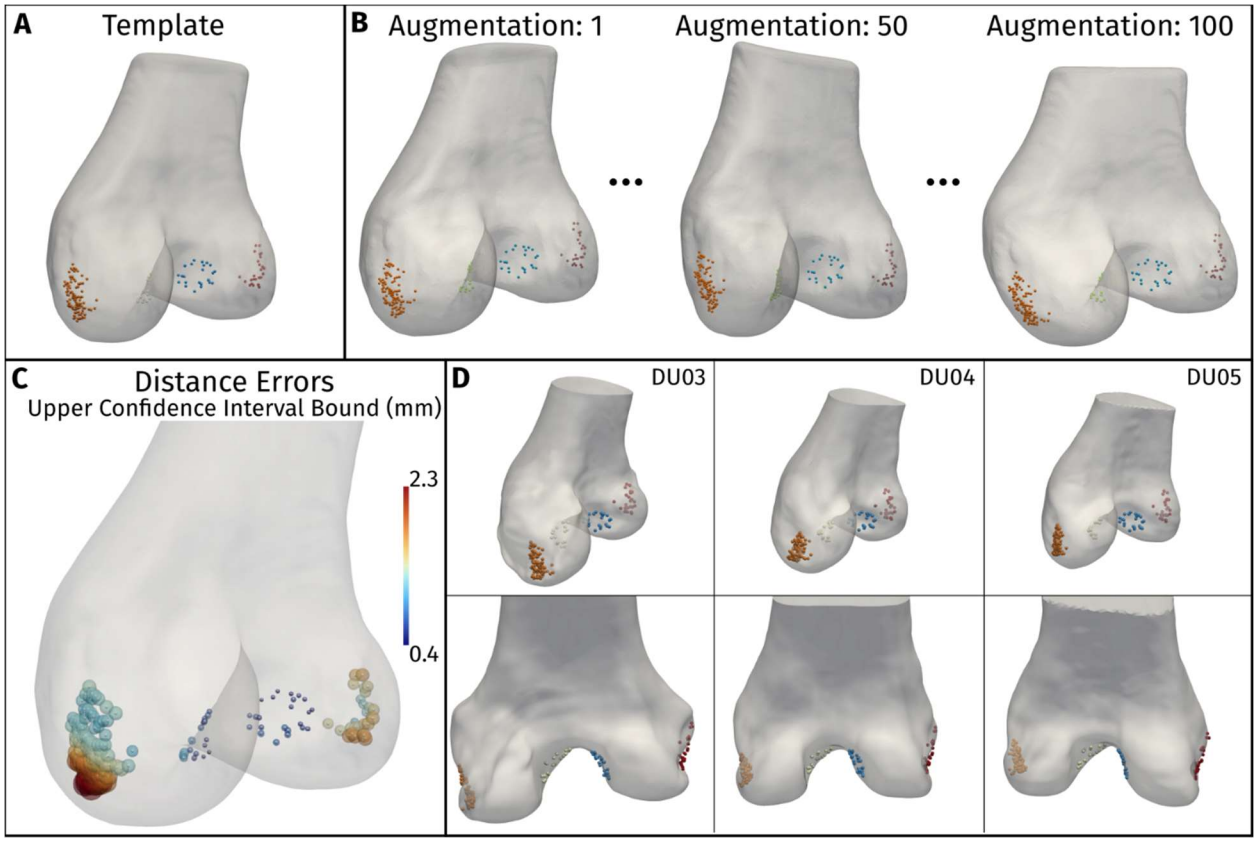
Introduction

Identification of ligament insertion sites is a critical task in physics-based simulation of joint mechanics. Challenges arise from limitations such as poor medical image resolution and signal strength leading to intra- and inter-observer variance. Identification is also arduous and time-consuming. Automated methods for identification are thus attractive. To this end, we explored the use of a geodesic-based Bayesian coherent point drift (GBCPD) algorithm [1] to map a template femur with identified insertions to a validation set, as well as image reconstructed anatomies.

Methods

The Natural Knee Data [2] specimen DU02 femur mesh and ligament insertion points were utilized as the template femur. Ligament insertion points were projected to the closest femur mesh vertex and assigned an integer ID (Figure 1A). The template mesh was then deformed with a randomly perturbed thin-plate spline transform to create a validation set of 100 femurs (Figure 1B). GBCPD was applied to determine maps from the template mesh to each augmented mesh. Distances between the ground truth and mapped ligament insertion points were evaluated. The template mesh was also mapped to the DU03, DU04, and DU05 femora.

Results



The mean and standard deviations of distance error aggregated per ligament were: ACL (0.54±0.26mm), PCL (0.59±0.38mm), MCL (1.26,0.86mm), and LCL (1.37mm,0.41mm). Pointwise errors are visualized in Figure 1C. Insertion points mapped to real anatomy are shown in Figure 1D.

Discussion

Mapping a template femur to target geometries using GBPCD for automated ligament insertion definition was demonstrated. Although the distance errors were acceptable, a future hyperparameter study to find optimal settings for the GBPCD algorithm may improve

performance. Errors of 5-8mm in ligament insertion identified in fluoroscopic images vs dissection have been reported [3], thus the observed distance errors are encouraging. Modifying the algorithm to include additional features such as mesh normals or interpolated image intensities will likely yield improved fidelity. Nevertheless, GBPCD template mapping was shown to be a viable method for the automated definition of ligament insertions.

Detecting Local Differences of *In Vivo* Bone Loading Direction Using Principal Trabecular Orientation Fields

Dr. Sebastian Bachmann[1], Dr. Marine Cazenave[2], Prof. Meir M. Barak Ph.D, DVM[3], Prof. Dieter H. Pahr[1], Dr. Alexander Synek[1]

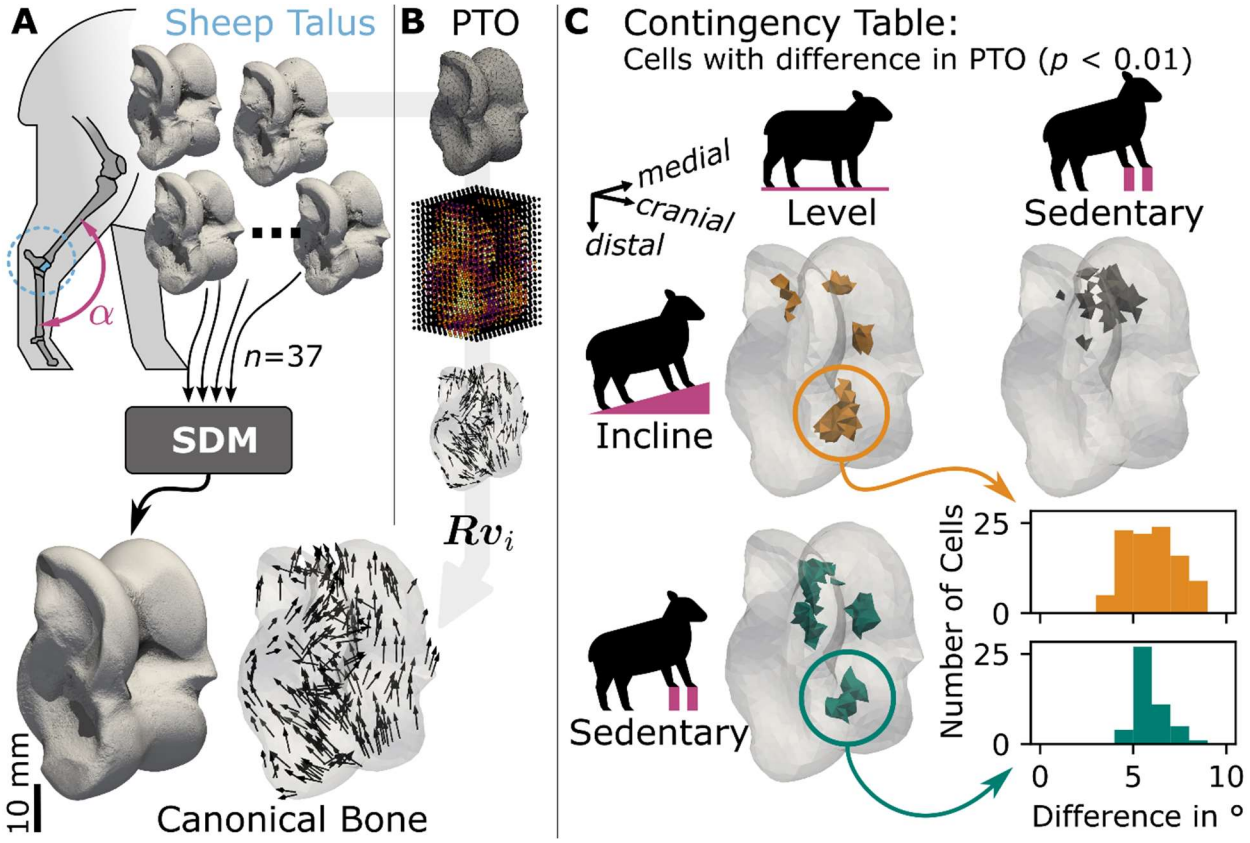
[1]Institute of Lightweight Design and Structural Biomechanics, TU Wien, Vienna, Vienna, Austria. [2]Department of Human Origins, Max Planck Institute for Evolutionary Anthropology, Leipzig, Saxony, Germany. [3]Department of Veterinary Biomedical Sciences, College of Veterinary Medicine, Long Island University, Brookville, NY, United States

Introduction

Trabecular bone is known to adapt to mechanical loading, a process known as “functional adaptation”. For example, apparent density or principal trabecular orientation (PTO) may change throughout the bone according to the loading magnitude and direction. Apparent density can be quantified, and compared holistically, i.e., on the whole bone level [1]. However, these holistic methods have yet to work for PTO analysis. To fill this gap, we developed a new method to analyze PTO fields and demonstrate its usage on experimental data.

Methods

37 micro-CT images of sheep tali (resolution 0.025 mm) were obtained from a previous study [2], in which three experimental conditions were defined:
Sedentary: the ankle-joint angle (α) was altered by approximately 7° using orthopedic shoes;
Incline: shoe-wearing except during training on a 7° inclined treadmill;
Level: control group, only trained on a level treadmill.
A statistical deformation model (SDM) was created to obtain a canonical bone, onto which all individuals were registered (Fig1A) [1]. PTO fields were measured for each individual using a mesh and background grid [1] and transformed into the canonical space using the rotational part of the deformation gradient (Fig1B) [3]. Statistical significant regions were found by removing cells with ill-defined PTO and applying permutation tests for group-wise differences in PTO [4] with $p<0.01$.



Results

Several significantly different regions were found between groups (Fig1C). In the sedentary and incline groups, cells in the distal-medial region showed a different direction than the level group, with differences between 4° and 10°. Cells in the proximal region showed a complex pattern and appeared in all group comparison, including incline versus sedentary group.

Discussion

While PTO differences in the distal-medial region can be explained by the altered joint angle of 7°, the proximal regions require further analysis. Overall, these preliminary results demonstrate the successful application of canonical PTO field analysis that is sensitive enough to detect small, localized PTO differences caused by a change of *in vivo* joint loading direction.

Preserved Bilateral Cycling Synergies with Selective Fatigue-Driven Reweighting

Dr. Shahram Rasoulian PhD, Mr. Reza Ahmadi PhD Candidate, Professor Walter Herzog PhD, Professor Amin Komeili PhD

University of Calgary, Calgary, AB, Canada

Introduction

Neuromuscular fatigue alters muscle activation, but its effect on the modular organization of cycling remains unclear. Muscle synergies, coordinated groups of muscles activated as functional units, simplify control while preserving task performance. This study examined how fatigue during constant-power cycling affects the bilateral structure and temporal organization of muscle synergies, focusing on inter-limb symmetry and time-dependent changes in synergy weights.

Methods

Twenty recreational cyclists (8 males, 12 females; 22.6±4.5 years) performed constant-power cycling at 70% of individual maximum power until task failure. Bilateral surface EMG was recorded from seven lower-limb muscles Vastus Medialis (VM), Rectus Femoris (RF), Vastus Lateralis (VL), Biceps Femoris (BF), Tibialis Anterior (TA), Gastrocnemius Medialis (GM), Soleus (SOL) and processed into linear envelopes. Four muscle synergies per limb were extracted using non-negative matrix factorization at three normalized time points: Initial, Midpoint, and Final. Synergy composition (muscle weights) and activation profiles were compared across time points with repeated-measures ANOVA or Friedman tests (α=0.05). Effect sizes were reported as partial η^2 or Kendall's W.

Results

Four synergies explained >95% of EMG variance at all time points. Synergies 1 and 3 and synergies 2 and 4 formed mirrored inter-limb pairs with ≈180° phase-shifted activation timing (Figure 1). The overall synergy structure was preserved, but selective time-dependent changes occurred within specific muscles: significant reweighting was observed for BF (Sy2&4, p≤0.05, $p\eta^2$=0.17-0.32), RF (Sy2&4, p≤0.02, $p\eta^2$=0.23-0.32), VL (Sy1&3, p≤0.03, $p\eta^2$=0.08-0.14), SOL (Sy1&4, p≤0.04, W=0.19-0.20), VM (Sy2, p=0.02, W=0.23), and GM (Sy3, p=0.02, $p\eta^2$=0.23). Other weights showed no time-point effects. These results indicate that fatigue does not reorganize the modular framework but selectively adjusts muscle weight within paired synergies.

Discussion

The persistence of four mirrored synergies and the 180° inter-limb phase shift demonstrate stable bilateral modular control of cycling. Selective reweighting of the quadriceps, hamstrings, and plantar flexors suggests targeted adaptation to maintain force direction and power output under fatigue. The central nervous system appears to preserve overall synergy architecture while refining muscle contributions to sustain performance, reflecting compensatory rather than reorganizational plasticity.

A Systematic Review of Measurement Techniques To Characterize Infant Cranial Anatomy

Ms. Shameka Kimmel[1], Mr. Tanner Pollock[2], Dr. Erin Mannen[1]

[1]Boise State University, Boise, ID, United States. [2]Idaho College of Medicine, Meridian, ID, United States

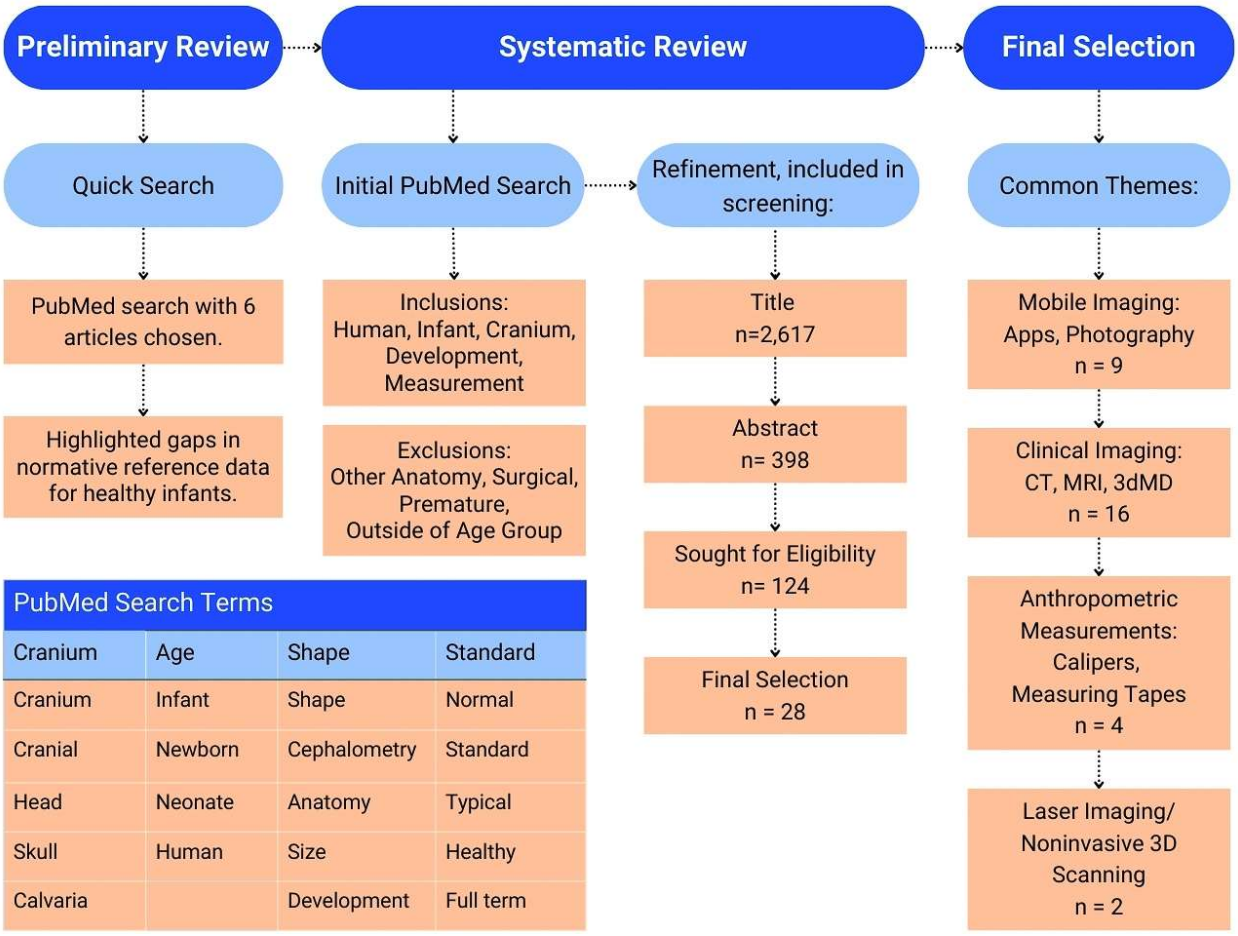
Introduction

The first 6-months of human life involve rapid skull growth driven by genetic and environmental factors. At birth, the cranium is ~25% of adult size, and by 6-months it has nearly doubled. Early identification of cranial deformities is essential for optimizing developmental outcomes, yet current assessment methods vary in accuracy, accessibility, and utility. Traditional 2D-anthropometric measures in pediatric clinics often underestimate abnormalities. Advanced imaging tools provide greater precision but remain limited by cost, feasibility, and availability. Additionally, normative data for healthy infants are scarce. This systematic review evaluates techniques used to characterize cranial morphology in infants 0–6 months and discusses the need for 3D-data to support early diagnosis and standardized assessment.

Methods

We performed systematic PubMed searches identifying studies reporting cranial measurements or shape assessments in healthy infants (<6-months). Search terms emphasized normative development, cranial shape analysis, and age. The search produced 2,617 articles, which were screened using predefined criteria. Eligible studies included healthy infant samples, objective measurement of cranial dimensions or morphology, and standardized/imaging-based methods. After screening, 28 studies met inclusion criteria.

Results



Measurement approaches varied widely, from manual anthropometric measurements (n=4) to high-resolution 3D-imaging (n=16) and noninvasive techniques capturing 3D-cranial shape (n=11). Most research targeted pathological populations or older ages, leaving limited data for ages 0–6 months. Among healthy infant studies, findings showed rapid, non-uniform cranial growth between 3–6 months [1], emphasizing needs for

repeatable measurement tools. Sample sizes were often small, geographically narrow, and methodologically inconsistent, limiting generalizability and development of reference standards.

Discussion

Existing studies provide baseline data while highlighting critical gaps. Most research on early cranial development focuses on extreme abnormalities, such as plagiocephaly and craniosynostosis, rather than natural variation [2]. 3D-imaging methods provide more precise measurements than traditional 2D-techniques. Comprehensive longitudinal studies tracking skull development in healthy infants are scarce, limiting clinicians' ability to distinguish normal variation and early deformities. Affordable 3D-modeling tools and measurement protocols are needed to support early detection, improve clinical decision-making, and advance computational modeling of infant cranial biomechanics.

Validation of Knee Extensor Moment Estimates via OpenCap During a Single Leg Vertical Jump

Ms. Sophia Stemler, Ms. Alexandra Lynch M.S., Dr. Fatemeh Aflatounian PhD, Mr. Lucas Gaston, Dr. Scott Monfort PhD

Montana State University, Bozeman, MT, United States

Introduction

Assessing asymmetries in the knee extensor moment (KEM) can identify unresolved compensatory strategies following anterior cruciate ligament reconstruction (ACLR) [1]. However, data collection typically requires costly lab-based motion capture (MoCap). OpenCap is an affordable alternative that uses 2+ iOS devices for motion capture, automated cloud-based kinematic estimation, and estimation of kinetics through additional simulation [2]. OpenCap kinematics are relatively comparable to MoCap, though OpenCap kinetics remain unexplored [3]. This study addresses that knowledge gap by comparing kinetics estimated from OpenCap with simultaneously collected MoCap data during the single-leg vertical jump (SLVJ) [1]. We hypothesized that OpenCap+simulation KEM estimates would strongly correlate with MoCap.

Methods

Eight participants (4F/4M, 22.5±3.5yrs, 1.72±0.08m, 69.5±14kg) completed 3 SLVJ trials on their right leg. Trials were recorded with an 8-camera markerless system (Qualisys) and a 3-device OpenCap setup. MoCap data were processed in Theia3D and Visual3D. OpenCap kinetics were estimated with torque-driven OpenSim algorithmic differentiation simulations [4]. One trial was omitted because the simulation did not converge. Peak KEM (pKEM) values for propulsion and landing were normalized by participant height and bodyweight, and averaged for each individual. Correlations between MoCap and OpenCap pKEM values were evaluated.

Results

A significant strong correlation between MoCap and OpenCap pKEM estimates was found in the landing phase ($R=0.875, p=0.004$), while no significant correlation was found in the propulsion phase ($R=0.435, p=0.282$) of the SLVJ (Figure 1).

Discussion

OpenCap-based estimation of pKEM via torque-driven simulation characterized a similar trend as laboratory-grade kinetics. These findings may support the use of

OpenCap+simulation to identify KEM asymmetries following ACLR as an alternative to more expensive MoCap. This validation study is in progress; additional participants and comparison to marker-based MoCap is forthcoming. These findings motivate deeper investigation on OpenCap kinetic estimation due to the important clinical relevance of an accurate, affordable motion analysis system. Additional work should address dynamic tasks and kinetic measures that were not investigated in this study.

Adaptive finite element simulation to understand stress shielding from prosthetic interfaces in people with transfemoral amputation

Mrs. Isna Riski Safira, Prof Spyros Masouros, Prof Anthony MJ Bull

Imperial College London, London, England, United Kingdom

Introduction

Transfemoral amputees (TFA) have been associated with a higher risk of having low bone mineral density (BMD) in the remaining femoral bone compared with able-bodied individuals. According to Wolff's Law, mechanical loading plays an important role in bone remodelling, where aberrant loading can be due to movement compensation or the non-physiological interaction of the limb with the prosthetic interface. Computational simulations offer a cost-effective method to study internal bone mechanics under varied conditions. This study aims to (a) develop a novel TFA model and (b) to simulate bone remodelling due to different types of prosthetic interfaces.

Methods

An MRI scan of a TFA (32yo, 185cm, 86kg) was segmented to develop three FE models, representing an able-bodied scenario and 2 TFA scenarios (an end bearing socket and an osseintegration prosthesis). A series of load-cases from gait data of healthy and TFA participants [1,2], representing different phases of the gait cycle, were simulated sequentially in each model using iterative, adaptive FEA; the mechanical stimulus for a remodelling algorithm [3] is computed after each loading, which then alters accordingly the input material properties of the next FEA iteration. All models were started from the same initial density.

Results

Figure 1a shows that the stress distribution was lower in TFA compared to the healthy condition. Osseointegration resulted in lower stresses than TFA with socket prosthesis in the periprosthetic area. The longitudinal simulation resulted in lower BMD in this area for TFA with osseointegration compared to TFA with socket or the healthy condition (Figure 1b).

Discussion

This is the first study to simulate bone remodelling in TFA with a socket prosthetic interface compared to osseointegration. The lower BMD in TFA compared to the healthy scenario demonstrates a potential mechanism for the unloading osteopenia previously hypothesised in the literature [4]. The reduction in BMD with time in the osseointegration scenario suggests stress shielding of the bone through the implant stem's length.

Personalized Rib Cage Geometry Substantially Alters Spinal Loading Predictions in Musculoskeletal Models of Adolescent Idiopathic Scoliosis

Prof. Dr. Stefan Schmid[1,2], Ms. Kim Lieball[1,3], Mr. Philippe Bähler[1,3], Mr. Salvatore Conticello[3,1], Mr. Tim Schär[1], Prof. Dr. Moritz C. Deml[4], Prof. Dr. Carol-Claudius Hasler[5], Prof. Dr. Philippe Büchler[3]

[4]Department of Orthopaedic Surgery and Traumatology, Inselspital, University Hospital Bern, University of Bern, Bern, Bern, Switzerland. [5]Orthopaedic Department and Spine Surgery, University Children's Hospital Basel, Basel, Basel, Switzerland

Introduction

Adolescent idiopathic scoliosis (AIS) is a three-dimensional deformity of the spine and rib cage of unknown etiology. Musculoskeletal models, however, typically rely on generic rib cage geometries, which may compromise the accuracy of predicted muscle forces and resulting spinal loads. This study investigated how implementing personalized rib cage geometry affects predictions of intervertebral joint forces in AIS.

Methods

An OpenSim-based musculoskeletal model of a 13-year-old girl with AIS (main curve: T6-T11, right convex, Cobb angle: 21.8°) was generated from biplanar radiographs following a previously described workflow [1], which relies on a generic rib cage geometry. A second model was then generated by integrating the patient's own rib cage geometry, obtained through semi-automated segmentation of the radiographs to define the rib centerlines (Figure 1A-B). Spinal loads during upright standing were calculated for both models (generic vs. personalized rib cage) based on muscle forces obtained from a static optimization enforcing equilibrium.

Results

The predictions indicated substantial differences between the two models (Figure 1C). In the upper part of the scoliotic curve, the personalized model showed higher anterior-

posterior shear forces (median change: +51%) and compressive forces (+14%), as well as lower medio-lateral shear forces (-15%). In the lumbar region, the personalized model predicted generally lower forces, including anterior-posterior shear (-38%), compressive (-11%), and medio-lateral shear forces (-13%).

Discussion

This study demonstrates that incorporating personalized rib cage geometry in musculoskeletal models alters predicted spinal loading patterns in AIS. While ribs could be segmented with relatively high precision on coronal radiographs, segmentation on lateral views proved challenging, primarily due to obstructed visibility in the upper thoracic region. Furthermore, it remains uncertain whether the personalized model provides more physiologically accurate predictions than the generic model, as suitable validation data are currently lacking. In conclusion, these findings underscore the influence of rib cage personalization on predicted spinal loading in AIS and highlight the need for subject-specific anatomical detail in future musculoskeletal modeling work, as well as the development of appropriate validation approaches to assess model accuracy and clinical relevance.

An OpenSim-based Full-Body Musculoskeletal Model and Its Preliminary Validation

Mr. Amadeo Hoxao Undergrad Student, Mr. Gustavo Paulon Ph.D. Student, Dr. Suman Chowdhury Associate Professor

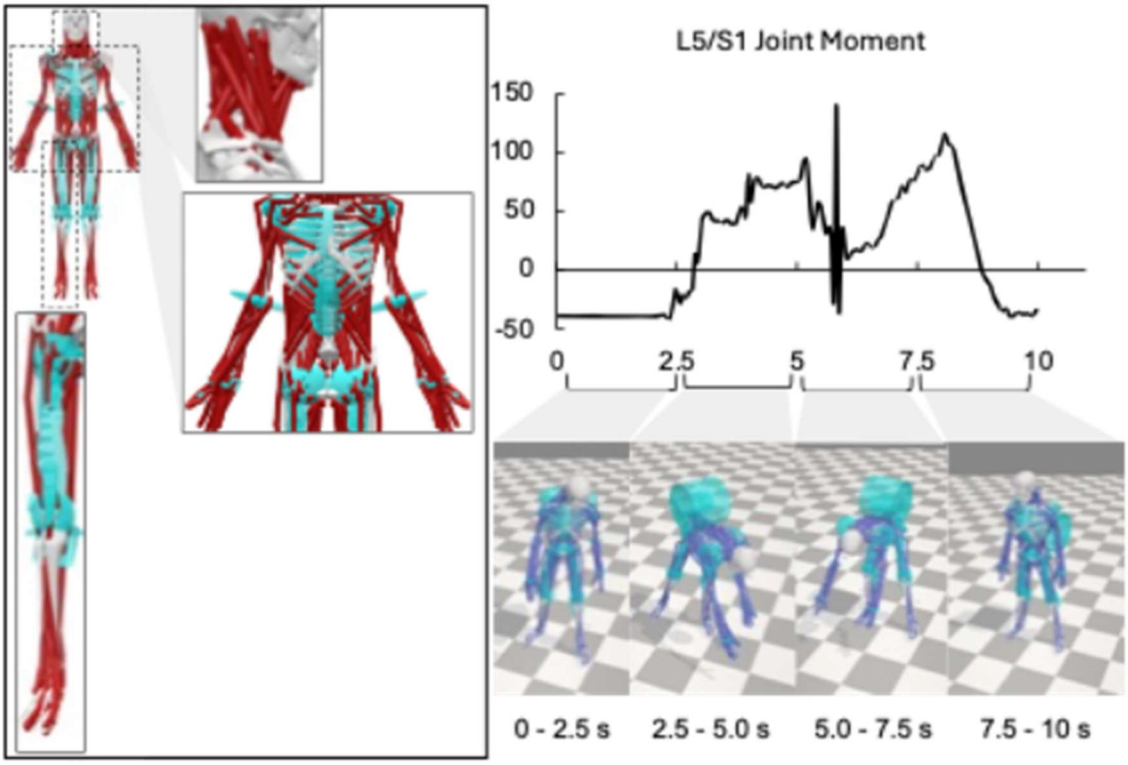
University of Florida, Gainesville, Florida, United States

Introduction

An OpenSim-based full-body musculoskeletal (MSK) model can facilitate the estimation of joint reaction forces (JRFs) and muscle activations for any given body region or the whole body, as most exertions in both occupational and daily life involve movements from multiple joints. However, developing such a full-body model requires extensive adjustments to the physiological and anatomical features of the whole-body MSK system. In this work, we will present our recently developed full-body OpenSim MSK model and demonstrate its ability to estimate muscle activations and JRFs across three work scenarios.

Methods

We started developing our model by treating the MASI model as the base structure and, using OpenSim Creator (V 0.6.2), added additional features, including 32 upper-limb muscles, 43 lower-limb muscles, 20 infra-hyoid muscles, and 377 torso muscles from previous studies. Our final model resulted in 176 bodies, 550 muscles, 131 joints, and 110 degrees of freedom. Furthermore, the scapula-clavicular joint was modeled to simulate shoulder joint kinematics by merging the acromioclavicular and the sternoclavicular joint motions with a glenoid-based reference system for the acromioclavicular joint. As of now, we have tested the Inverse Kinematics (IK) and Inverse Dynamics (ID) pipelines of our model by using data from a simple lifting task in which the subjects lifted boxes from the ground in their mid-sagittal plane and then placed them in the mid-frontal plane of their dominant side.



Results

Our preliminary results show that T4-T12 curvature falls under the hyperkyphosis range, with about 20 degrees of additional Cobb angle. Besides, our IK trials yielded Least Squares Errors (LSEs) between 0.02 and 0.05 m, increasing with increasing range of motion, with one trial reporting LSEs between 0.02 m and 0.03 m. Lastly, the model showed a maximum joint moment at L5/S1 of 115 N.m in the sagittal plane.

Discussion

The bending moment in the sagittal plane at the L5/S1 joint was consistent with previous studies; however, the observed hyperkyphosis of the T4-T12 curvature and the excessive Cobb angle indicated that the thoracic spine still needs adjustments. Currently, we are adjusting the model to validate its forward dynamics pipelines.

Effects of AI-Assisted Video Analysis on Interrater Reliability of Landing Movement Quality Assessment During a Vertical Hop

Dr. Teresa Szu-Hua Chen PT, PhD, Mr. Nathaniel Young SPT, Dr. Karen Lomond PhD, Dr. Katherine Spencer PT, DPT, OCS

Ithaca College, Ithaca, NY, United States

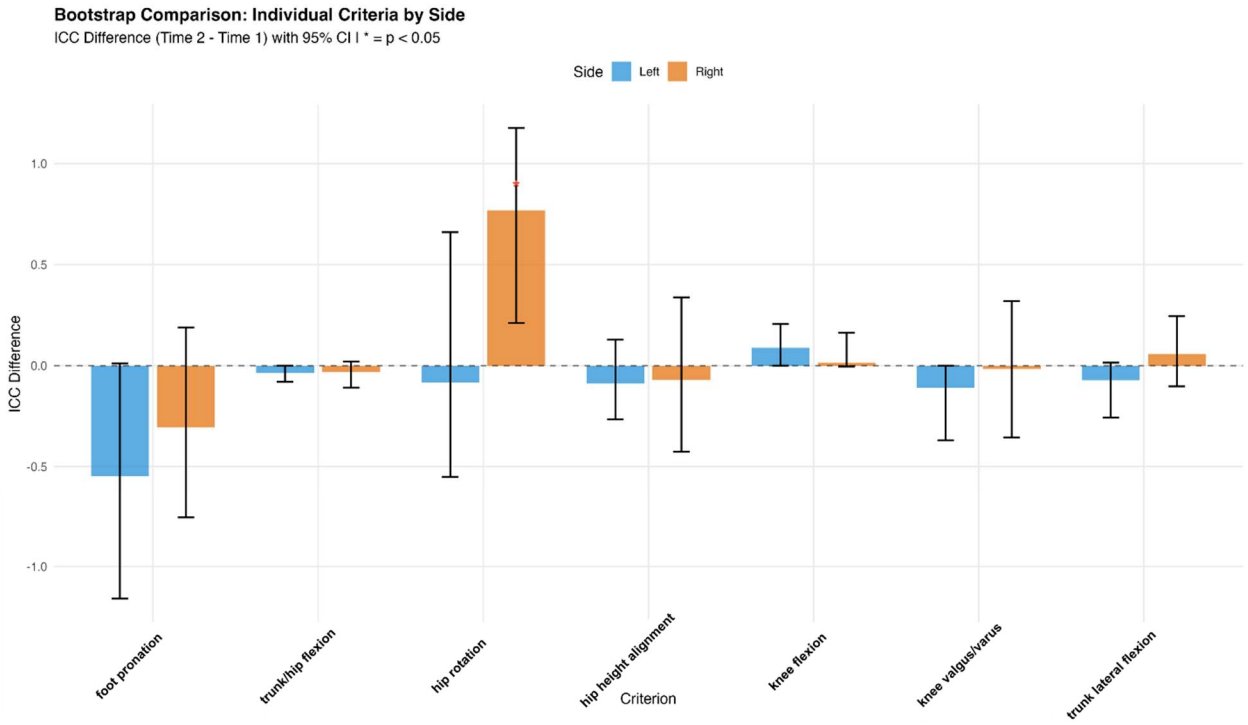
Introduction

Quality of movement assessments have become increasingly popular in rehabilitation due to their ability to detect compensatory patterns that traditional methods miss. For individuals recovering from ACL reconstruction, widely used hop tests with limb symmetry indexes often assess performance rather than movement quality, missing compensatory deficits and poorly predicting reinjury. The "Quality First" assessment offers quantitative measures to evaluate movement quality, which better predict reinjury, but interrater reliability remains uninvestigated [1]. Recent advancements in AI-assisted video analysis platforms, like Yogger, offer a potential method for reducing scoring variability between clinicians of different experience levels. This study examined whether an AI-assisted application improves interrater reliability when evaluating landing movement quality during a hop.

Methods

Twelve healthy adults participated (6 females; age: 21.8±1.4 years; height: 169.4±14.2 cm; mass: 71.1±14.5 kg). Each participant completed three vertical hop trials per leg while movements were captured from frontal and sagittal views using two iPads. KS (experienced physical therapist) and NY (first-year student physical therapist) conducted video-based scoring using "Quality First" criteria (7 items) at Time 1; NY then rescored the videos with Yogger at Time 2. Interrater reliability was calculated via intraclass correlation coefficient (ICC) and compared between conditions using bootstrap resampling with 1000 iterations. $\alpha = 0.05$.

Results



ICC revealed moderate interrater reliability at Time 1 (Left: $ICC_{(2,1)} = 0.675$, p=0.004; Right: $ICC_{(2,1)} = 0.511$, p=0.042). With Yogger, the improvement in total score was not significant for either side (Left: $\Delta = -0.073$, p=0.198; Right: $\Delta = 0.118$, p=0.354). Among individual

criteria, 1 of 7 comparisons showed significant improvement, with the largest effects in right hip rotation (Figure).

Discussion

Although overall interrater reliability did not significantly improve with Yogger, it significantly enhanced reliability for right hip rotation. This suggests AI-assisted technology might help less experienced clinicians quantify movement quality, especially for movements not easily observed, like hip rotation. In this study, the iPad captured only one frontal view, causing the right leg to be blocked by the left during landing. Future studies using two iPads for bilateral frontal views may yield greater improvements in reliability.

Optically Tracking Bone Interfragmentary Motion During Mechanical Testing of Circular External Fracture Fixators – Methodology Verification.

Mr Thomas Irish MEng, BEng[1], Dr Hemant Sharma FRCS (Trauma & Orth), MCh (Trauma & Orthopaedics)[2], Dr Ross Muir FRCS[2], Dr Todd Stewart PhD[1], Dr Marlène Mengoni PhD[1], Dr Peter Watson PhD[1]

[1]Institute of Medical and Biological Engineering, Leeds, West Yorkshire, United Kingdom. [2]Department of Trauma and Orthopaedics, Hull University Teaching Hospitals NHS Trust, Hull, East Yorkshire, United Kingdom

Introduction

Long bone fractures are commonly treated by circular external fixation to support the fracture and encourage healing via controlled micromotion at the fracture site. To understand the support provided, mechanical tests are often performed to determine frame stiffnesses. In recent times, a direct measure of permitted interfragmentary bone motion has become a desired measure of frame mechanics. However, 3D measurement of interfragmentary motion is difficult as the scale of motion ranges from 0.1 – 10mm within a complex construct [1]. The aim was to investigate reliability of optical tracking for measurement of axial and shear interfragmentary motion.

Methods

An Ilizarov-style Orthofix TrueLok frame was assembled with 4 pins and wires utilising 2 polycarbonate tubes as surrogate bones. A +/- 700N load was applied axially using an Instron E10000 mechanical testing machine. OptoTrak Smart Markers were placed at either side of the surrogate fracture site and tracked using an OptoTrak camera to measure interfragmentary motion. To investigate variability of the system, a series of tests were performed: Control – the frame was loaded for 10 consecutive cycles, 3 times; Frame Placement - the frame was removed and re-mounted in the E10000 machine and 10 consecutive cycles were performed, repeated 3 times; Marker Placement - a marker was altered, and 10 consecutive cycles were performed, repeated 3 times.

Results

The maximum relative error in axial interfragmentary motion was 0.10%. In comparison, maximum relative error in shear interfragmentary motion was 7.1% attributed to the lower magnitude of motion (0.1mm between 1.4 and 1.5mm). The standard deviation for each test scenario of 30 cycles was consistently minimal (0.003-0.02mm) [Figure1].

Discussion

A low (<0.03mm) standard deviation for each test and acceptable relative errors across the test scenarios shows that regardless of frame/marker physical movement and re-positioning, often required during such testing, the OptoTrak Certus tracking system could measure axial and shear motion at the fracture site with high accuracy and repeatability. Whilst the technology requires a line of sight to the imaging camera, its ability to compare fracture characteristics is very advantageous to orthopaedic surgeons wanting to understand frame mechanics.

Images (Optional)

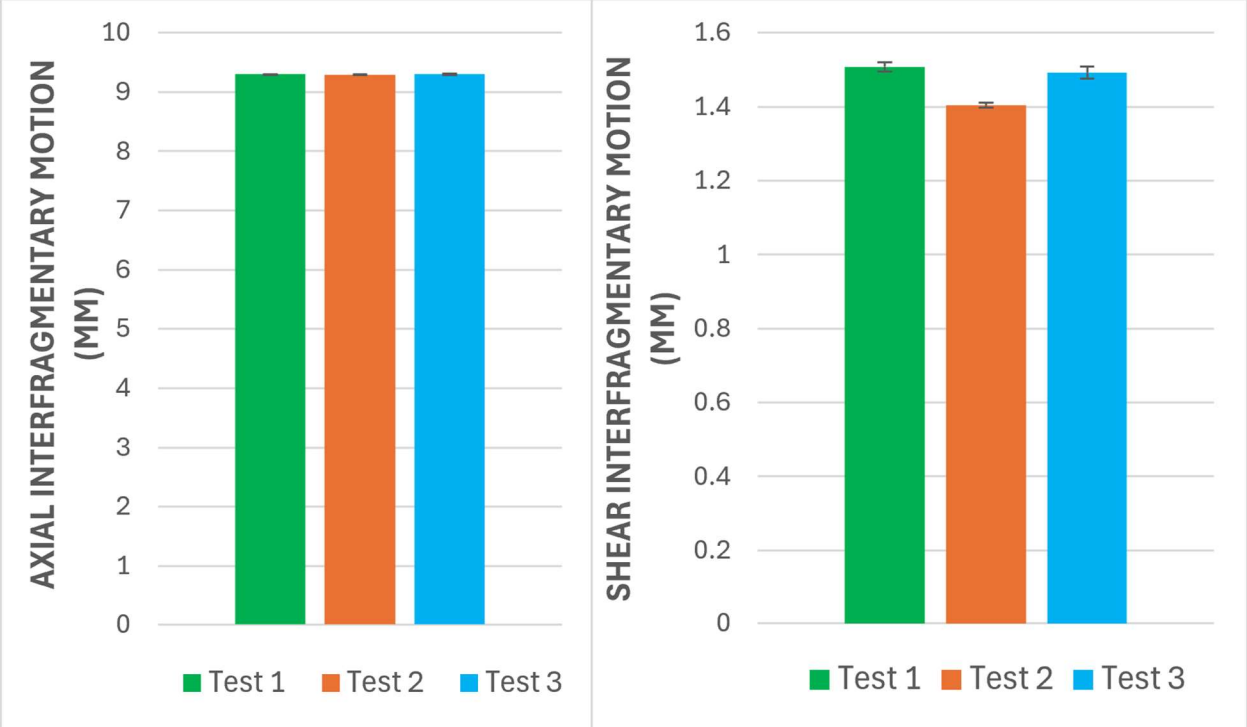

Figure 1. (left) Axial interfragmentary motion and (right) Shear interfragmentary motion during 700N compression. Error bars represent standard deviation across all 30 cycles for each test scenario.

Assessing Forearm Muscle Activity During Grip Strengthening Exercises

Mr. Travis Winteler[1], Dr. Mike Sonne PhD[2], Dr. Michael Holmes PhD[1]

[1]Brock University, St. Catherines, Ontario, Canada. [2]Chicago Cubs, Chicago, Illinois, United States

Introduction

Baseball pitchers often injure the Ulnar Collateral Ligament (UCL). One mechanism of injury suggests that increased load is placed on the UCL when the forearm muscles fatigue due to repetitive high intensity throwing [1]. The flexor digitorum superficialis (FDS) supports the UCL by countering elbow torque [2]. However, it is difficult to measure the individual finger flexor compartments of FDS with surface electromyography. We aimed to assess the effect of grip strengthening devices on forearm muscle activity. A secondary aim was to explore the use of motor point detection to measure FDS.

Methods

10 university aged adults (6M/4F) completed a repeated measures protocol involving 3 grip devices: Grip Master, Handexer, and FlexPro Grip (Figure 1). Participants performed gripping tasks with both a “heavy” and “medium” intensity (defined by device). Electrodes with an 11 mm interelectrode distance (Grass Technologies, USA) were applied over flexor carpi ulnaris/radialis (FCU/FCR) and compartments of FDS. FDS compartments (index, middle, ring, little) were determined via stimulation of the motor point. Data were processed with MATLAB and included a linear envelope at 6Hz and normalized to maximal voluntary contractions (MVC).

Results

There was a significant main effect of intensity for average FCU activity ($p=.048$), as the heavy intensity generated greater muscle activity (13.5 ± 5.9 %MVC). There was no main effect of exercise for any of the muscles. Muscle activity in the FDS compartments across all conditions is listed lowest to highest: index (33.7 ± 6.7 %MVC), little (34.8 ± 5.5 %MVC), ring (45.8 ± 5.1 %MVC), and middle finger (60.2 ± 12.6 %MVC).

Discussion

Grip device did not influence muscle activity of the FDS, FCU, and FCR. Our novel motor point approach was critical to minimize crosstalk and allow isolation of FDS compartments. The FDS provides elbow stability [1] and, has lacked investigation due to measurement complexity. Many variables influence muscle development, and the notion

that higher activity directly relates to gains in strength or hypertrophy should be treated with caution [3].

Mr. Vahid Zare

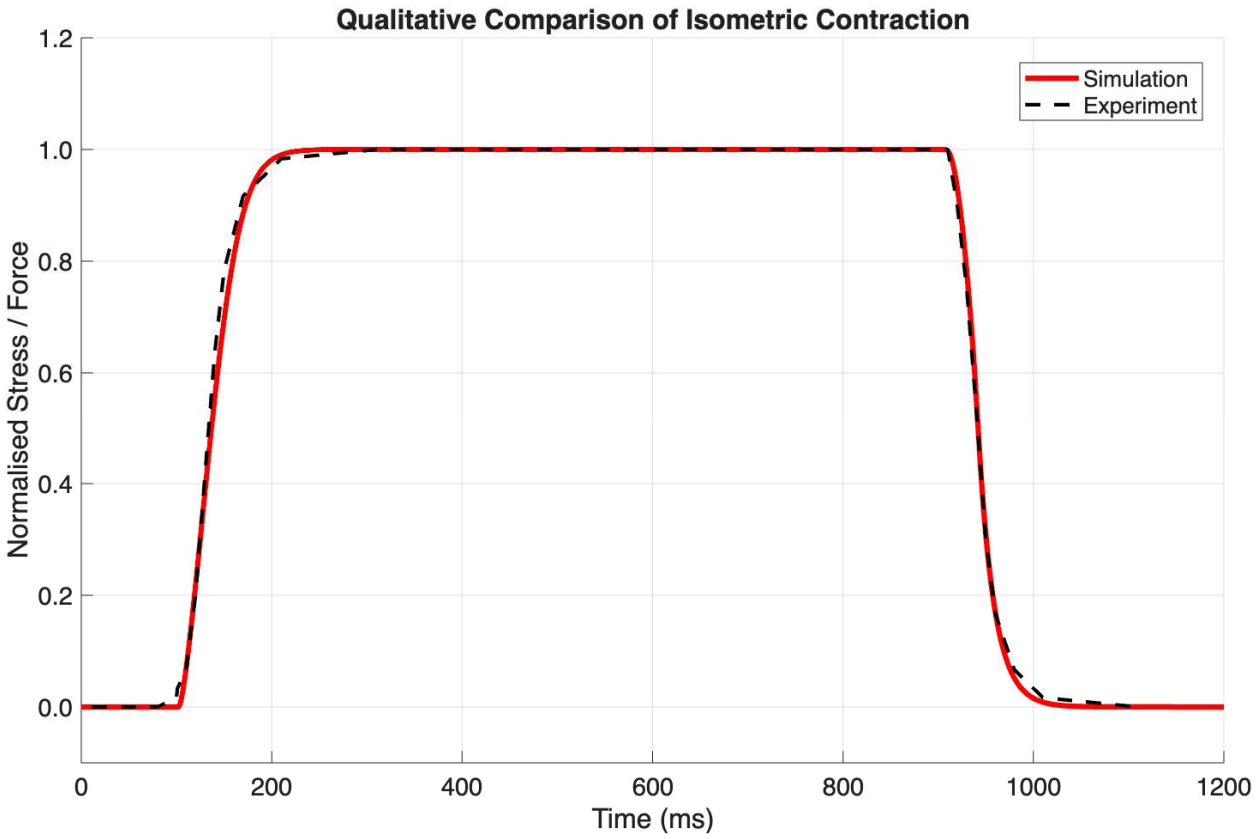
Dr. Alessio Gizzi

Introduction

The mechanism of muscle contraction started to become clear only in the 1950s. The discovery of the arrangement of the actin and myosin filaments led to the sliding filament theory and, shortly after, to the cross-bridge model of force production. Continuum mechanical models describe the bulk behaviour of muscle and use either an additive decomposition of the stress or a multiplicative decomposition of the deformation. We propose a novel approach, based on the multiplicative decomposition of the deformation and the Fenton-Karma electrophysiological model [1].

Methods

Muscle tissue is modelled as an active medium by multiplicatively decomposing its deformation into an active part, due to activation/contraction, and a passive, elastic part (this approach has historically been devised to model elastoplasticity). The active deformation, which is not measurable experimentally, is treated as an additional kinematical variable describing a rearrangement in the muscle's structure. The application of the principle of virtual work and the second principle of thermodynamics reveals a corresponding configurational force, which exerts work on the active deformation, and must be defined via a constitutive equation [2]. The configurational force, which we call activation, depends on electrophysiological (via the Fenton-Karma model), chemical (calcium concentration) and mechanical variable (muscle total and active stretch).



Results

The coupled mechano-electrophysiological model was solved to determine active stretch, total stretch and force generation. The model was used to reproduce the cases of isometric and isotonic contractions, as well as the classical force-length relationship. The figure shows the normalised force-time history during an isometric tetanic contraction. The solid red line represents the simulation results obtained from the proposed coupled continuum model, while the dashed black line represents the experimental data [3].

Discussion

The proposed framework robustly captures fundamental mechanical behaviours from experimental data. However, replicating complex history-dependent phenomena such as residual force enhancement requires further expanding the current kinematics. Future iterations of the model must explicitly incorporate the titin molecule to bridge this gap between standard mechanics and microstructural reality.

[9]Department of Clinical Radiology, Kuopio University Hospital, Kuopio, -, Finland

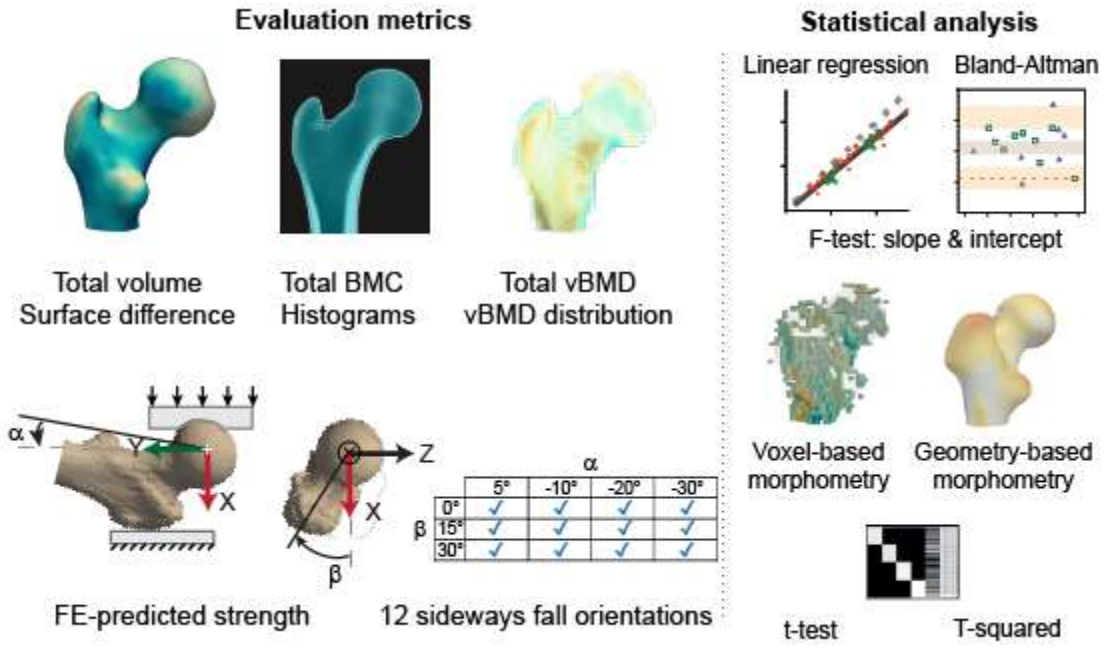
Introduction

Assessments of 3D geometry, bone density distribution and bone strength currently require the use of computed tomography (CT). Estimations of 3D shape and density distribution of the proximal femur from 2D dual-energy x-ray absorptiometry (DXA) images, by using statistical shape and appearance models (SSAM), has been proposed as a low-cost and low-radiation alternative [1]. One implementation of SSAM is the commercially available 3D-Shaper software. However, there is currently no independent validation of this software on *in vivo* clinical images, across a multi-ethic dataset.

Methods

120 paired DXA and CT images from five cohorts (age: 20–85; aBMD:0.61–1.21 g/cm2; absence of disease treatment) were included in the study (Fig 1). Following semi-automatic segmentation to obtain the femoral geometry, bone mineral density (BMD) was derived from the X-ray attenuation coefficient using calibration phantom relationship. Simulated CT volumes and surfaces, termed 3D-DXA, were generated from 2D-DXA images (3D-Shaper Medical, Spain). 3D-DXA was compared to CT models to assess the geometrical and density distributional errors, using vertex-to-surface distance and voxel-based morphometry, respectively. The effect of the combined errors on predicted femoral

strength was evaluated with finite element analysis (FEA) of sideways fall in 12 orientations [2].



Results

Linear regression results showed that total bone mineral content were similar between 3D-DXA and CT models [AW1.1](slope=0.96, bias=1.6g), but volumetric measurements of 3D-DXA were underpredicted [AW2.1]for bone volume (slope=0.89, bias=9.73cm3) and total vBMD (slope=0.88, bias=6.27g/cm3). Cohort-specific differences in spatial distribution of vBMD were largest below the lesser trochanter and within 4 mg/cm3. However, differences in surface distance were not significantly different (Hotelling T-test). Modified Bland-Altman plots revealed positive slopes across all 12 orientations, as 3D-DXA femoral strengths were underpredicted at higher CT strengths.

Discussion

The low difference of total bone volume and error in surface distance shows that the shape of the femur is largely similar across the cohorts. However, the altered BMD distribution contributed to the underperformance of predicted bone strength. This reveals the limit of 3D-DXA as a surrogate for CT without further retraining of the statistical shape and appearance model.

Leveraging Thumb Muscle Redundancy With EMG-Based Clustering to Reduce Intramuscular Needle Insertions

Mr. Victor Akpaloo MS, Mr. Benjamin Nowak, Dr. Jennifer Nichols Ph.D.

University of Florida, Gainesville, Florida, United States

Introduction

Intramuscular electromyography (EMG) uses fine-wire needle electrodes inserted directly into muscles to record electrical activity with high spatial precision. This is especially useful for the small, overlapping muscles in the hand, where surface EMG cannot reliably separate individual muscles' activity. However, inserting electrodes into multiple muscles can cause pain and discomfort for participants and may not be necessary, as several thumb muscles are functionally redundant. As a critical first step toward designing future experiments that reduce intramuscular needle insertions without sacrificing data quality, this study aimed to identify clusters of thumb muscles with similar EMG patterns.

Methods

This analysis included 20 participants (18 females, 2 males; age: 67.5±9.5 years). Intramuscular EMG was collected from eight thumb muscles while participants performed three trials of key pinch. The EMG signals were processed using standard methods (filtering and rectification) and amplitude normalized using participant-specific maximum voluntary contractions. To identify muscle clusters, we applied and compared two k-means methods, namely a feature-based method and a method incorporating dynamic time warping (DTW) distance. Both were evaluated across k=2-7 clusters using silhouette analysis.

Results

The number of distinct muscle clusters identified were three (feature-based method) and four (DTW method). Both methods isolated EPL as a unique cluster, indicating it requires its own intramuscular insertion. The DTW method separated the remaining muscles into a flexor cluster (FPL-FPB), a radial abduction/opposition cluster (APL-EPB-OPP), and an intrinsic ulnar cluster (ADD-FDI), based on similarities in activation timing and shape (Fig. 1a). In contrast, the feature-based method separated the remaining muscles into an intrinsic cluster (FPB-ADD-FDI-OPP) and an extrinsic cluster (FPL-APL-EPB), driven by similarities in overall amplitude and variability (Fig. 1b).

Discussion

DTW identified four functionally-driven clusters, whereas feature-based clustering yielded fewer, yet intuitive, clusters at the cost of combining some temporally distinct intrinsic muscles patterns. Both approaches support the presence of thumb muscle redundancy and indicate that recording from only 3–4 representative muscles may approximate the behavior of all eight during key pinch. Ongoing work will test whether this strategy generalizes to other thumb tasks and enables accurate prediction of muscle activity from a reduced number of electrodes.

Images (Optional)

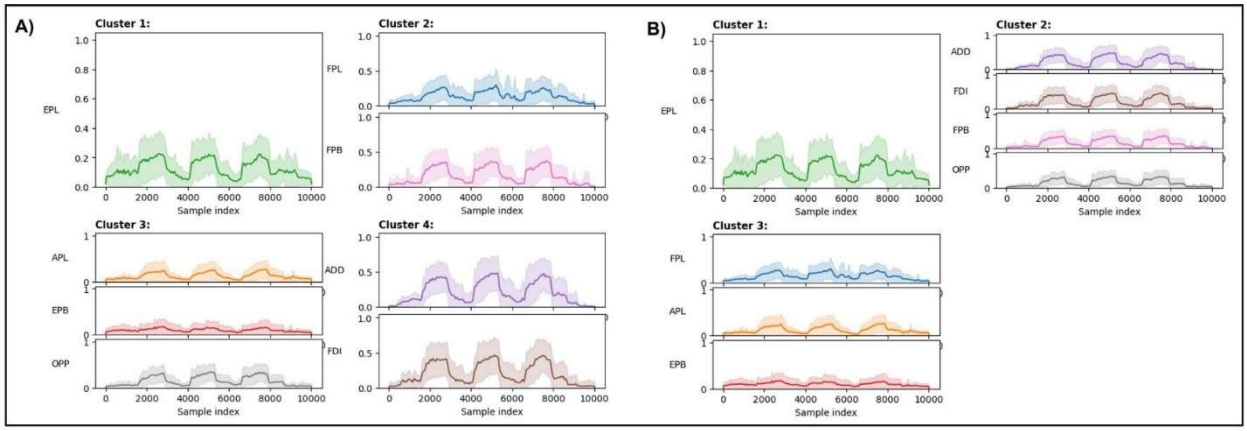

Figure 1: Average muscle activity normalized on a zero to one scale shown for (A) the four clustered identified using k-means with DTW distance metric versus (B) the three clusters identified using the feature-based k-means method. Shaded regions indicate standard deviation across subjects.

Biomechanical Effects of Architecture in Skeletal Muscle: Fusiform vs. Unipennate Morphologies

Dr. Wei Zeng

New York Institute of Technology, Old Westbury, New York, United States

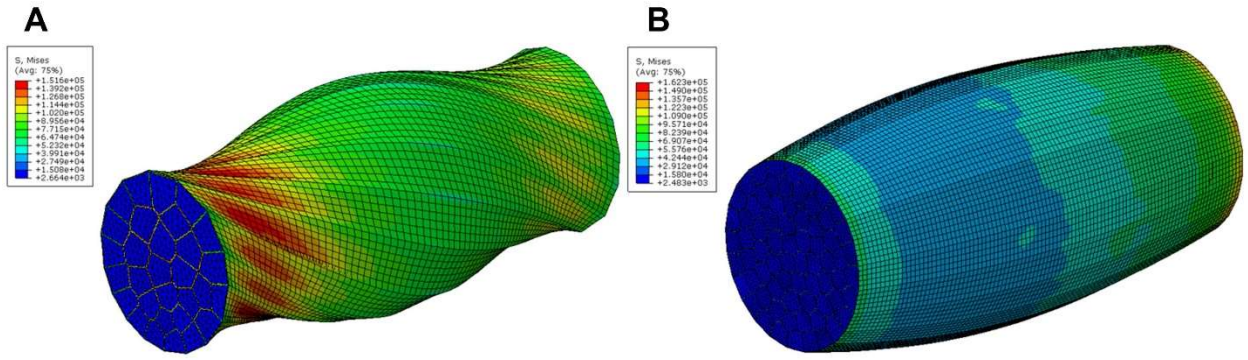
Introduction

Skeletal muscles exhibit diverse architectural patterns—including fusiform, unipennate, bipennate, and multipennate—each influencing mechanical performance. While fusiform muscles contain fibers aligned with the main axis, unipennate muscles incorporate a consistent pennation angle that alters force transmission. Capturing how these architectural differences shape active and passive behavior remains an unmet need in computational biomechanics. This study aims to develop a morphology-aware finite element (FE) framework for generating and simulating three-dimensional representative volume elements (RVEs) of fusiform and unipennate muscles using a Hill-type constitutive model with activation dynamics [1].

Methods

RVEs were constructed using Lloyd's algorithm and Centroidal Voronoi Tessellation (CVT) to generate a biofidelic distribution of fascicle-like inner cells surrounded by extracellular matrix (ECM). Two muscle morphologies were modeled: fusiform and unipennate, the latter evaluated at pennation angles of 10°, 20°, and 30°, consistent with clinical observations. Geometries were inflated to approximate physiological cross-sectional profiles. All models were meshed with 6-node C3D6 elements (element size: 0.05), with full node-to-node connectivity between fascicles and ECM. FE simulations incorporated two materials: fascicles governed by a Hill-type active model implemented through a user subroutine via Abaqus, and ECM modeled as passive connective tissue. A cohesive interaction maintained fascicle-ECM contact. Boundary conditions fixed one end of the RVE, while the opposite end underwent 10% axial elongation. Each morphology was analyzed under passive and fully activated states.

Results



The framework successfully generated and simulated fusiform and unipennate RVEs with controlled activation. Fusiform muscles exhibited uniform stress distribution with a passive peak stress of 1.62×10^{5} Pa. In contrast, unipennate RVEs showed asymmetric stress concentrations localized near regions of reduced cross-sectional area, with patterns

varying systematically with pennation angle. Morphology-driven differences were evident across both passive and active conditions.

Discussion

This framework provides a robust approach for analyzing how muscle architecture influences mechanical response. Results highlight substantial differences between fusiform and unipennate geometries, underscoring the need for morphology-specific modeling. Future work will extend the framework to higher pennation angles, asymmetric fusiform shapes, and more complex architectures (e.g., bipennate and multipennate muscles), enabling patient-specific simulations for clinical and rehabilitation applications.

A New Load-Transfer-Based Assessment Approach for Hip Stems: Application to a Cementless Stem During Walking

Dr. Mohamed Bendjaballah, Dr. Wissal Mesfar

King Saud University, Riyadh, Central Region, Saudi Arabia

Introduction

Stress shielding remains a key concern in total hip replacement, arising when the stiff stem carries loads normally borne by the proximal femur. Existing analytical and experimental studies describe load-transfer patterns but lack a simple metric to compare stem–bone load sharing or assess how bone loading changes after implantation. This study introduces the D50/50 parameter, the stem location where implant and cortical bone carry equal internal load and physiological cortical loading begins to recover. From subject-specific FE simulations, internal loadings along the femoral shaft were used to compute D50/50, enabling comparison of cementless stem designs.

Methods

3D intact and implanted femoral models were reconstructed from CT data, refined in Geomagic Studio®, and combined with a SUMMIT-type stem in SolidWorks®. The models were meshed in ABAQUS using C3D20R elements, with orthotropic cortical bone and isotropic cancellous bone and Ti–6Al–4V stem; all interfaces were bonded. Hip joint and muscle loads from Heller et al. simulated walking [1]. Internal forces and moments were computed at 35 equidistant cross-sections and plotted along the shaft length. The D50/50 point was identified as the intersection of implant and bone curves, beyond which bone recovers its physiological load.

Results

Equal bone–stem load sharing occurred at **32% of the stem length** for axial force (Fx) and **36%** for lateral bending (My) (Figure 1), the components generating normal stress. Internal shear forces and torsional moments were minimal. The forward bending moment (Mz) increased distally under antero-posterior loading with little interplay. Thus, the **worst-case D50/50 was 36% for the studied stem under walking**.

Discussion

Model predictions showed good agreement with in-vivo and analytical reconstructions for both intact and implanted femora [2, 3], supporting the validity of the internal force calculations. The study's key contribution is the introduction of the **D50/50** parameter, a

novel, dimensionless indicator that identifies where bone and stem share equal load. By quantifying the spatial recovery of physiological loading, D50/50 offers a clear, comparative and clinically meaningful measure of stem load-transfer performance.

A Proposal for a Non-invasive Ligament Elongation Measurement Method

Mr. Yudai Yamamoto MA, Mr. Md Fahad Sahed BA, Dr. Katsuyuki Morishita Assistant Professor, Dr., Prof. Ikuo Mizuuchi Professor

Tokyo University of Agriculture and Technology, Koganei, Tokyo, Japan

Introduction

Measuring ligament elongation helps clarify injury mechanisms, prevent injuries, and evaluate treatment outcomes. Non-invasive methods such as fluoroscopy, CT, MRI, and motion capture exist. Although motion capture allows unrestricted, dynamic movement, it is affected by soft-tissue motion, which can introduce positional errors up to 20 mm[1]. This research aims to reduce these errors by modeling soft-tissue deformation.

Methods

We modeled knee in the frontal place by representing connections between skin and bone using ligament, flesh, and skin springs. Joint angle was estimated as the angle that minimizes total stored potential energy. We compared ligament-elongation estimation methods: (A) our proposed method, (B) estimating roll angle by minimizing error between skin-marker positions and those predicted by a rigid-link model, and (C) estimating roll angle by averaging posture defined by two selected skin markers.We also conducted an experimental comparison using a knee-joint prototype with springs representing ligament, flesh, and skin. The stiffness ratios were set to emulate human joint stiffness around the sagittal axis, and we compared method (A), (B) and (C).

Results

Using the mathematical model, we compared angle errors between the true angle and the angles estimated by each method. For all methods, error increased as the joint angle approached 30 deg. When flesh stiffness equaled skin stiffness, estimation erros tended to increase. Our proposed method outperformed the others. Evaluations using the physical prototype showed that our method achieved the highest accuracy for angles 1 to 2.5 deg. At approximately, -2.5 to 1 deg, results differed from those of the mathematical model due to measurement and modeling errors.

Discussion

Method (C) is less affected because it uses markers rigid to the shin, avoiding skin and flesh deformation. In method (B), only skin deformation is considered, causing its estimation accuracy to degrade more than that of method (A). Method (A) accounts for

both skin and flesh deformation, however contains angle estimation error due to irreversibility between forward and inverse optimization processes. Improving measurement accuracy and obtaining more precise spring coefficients, dimensions, and attachment locations would further demonstrate the superiority of the proposed method (A).

Images (Optional)

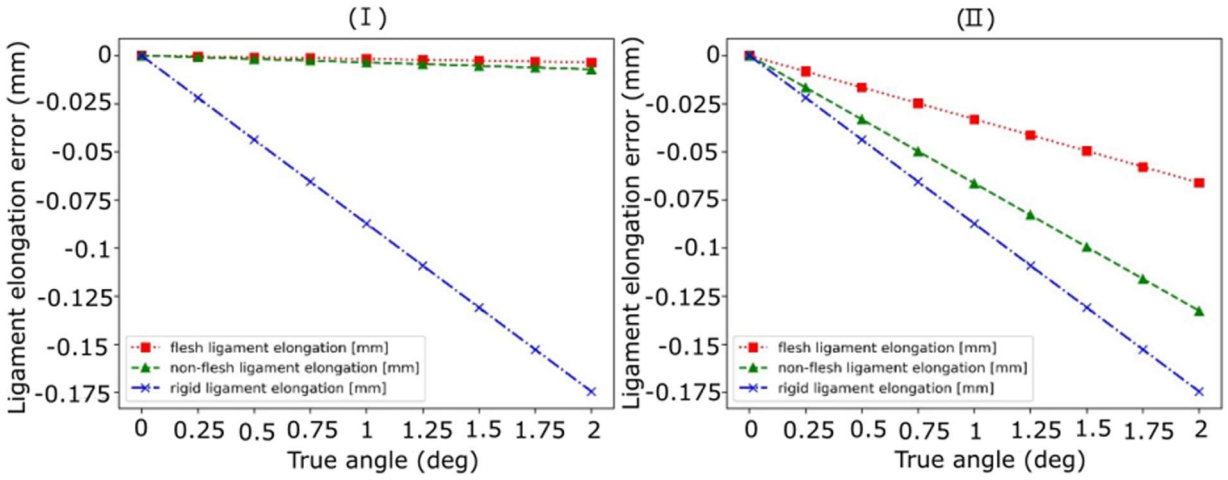

Fig.1 Ligament elongation errors (0-2 deg) obtained by three estimation methods under two parameter conditions (Ⅰ)$k_{MCL} = k_{LCL} = 1.07 \times 10, k_{flesh} = 1.5, k_{skin} = 2.5 \times 10^{-2}$ [N/mm], and(Ⅱ)$k_{MCL} = k_{LCL} = 1.07 \times 10, k_{flesh} = k_{skin} = 2.5 \times 10^{-2}$ [N/mm]. Square markers denote our proposed method (A), triangle markers indicate method (B), and cross markers indicate method (C).

Influence of Transverse Work on Muscle Power Output During Cyclic Contraction

Ms. Zahra Heydari PhD Student, Biomedical Physiology & Kinesiology (BPK), Simon Fraser University[1], Mr. Harshil Pathak PhD Student, Department of Mathematics, Simon Fraser University[2], Dr. James M. Wakeling Professor, Biomedical Physiology & Kinesiology (BPK), Simon Fraser University[3], Dr. Nilima Nigam Professor, Department of Mathematics, Simon Fraser University[2]

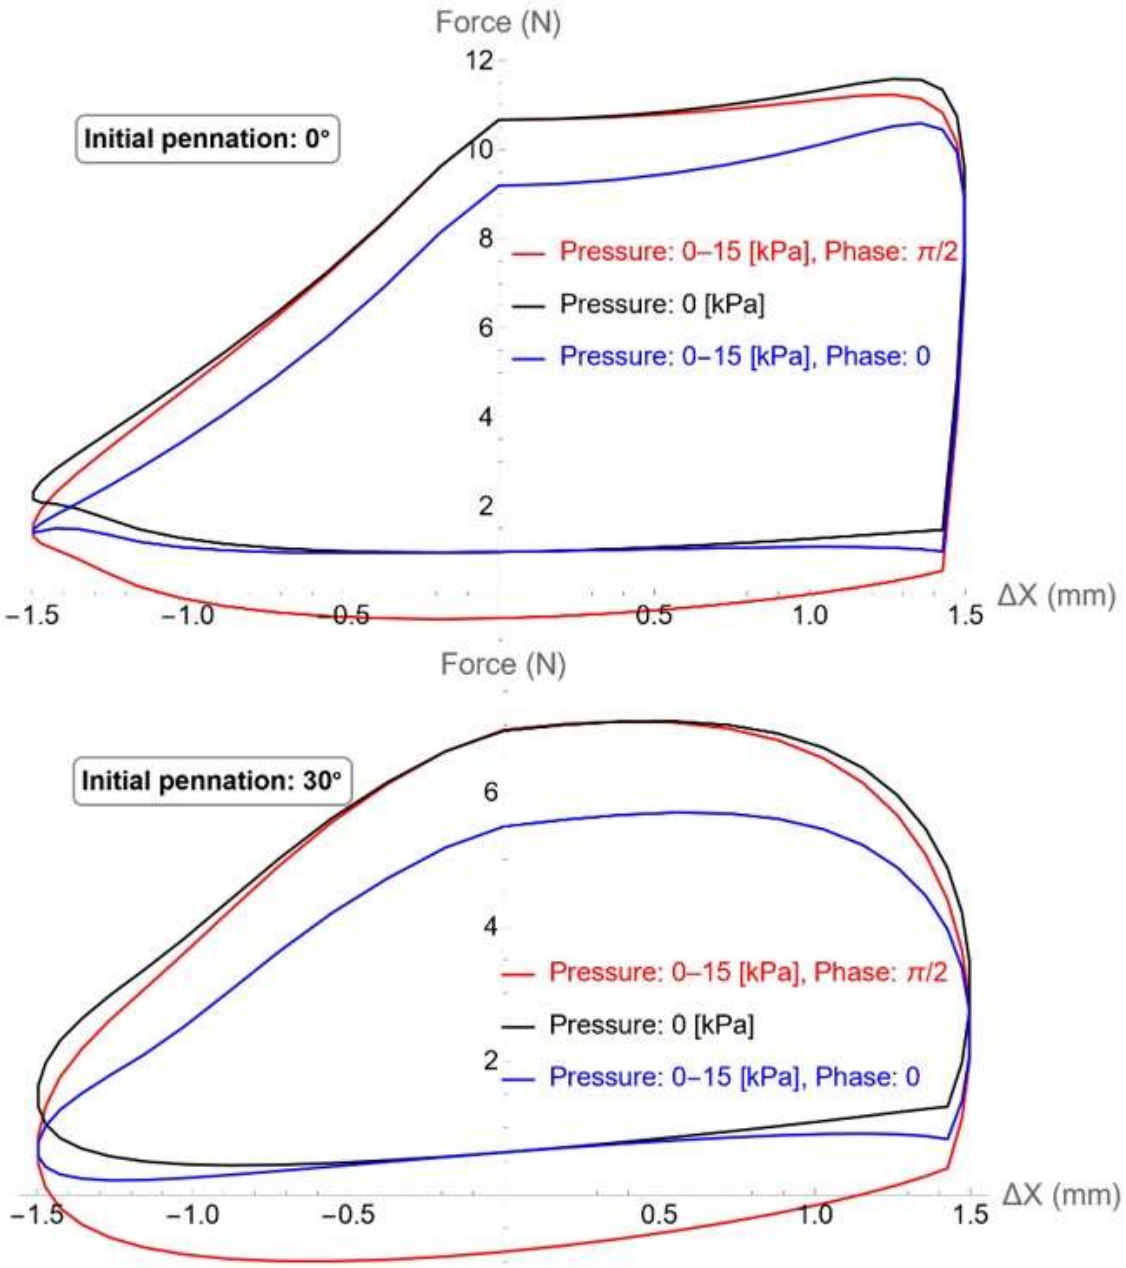
[1]Biomedical Physiology & Kinesiology (BPK), Simon Fraser University, Burnaby, British Columbia (BC), Canada. [2]Department of Mathematics, Simon Fraser University, Burnaby, BC, Canada. [3]Biomedical Physiology & Kinesiology (BPK), Simon Fraser University, Burnaby, BC, Canada

Introduction

Muscles perform mechanical work and power in their line of action. As muscles change in length their cross-sectional area must change in an attempt to maintain their volume. Transverse bulging has can perform" lifting work", and transverse compression acts to decrease the longitudinal forces of the muscle; however, these considerations have only been for isometric contractions. This study investigated whether an oscillating transverse load could modify the power that the muscle generates in its line of action during a cyclic contraction.

Methods

A three-dimensional muscle model (Flexodeal-lite, an open-source model that represents muscle as a fibre-reinforced composite biomaterial) was used. We simulated cyclic contractions of a block of muscle that was largely active during its shortening phase. Transverse, time-varying, pressures were applied to the transverse faces of the block. The phase of these pressures relative to the longitudinal length-changes were varied. 16 conditions were tested: 2 initial pennation angles (0 and 30°), 2 compression levels (0 and 15 kPa), and 4 phases.



Results

The muscle block acted line a “motor” generating positive power in its line-of-action. The oscillating transverse pressure resulted in both augmentation and suppression of the power. These general effects were consistent between the parallel-fibred block (0° pennation) and the pennate (30° pennation) blocks of muscle that were simulated; however, in the 0° pennation block the deformations and transverse work were the same in the width and thickness directions, but the deformations and work differed between the width and thickness directions for the 30° pennation block.

Discussion

Doing external work on the transverse surfaces of a muscle can alter the longitudinal work done by the muscle in its line-of-action. This has implications for future design of prosthetic devices or inspire novel mechanisms for augmenting joint work and power when we move. The optimal conditions for enhancing longitudinal muscle work have not been established yet, however, even in these preliminary simulations we are observing an efficiency of about 50% that relates the transverse work applied to the enhancement of the longitudinal work

Cortical Bone Adaptive Response to Loading is Impaired in Male *Col1a1$^{Jrt/+}$* Mouse Model of Osteogenesis Imperfecta

Mr Abhimanyu Mertiya[1,2], Dr Mayumi Umebayashi[1], Mr Richard Ilianu[1], Mr Karim Elsayed[1], Dr Meet Shah[1], Dr Michael Bruccoleri[1], Dr Frank Rauch[1,3], Dr Bettina Willie[1,2]

[1]Shriners Hospital for Children, Research Center, Montreal, Quebec, Canada. [2]Faculty of Dental Medicine and Oral Health Sciences, McGill University, Montreal, Quebec, Canada. [3]Department of Pediatrics, McGill University, Montreal, Quebec, Canada

Introduction

Osteogenesis Imperfecta (OI) is a heritable bone fragility disorder, with the majority of cases caused by mutations in genes encoding type I collagen (*COL1A1* and *COL1A2*). The cross-sectional area of long bones is persistently low in people with OI, and thus may be a key factor leading to increased long bone fracture rates. We hypothesize that this reduced bone circumference is the result of reduced periosteal apposition caused by an altered response to mechanical loading. To test this hypothesis, we examined mechano-adaptation in a mouse model of OI.

Methods

Sixteen-week old male *Col1a1$^{Jrt/+}$* OI mice and their wild type (WT) littermates (n=10 mice/genotype) underwent two weeks of dynamic, compressive *in vivo* tibial loading to the left tibia (once daily, 5 days/week), while right tibia served as non-loaded control (Fig 1A). *In vivo* micro-computed tomography analysis was performed at baseline (day 0) and day 15 to quantify changes in diaphyseal cortical and metaphyseal trabecular bone mass and microstructure. ANOVA, Tukey's post-hoc, and paired t-tests were performed ($p<0.05$).

Results

Loading led to a 134% greater increase in cortical thickness of left limb compared to non-loaded right limb in WT mice (Fig 1B). We also observed a 118% greater decrease in marrow area of loaded limb compared to non-loaded limb in WT mice, although this was only trending towards significance ($p=0.06$, Fig 1C). Whereas no significant difference was measured in cortical thickness or marrow area between the loaded and non-loaded limbs in the *Col1a1$^{Jrt/+}$* mice (Fig 1B & 1C). Loading did not significantly increase metaphyseal trabecular bone in WT mice, but showed a trend of increased bone deposition in trabecular bone volume (per unit total volume) in loaded limb as compared to non-loaded limb for WT

mice, and a trend of bone loss (reduced trabecular volume per unit of total volume in loaded limb) in the *Col1a1*$^{Jrt/+}$ mice (Fig 1D).

Discussion

In line with our hypothesis, male *Col1a1*$^{Jrt/+}$ OI mice did not respond to loading. Studies in female *Col1a1*$^{Jrt/+}$ mice are ongoing. These results indicate that the male *Col1a1*$^{Jrt/+}$ OI mouse model has a reduced cortical mechano-adaptive response.

Images (Optional)

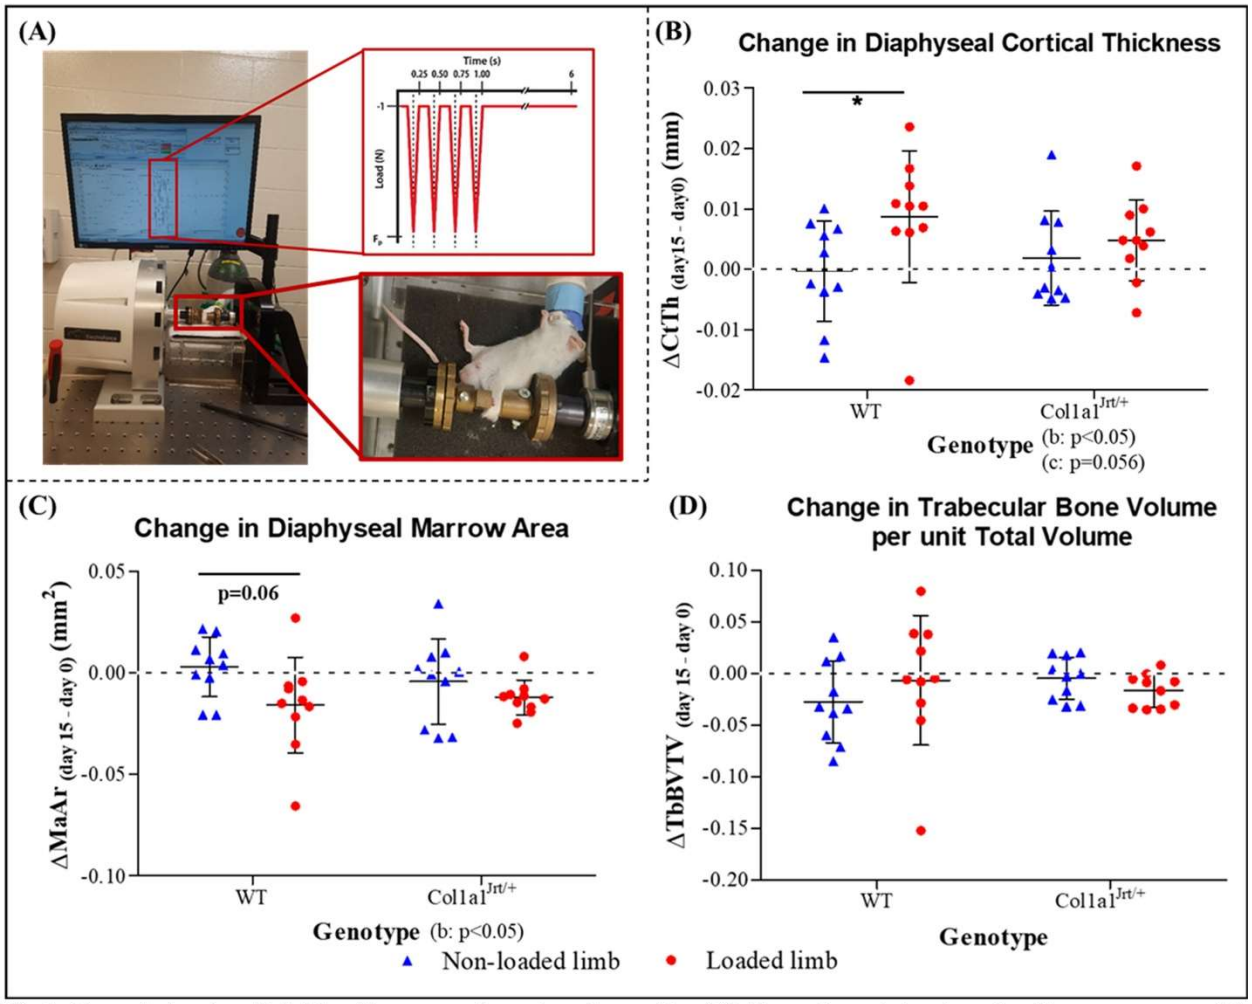

Fig.1. 2-week *in vivo* tibial loading experiment and results: (A) Experimental setup: loading apparatus with mouse position shown in bottom right and loading waveform shown in upper right; **(B) change in cortical thickness (ΔCtTh (day 15-day 0)); (C) change in marrow area (ΔMaAr (day 15-day 0)); (D) change in trabecular bone volume per unit total volume (ΔTbBVTV (day 15-day 0));** Means ± SD; ANOVA (a=genotype, b=loading, c=interaction), tukey's posthoc test; paired t-test (* p<0.05).

Correlating MRI-Based Paraspinal Muscle Quality and Single Fibre Contractile Function in Canines With Spinal Degeneration

Mr Adam Bui MSc[1], Dr Josh Briar PhD[1], Dr Francesca Samarani DVM[2], Dr Alex Chan DVM[1], Dr Fiona James DVM[1], Dr Stephen Everest DVM[1], Dr Stephen Brown PhD[1]

[1]University of Guelph, Guelph, Ontario, Canada. [2]Canada West Veterinary Specialists and Critical Care Hospital, Vancouver, British Columbia, Canada

Mr Adam Bui

Dr Josh Briar

Introduction

Paraspinal muscle dysfunction has been associated with low back pain in humans [1]. Magnetic resonance imaging (MRI) provides a non-invasive method for evaluating structural changes related to muscle quality. However, how this relates to contractile function is unclear. The purpose of this study was to correlate MRI-based muscle quality to single-fibre contractile function in canines being surgically treated for IVD extrusion. It was hypothesized that lower quality muscle presented on MRI would correlate to lower performance in contractile function.

Methods

Preoperative imaging of the thoracolumbar spine was performed using MRI (n=11) in canines being surgically treated for IVD extrusions. T1-weighted MRI DICOM images were taken at the level of extrusion. Regions of interests were drawn to include the bulk of the multifidus. MRIs utilized pixel intensity of the muscle normalized to a region of adjacent subcutaneous fat to create a muscle-fat index; a higher muscle-fat index indicated lower muscle quality. Muscle biopsies (n=11) were obtained during surgery, chemically permeabilized and single fibres were extracted. Single fibres were maximally activated in a calcium-rich solution, and specific force was measured.

Results

A weak positive correlation (r^2=0.17, p=0.20) was observed between T1-weighted MRI muscle-fat index and muscle fibre specific force (Figure 1).

Discussion

It was expected that lower muscle quality measured by MRI would correlate with lower performance in single-fibre contractile function. A higher muscle-fat index indicates greater fatty infiltration, or lower-quality muscle. Contrary to the hypothesis, as the muscle-fat index increased, muscle-specific force also increased, albeit in a weak, non-statistically significant manner. Previous literature has investigated the relationship between fatty infiltration and muscle force production, suggesting that an increase in fat infiltration is associated with decreased force production [2]. However, this novel study investigates force production on a single fibre level, which may offer insights into compensation mechanisms related to fatty infiltration in muscle due to lost strength in neighbouring degenerated fibres. Next steps are to increase the sample size to determine if this relationship between muscle quality and contractile function strengthens or weakens.

Images (Optional)

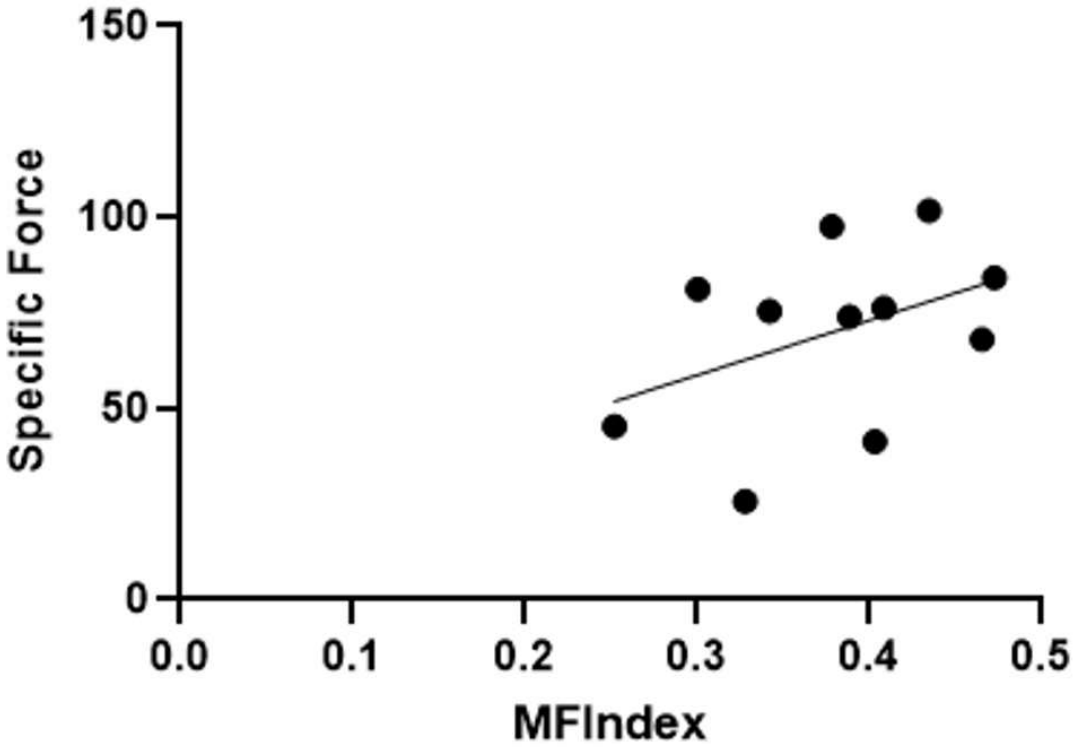

Figure 1. Relationship between MRI-based muscle-fat index and single fibre specific force. Note that a higher MFIndex indicates higher fatty infiltration.

Investigating Stretch-Shortening Cycle Performance Enhancement in Single Muscle Fibres Following Acute Hindlimb Immobilization of the Rat

Dr. Alexander Zero PhD, Dr. Geoffrey Power PhD

University of Guelph, Guelph, Ontario, Canada

Introduction

Power production of single muscle fibres is impaired following periods of immobilization. However, muscles are sensitive to their activation history and thus isolated activations may not be representative of their contractile capacity. For example, during locomotion muscles undergo stretch-shortening cycles (SSCs) in which active muscle shortening is directly preceded by active muscle lengthening. Indeed, the SSC effect can be characterized by the enhancement of power during shortening that is preceded by active lengthening compared to a pure shortening contraction. Therefore, the purpose was to assess the effect of immobilization on SSC performance of single muscle fibres.

Methods

The left hindlimb of three Wistar rats (~11 weeks) was placed in a cast and immobilized in full plantar flexion for 14 days, the right leg was an internal control. Following immobilization, fibres were dissected and chemically permeabilized from the soleus and medial gastrocnemius of both legs. Single fibres were maximally activated (pCa 4.5, 12°C) while mounted between a force transducer and length controller. For SSCs, fibres were stretched from a sarcomere length of 2.5 to 3.0μm and immediately shortened back to 2.5μm at a speed of 0.6 Lo/s for both phases.

Results

Thirty-eight fibres (11 soleus and 27 medial gastrocnemius) were tested (16 from the immobilized limb). Fibres from the immobilized limb had a ~40% smaller cross-sectional area. At a sarcomere length of 2.5μm absolute and normalized force from the immobilized limb were ~58% and ~26% lower, respectively. During active stretch (2.5 to 3.0μm) peak absolute and normalized eccentric force of the immobilized limb was ~68 and ~42% lower, respectively. During active shortening (3.0 to 2.5μm) the immobilized limb had a ~65 and ~38% lower absolute and normalized power, respectively. Following immobilization, the SSC effect occurred such that when active stretch preceded active shortening normalized power increased ~66% relative to a pure shortening contraction. However, the non-casted limb displayed a larger SSC effect of a ~84%.

Discussion

The SSC effect is still apparent at the single fibre level following acute immobilization. Therefore, despite impairments in contractile capacity, single fibres are still sensitive to activation history force enhancement albeit likely in a reduced capacity.

Adaptations of Serial Sarcomere Number and Mechanical Function Following Unilateral Hindlimb Immobilization and Recovery in the Plantar Flexors of Female Ovariectomized and Intact Rats

Ms. Alexandra Q. Kirkup, Ms. Amelia Rilling, Dr. Alexander M. Zero, Dr. Geoffrey A. Power

University of Guelph, Guelph, Ontario, Canada

Introduction

Immobilization of muscle in a shortened position induces marked reductions in serial sarcomere number (SSN), thereby impairing contractile function. While this response is well documented in male rodents, the effects of estrogen on SSN and contractile function in female rodents following immobilization and re-ambulation remain unclear. The purpose of this study was to investigate estrogen-mediated differences in loss and subsequent recovery of SSN in the soleus and medial gastrocnemius (MG) and plantar flexor contractile function following 14 days of unilateral hindlimb immobilization and 4 weeks of voluntary ambulation.

Methods

The left hindlimb of intact (normal estrogen; n = 24; mass = 290.6g ± 25.1g) and ovariectomized (OVX; low estrogen; n = 24; mass = 317.8g ± 27.3g) adult female Sprague-Dawley rats was immobilized in maximal plantar-flexion for 14 days. In-vivo plantar-flexor mechanical testing was performed pre-cast and at 4 recovery timepoints (post-cast, 1-,2-,4- weeks following cast removal). At each recovery timepoint, n = 6 intact and n = 6 OVX rats were euthanized, both legs were fixed in formalin, the soleus and MG were harvested, and connective tissue was digested in nitric acid, then muscles were stored in glycerol. Fascicle length was measured, and laser diffraction was performed to measure sarcomere length. Serial sarcomere number was then calculated.

Results

Soleus SSN loss and plantar flexor peak torque followed similar trajectories, with comparable ~16% and ~45% decreases in both groups, respectively, immediately following casting ($P < 0.05$). By 4 weeks, intact rats demonstrated full architectural and functional recovery, with SSN returning to baseline (–1%) and torque surpassing pre-cast values (+28%; $P < 0.05$). In contrast, OVX rats showed blunted recovery across all measures, with

persistent deficits in SSN (–10%) and torque (–14%; both $P < 0.05$), indicating impaired recovery under low-estrogen conditions.

Discussion

The parallel recovery trajectories of SSN and peak torque indicate that estrogen may facilitate serial sarcomerogenesis and restoration of muscle contractile capacity following acute immobilization in female rats. Overall, these results identify estrogen as an important modulator of longitudinal muscle morphology and whole muscle contractile function in female rats.

Effects of Asymmetric Glycerol-Induced Paraspinal Muscle Degeneration on Spinal Curvature

Ms Aliza Siebenaller MSc, Dr Stephen Brown PhD

University of Guelph, Guelph, Ontario, Canada

Ms Aliza Siebenaller

Introduction

Adult degenerative scoliosis (ADS) is associated with paraspinal muscle degeneration and dysfunction; however, it remains unclear if these muscular changes drive deformity. Interestingly, this muscle degeneration presents asymmetrically in some ADS patients [1]. The purpose of this study was to evaluate the effects of induced asymmetric lumbar and thoracic paraspinal muscle degeneration on spinal deformity in mice. A resulting coronal plane imbalance and scoliotic curvature were hypothesized to occur.

Methods

23 female C57BL/6 mice were divided into three groups: control (n=6), ipsilateral (n=9), and contralateral (n=8). To induce muscle degeneration, glycerol [2] was injected into multifidus (15ul) and erector spinae (20ul) muscles of the right lumbar and thoracic regions (ipsilateral), or right lumbar and left thoracic regions (contralateral). Injections were administered two weeks apart for a total of 4 timepoints, and mice were sacrificed two weeks after the last injection. Control animals received no injections. Micro-CT imaging was used to measure spinal curvature (Cobb angle) in the coronal and sagittal planes throughout the study. Statistical significance was determined using two-way repeated measures ANOVA (a=0.05) and Tukey's multiple comparisons test.

Results

Mean coronal Cobb angles were small (<6°) at all timepoints and no significant difference was found between groups. In the sagittal plane, a significant effect of group ($p=0.0007$), time ($p=0.0002$), and interaction ($p<0.0001$) were found. Post-hoc analysis showed that only the contralateral group demonstrated a significant decrease in sagittal plane Cobb angle over time (Figure 1).

Discussion

Contrary to the hypothesis, no clinically meaningful differences were found in coronal plane Cobb angles following muscle glycerol injections. Surprisingly, significant decreases in sagittal plane Cobb angles were found in the contralateral group. The contralateral group did have higher baseline Cobb angles than the control and ipsilateral groups which could explain why a more significant decrease was observed.

Images (Optional)

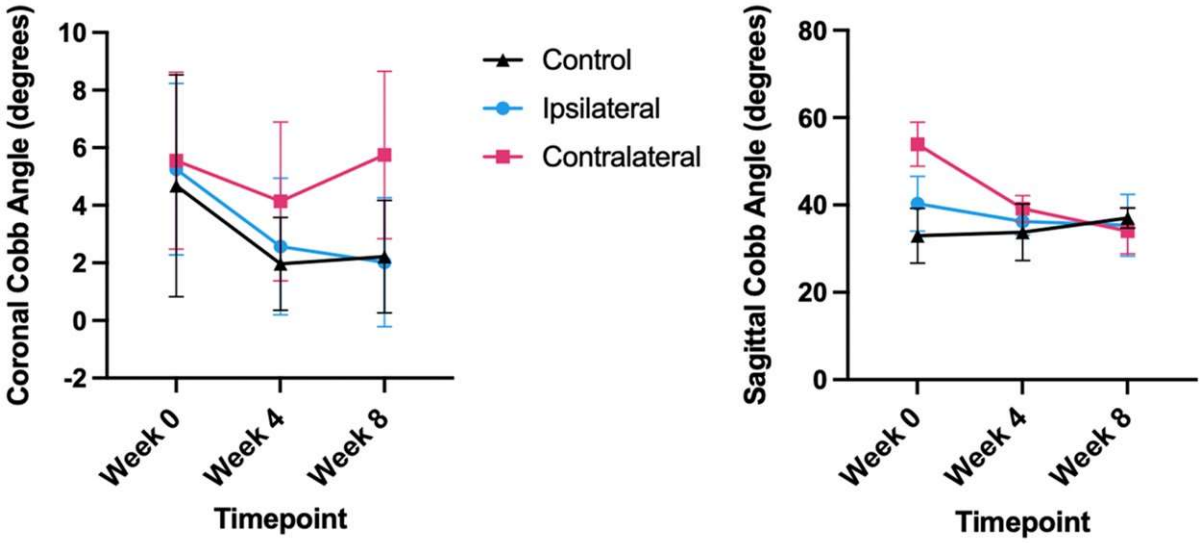

Figure 1. Mean ± SD Cobb angles in the coronal and sagittal planes for the control, ipsilateral, and contralateral groups at 0, 4, and 8 weeks

The Impact of Eccentric Overload Training and Conventional Resistance Training on Sarcomerogenesis and Mechanical Function in Ovariectomized and Intact Rats

Ms. Amelia Rilling, Ms. Alexandra Q. Kirkup, Dr. Geoffrey A. Power

University of Guelph, Guelph, ON, Canada

Introduction

Sarcomerogenesis is the serial addition of sarcomeres in a muscle, which can impact the muscle's contractile performance. Eccentric exercise, where the muscle is stretched to long lengths, promotes sarcomerogenesis owing to the stress and strain throughout the muscle's excursion. However, during conventional (CONV) resistance training, eccentric contractions are typically performed with concentric contractions. The load-bearing capacity of eccentric contractions exceeds concentric contractions, resulting in a sub-maximal eccentric stimulus. Eccentric overload ($ECC_{OVERLOAD}$) training offers a maximal eccentric stimulus. Recently, we found a 15% greater soleus serial sarcomer number (SSN) response with $ECC_{OVERLOAD}$ training in young male and female rats. Females had the largest response. Therefore, female sex hormones may play a role in longitudinal remodeling. Estradiol, a female sex hormone, has been shown to augment muscle recovery after eccentric exercise-induced muscle damage, and thus may have a role in the muscle's response to eccentric exercise.

Methods

Using an *in-vivo* rodent model, we investigated the impact of estradiol and estradiol deficiency on the mechanical and morphological response to resistance training. Forty ovariectomized (n=20) and ovary-intact (n=20) female rats completed 4 weeks of plantar flexor $ECC_{OVERLOAD}$ (n=20) or CONV (n=20) resistance training of the left leg 3 days/week with the right leg as an internal control. Mechanical outcomes (torque at short (90°) and long (70°) muscle lengths, passive tension, and power) were assessed pre- and post-training. Following training, rats were sacrificed, the legs were fixed in formalin, and the soleus and medial gastrocnemius were harvested. Fascicles were measured, and sarcomere length was determined using laser diffraction. Fascicle length and sarcomere length were used to calculate SSN.

Results

Torque increased with training at 90° ($p<0.01$) ~17% in the $ECC_{OVERLOAD}$ and ~11% in the CONV group, similarly between groups and estradiol conditions ($p>0.05$). However, passive tension at 90° was 60% greater in OVX compared to ovary-intact rats following training

($p<0.05$). Ongoing morphological analysis currently shows soleus SSN increased ~22% in the ovary-intact and ~11% in the OVX $ECC_{OVERLOAD}$ group. Comparatively, SSN increased ~1% in the ovary intact, and ~5% in the OVX CONV group.

Discussion

Therefore, estrogen may influence longitudinal muscle remodeling in response to $ECC_{OVERLOAD}$ training.

Fit2Tissue: A Scalable Web Platform with Hierarchical Bayesian Data Selection

Miss Amna Aamir[1], Dr Olga Barrera[1,2], Miss Saduni Wanniarachchi[1], Dr Eleni Elia[1], Dr Hussein Rappel[3]

[1]Oxford Brookes University, Oxford, Oxfordshire, United Kingdom. [2]University of Oxford, Oxford, Oxfordshire, United Kingdom. [3]University of Exeter, Exeter, Devon, United Kingdom

Introduction

Hyperelastic constitutive models play a significant role in the modelling of soft tissue and other biological systems by capturing their non-linear mechanical response and facilitating their description through concise sets of material model coefficients. The organisation of these parameters in the literature for soft tissue remains a complex challenge due to the inherent heterogeneity of biological materials, the custom sample preparation and testing procedures and varied optimisation methods. Therefore, there is an acute need in the field for a unified collection of parameters across soft tissue with a built-in framework to link these relevant characteristics, such as sample dimensions, anatomy-specific properties and employ statistical methods such as Bayesian analysis, which leverage the accumulation of data for better informed predictions of these coefficients across datasets using a host of predictor variables.

Methods

The first phase involved developing a web-based application integrating a hyperelastic model-fitting tool and database. Platform validation used open-access data to model and store material parameters with metadata. Material models were implemented as closed-form incompressible solutions, with optimisation via non-linear least squares or minimisation using SciPy's optimise library.

To extend this architecture with a Bayesian approach, analyses are being conducted on material coefficients of a new porcine meniscus dataset, using layer depth and fibre orientation as predictors and material coefficients as targets.

Results

The robustness of the web app's model-fitting and upload functions was demonstrated using porcine aortic valve (n=12) and bovine meniscus (n=50) datasets. The influence of

independent data-related characteristics and the optimisation settings for two hyperelastic functions were reflected in the varied RMSE across the input data and their subgroups. The preliminary work on Bayesian hierarchical modelling for the porcine meniscus dataset has quantified natural variation, yielding narrower credible intervals and reduced overfitting through partial pooling

Discussion

Fit2Tissue provides a reproducible, collaborative framework for soft-tissue biomechanics by combining model-fitting tools with a growing data repository. This infrastructure enhances transparency, encourages community contribution, and supports predictive modelling. Ongoing Bayesian analyses on heterogeneous musculoskeletal data demonstrate its ability to provide probabilistic insights alongside traditional deterministic model-fitting approaches.

Hormonal and Mechanobiological Model for Epiphyseal Bone Growth

Dr.-Ing. Andreas Lipphaus[1,2], Prof. Dr.-Ing. Ulrich Witzel[1], Prof. Dr. med. Ralf-Bodo Tröbs[3], Dr.-Ing. Marc Neumann[1], Prof. Dr. med. Jochen Hubertus[2]

[1]Biomedical Engineering Lab, Ruhr-University Bochum, Bochum, NRW, Germany. [2]Clinic of Pediatric Surgery, Marienhospital, Witten, NRW, Germany. [3]Department of Pediatric Surgery, St. Vinzenz Hospital, Paderborn, NRW, Germany

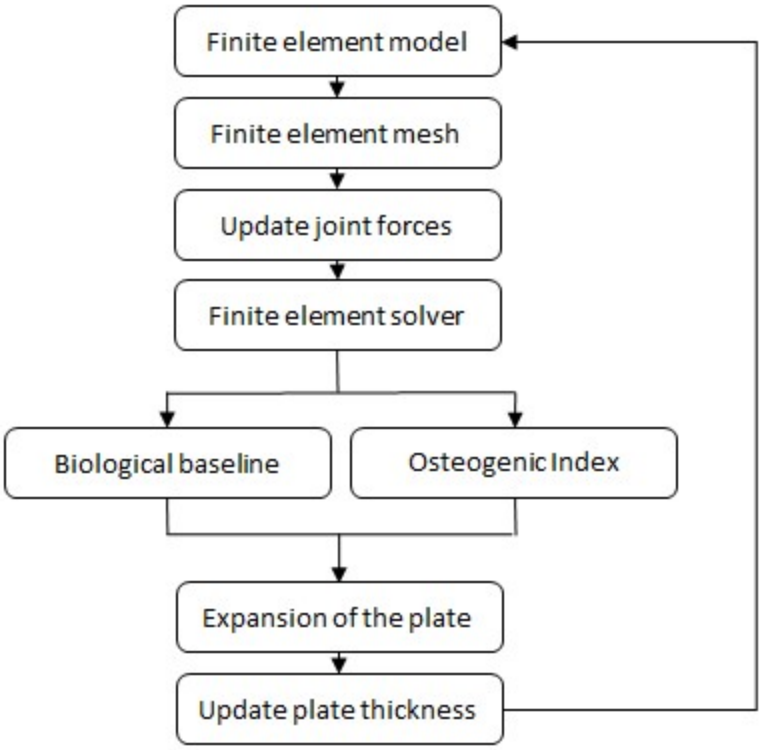
Introduction

Several mechanobiological models of bone growth at the epiphyseal plates exist in the literature. These models typically use a constant biological growth rate and a variable mechanical component based on the osteogenic index. However, during growth, the biological baseline changes due to cellular senescence and pubertal growth spurt.

Methods

The model presented here combines a mechanobiological model of epiphyseal growth [1], the narrowing of the growth plate due to cell senescence and ossification as a logarithmic function, and the increase in the biological growth rate during puberty as a Gaussian function [2]. A two 2 rotational finite element model using PLANE183 elements is established in ANSYS Mechanical 19.2. The model includes articular cartilage, cancellous and cortical bone, bone marrow, and the proliferative and hypertrophic zone of the growth plate. Growth in the proliferative zone is modeled as isotropic expansion. Growth in the hypertrophic zone is modeled as unidirectional growth in the direction of element distortion. Appophyseal growth of bone is included based on Wolff´s Law. The increase in joint load is approximated to be equal to the increase in body weight. After each iteration representing one month the model dimensions are updated and remeshed to avoid element distorsion.

Results



Simulating longitudinal bone growth between the age of 1 and 18 matches clinically observed growth curves by Green and Anderson [3]. The closure of the growth plates in the simplified bone is reached at the age of 16.

Discussion

To apply bone growth simulations clinically, it is necessary to take age-appropriate growth rates into account. Long-term bone growth can be modeled using remeshing to avoid element distortion. The interaction between these three factors remains unclear to date.

The combination of the presented model with a genuine bone structure and age-accurate boundary conditions is necassary for validation and clinical use.

Investigating Asymmetrical Bone Adaptations of the Third Metacarpal in Clockwise Racing Thoroughbreds

Mr Andrew Koshyk[1], Mr Tadiwa H Waungana[1], Mr Moustafa Abbadi[1], Dr Samuel Smalley[2], Mr Martin Wong[2], Dr W Brent Edwards[1]

[1]University of Calgary, Calgary, Alberta, Canada. [2]Hong Kong Jockey Club, Hong Kong, SAR, China

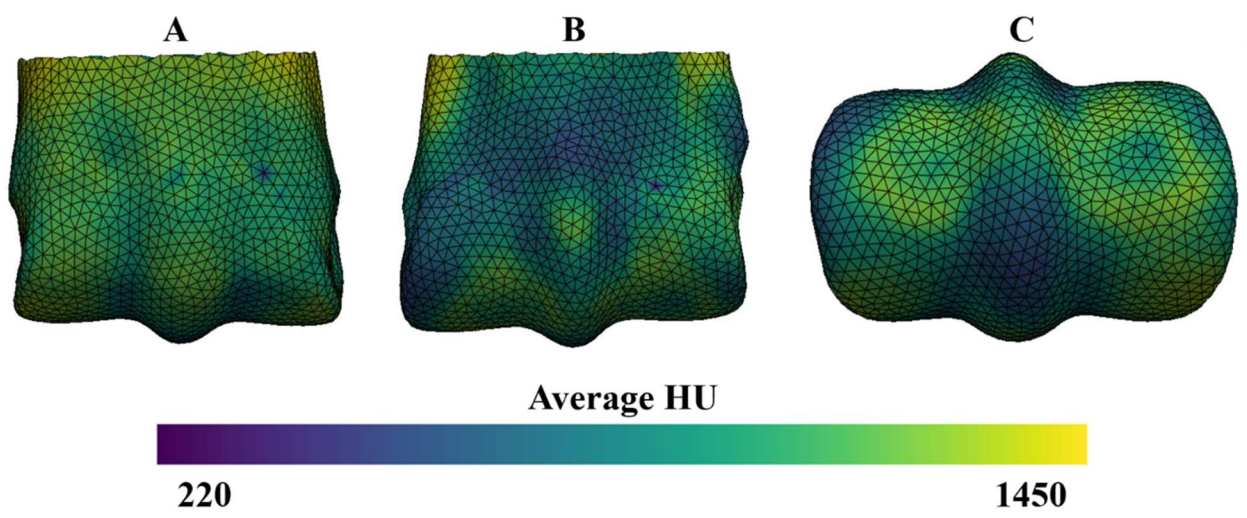
Introduction

Fractures at the metacarpophalangeal (MCP) joint are among the most common and fatal injuries experienced by Thoroughbred racehorses. Thoroughbreds race at a gallop, a naturally asymmetrical gait, and consistently race and train in the same direction around a track. Consequently, their left and right forelimbs may be exposed to unequal loading, potentially leading to distinct bone adaptations and fracture risk. The objective of this work was to assess differences in bone geometry and density between the left and right forelimbs of clockwise racing Thoroughbreds.

Methods

Bilateral computed tomography scans of MCP joints were obtained from 28 clockwise racing Thoroughbreds (Canon Medical System; acquisition settings: 120 kVp, 450 mA, in-plane resolution of 0.625 × 0.625 mm, slice thickness of 0.3 mm). Third metacarpal (MC3) bones were segmented using Mimics (Materialise, Leuven, Belgium) and cropped to retain the distal most 55 mm.

Subchondral bone density was estimated at each node across the MC3 joint surface (see Figure) by averaging Hounsfield units along a 5 mm ray projected normal to the surface using the Visualization Toolkit, Simple Insight Toolkit, and PyVista libraries within Python (v3.8.5). A statistical shape model incorporating density was developed using ShapeWorks [1]. Shape and density differences between left and right forelimbs were evaluated at each particle in the model ($\alpha = 0.05$).



Results

The statistical shape model captured 85% of the total anatomical variation within the first 8 principal components (PCs). Including all PCs, the model achieved a generalization error of 0.36 mm and a specificity of 0.78 mm. Statistical analyses revealed no significant differences in shape or density between left and right MC3 bones.

Discussion

No significant asymmetries in MC3 bone morphology or density were observed between the left and right forelimbs of clockwise racing Thoroughbreds. These results suggest that left and right forelimbs, while potentially subjected to unequal loading, undergo similar bone adaptations.

Images (Optional)

Subchondral bone density mapped across the (A) dorsal, (B) palmar, and (C) distal aspects of the MC3 joint surface by averaging Hounsfield units (HU) along a 5 mm ray projected normal to the surface.

Why Does Wearing High Heels Stiffen the Achilles Tendon?

Mr. Andrew Thornton[1], Dr. Jordyn Schroeder[2], Dr. Gregory Sawicki[2,3], Dr. Owen Beck[1]

[1]University of Texas at Austin, Austin, Texas, United States. [2]Woodruff School of Mechanical Engineering, Atlanta, Georgia, United States. [3]School of Biological Sciences, Atlanta, Georgia, United States

Introduction

Modern footwear is typically designed to improve user biomechanics while worn, but not after. Habitually wearing high heels may increase user Achilles tendon stiffness [1], which has functional implications after the high heels are doffed. Interestingly, high heel use may not increase peak strain on the Achilles tendon, which is a primary factor governing tendon stiffening [2]. Here, we seek to determine the factors governing tendon stiffness changes with habitual high heel use.

Methods

Eight participants naïve to high heel use (3 female) wore shoes that set the ankle at 14° plantar flexion during standing for 13-16 weeks. Participants reported their daily steps with and without the heel lifts. We computed Achilles tendon stiffness consistent with (3) and slack length using dynamometry and ultrasonography. We calculated Achilles tendon slack length using the distance between the junction of the muscle-tendon and the insertion at the onset of passive force development during passive dynamometer trials. Further, we estimated participant Achilles tendon strain during treadmill walking at 1.3 m/s. To do so, we multiplied ground reaction forces by the ankle's gear ratio and divided by stiffness and tendon slack length.

Results

Achilles tendon stiffness increased in participants who walked in heel lifts for >1500 steps/day ($p = 0.040$), but not in those who took <1000 steps/day ($p = 0.307$). Walking in heel lifts vs. flats improved ankle effective mechanical advantage 9.1% ($p = 0.003$), contributing to the 13.7% reduced peak tendon strain per step ($p < 0.001$). Neither change in peak strain from flats to heel lifts ($p = 0.163$) nor daily steps in heel lifts ($p = 0.112$) independently related to the change in tendon stiffness due to habitually wearing heel lifts. Achilles tendon slack length did not change in heel lift users or non-users ($p \geq 0.172$).

Discussion

Habitually wearing heel-lifted footwear increased user Achilles tendon stiffness despite reducing peak strain on the tendon. The mechanism(s) underlying the Achilles tendon stiffening due to chronic high heel use remains elusive.

[6]Neurorestoration Center and Department of Neurological Surgery, Univ. of Southern California Keck School of Medicine, Los Angeles, CA, United States. [7]Department of Biomedical Engineering, Univ. of Southern California, Los Angeles, CA, United States

Introduction

Previous reaching studies with infants have primarily examined muscle activation in the reaching arm only. Herein, we recorded simultaneous electromyography (EMG) data from both the reaching arm and the contralateral non-reaching arm during repeated unimanual reaching actions. By looking at muscle activations in both arms, we aim to determine their coactivation and muscle synergies.

Methods

Infants (6–8 months old) participated in a single experimental session structured into alternating blocks of resting state (30s) and goal-directed reaching (60s). EMG data were collected for the following muscles on both sides of the body: anterior (AD) and posterior (PD) deltoids, biceps brachii (BB), and triceps brachii (TB). Session video recordings were used to determine the reaching onset and offsets. The raw EMG signals were filtered, full-wave rectified, and low-pass filtered to generate linear envelopes. Each EMG envelope was normalized using peak activation dynamics (i.e. maximum activation observed during reaching). To quantify how strongly muscle pairs were activated together, we computed the coactivation index (CI). The degree of coactivation CI ranges between 0 (maximal reciprocal activation) and 1 (maximal coactivation). Statistical analysis evaluated whether the level of CI for the antagonist (BB-AD and TB-PD) and agonist (BB-TB and AD-PD) muscle

pairs varied between the reaching and non-reaching arms during a reach. In addition, non-negative matrix factorization (NMF) was applied to extract the underlying muscle synergies, with the number of synergies selected based on the variance accounted for.

Results

Reaching duration was on average 0.73±0.25s. No significant differences were observed in CI levels for the antagonist and agonist muscle pairs between the reaching and non-reaching arms; however, the CI values for the antagonist and agonist muscle pairs were respectively 0.83-0.89 and 0.84-0.85, indicating a high level of coactivation. For the reaching and non-reaching arms, NMF analysis identified respectively 1–3 and 2-3 muscle synergies. Each synergy consisted of a distinct level of muscle weights.

Discussion

By characterizing the degree of coactivation and muscle synergies, this work provides insights into how infants simplify their motor control during reaching actions.

Failure Patterns in the Dura Mater Across Location and Loading Rates

Mr. Brandon Chelstrom[1], Mr. Will Martin[1], Dr. Corinne Henak[1,2,3]

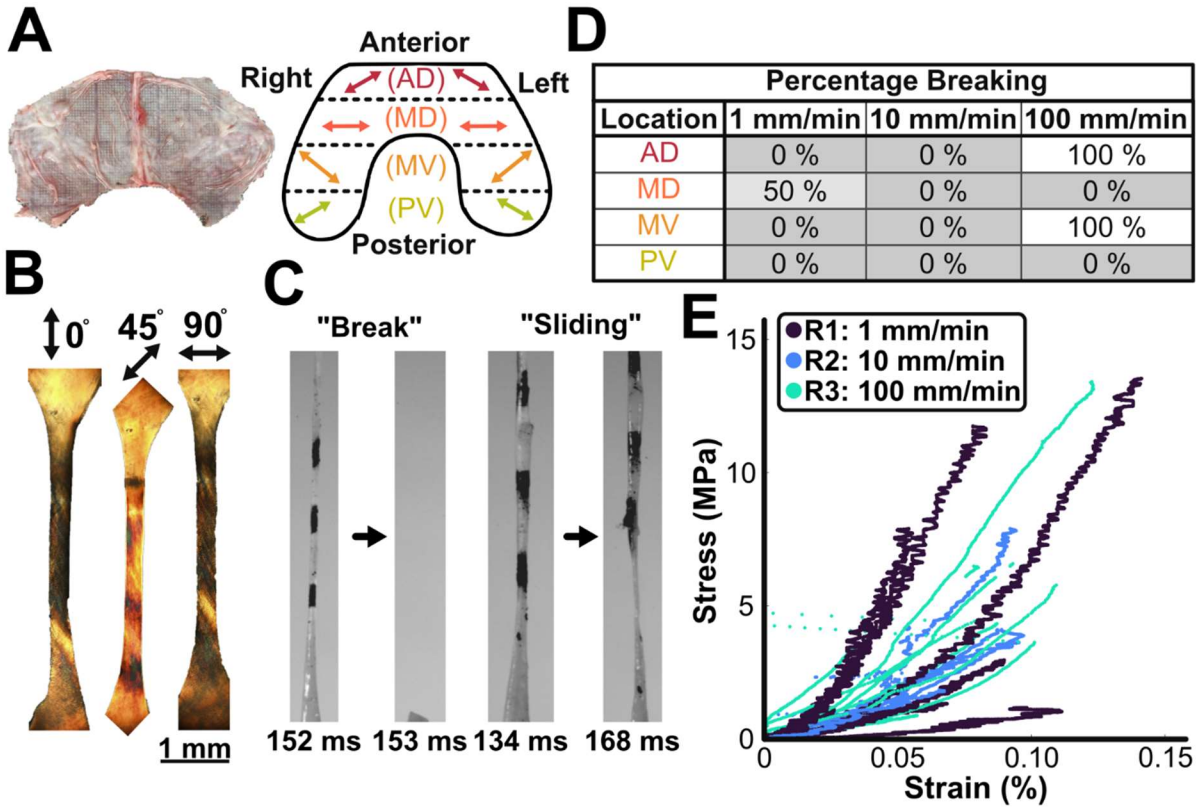
[1]Department of Biomedical Engineering, University of Wisconsin-Madison, Madison, Wisconsin, United States. [2]Department of Mechanical Engineering, University of Wisconsin-Madison, Madison, Wisconsin, United States. [3]Department of Orthopedics and Rehabilitation, University of Wisconsin-Madison, Madison, Wisconsin, United States

Introduction

Damage to the dura mater, the dense collagenous membrane of the meninges, can lead to severe hemorrhages. While the dura mater has been shown to be nonlinear, heterogeneous, and rate-dependent, there is a lack of information on the driving factors behind how the dura mater fails. Our objective is to investigate how the underlying tissue structure and loading rate influence the failure behavior of the dura mater.

Methods

Inferior brain surface samples (Wisconsin Miniature Swine, n = 5) were collected within 2 hours post-mortem and maintained in artificial cerebral spinal fluid (aCSF) until testing. Tensile dog-bone samples (gauge: 10 mm x 1 mm) were punched from 8 anatomical locations with specific orientations (Fig.1A). Prior to mechanical testing, each sample was imaged using polarized light at 0°, 45°, and 90° to the long axis of the dog-bone to visualize the underlying collagen structure. Samples were preconditioned (1 Hz to 2 mm extension for 30 cycles), subjected to a 0.03 N preload, then loaded to failure at either 1, 10, or 100 mm/min. Gauge strain was measured via a high-speed camera using charcoal strain lines gently stamped onto the sample. Failure location was grouped into 4 bins along the sample and compared with the dominant collagen fiber orientation for that group.



Results

Collagen fiber orientation is highly variable both within and between samples (Fig.1B). Two distinct failure patterns were observed across all samples: breaking and sliding (Fig.1C). Failure patterns vary with anatomical location and loading rate (Fig.1D). No consistent rate-dependent trend is observed in mechanical behavior (Fig.1E).

Discussion

Porcine dura mater samples were tested under uniaxial tension with varying loading rates to investigate various failure patterns. The dura mater more commonly exhibits a slower "sliding" failure but also exhibits a rapid "breaking" failure at higher rates for anterior and posterior samples (Fig.1C/D). Failure often occurred in regions with larger variation in the underlying collagen structure (Fig.1B). Rate-dependence was not observed which could be due to the relatively slow loading rate magnitudes (Fig.1D). These results give insight into the factors that influence failure of the dura mater to better predict injury outcomes.

Exploring Quantitative Magnetic Resonance Imaging Determinants of Passive Supraspinatus and Infraspinatus Shear Wave Velocity

Dr. Caleb Cordes PhD[1], Ms. Denali Hutzelmann[2], Ms. Colleen Vogel[2], Dr. Whitney Wolff PhD[1], Dr. David Lipps PhD[3], Dr. Joshua Leonardis PhD[1]

[1]The Ohio State University, Columbus, OH, United States. [2]University of Illinois at Urbana-Campaign, Urbana, IL, United States. [3]University of Michigan, Ann Arbor, MI, United States

Introduction

Shear wave elastography (SWE) estimates tissue elasticity by measuring shear wave velocity (SWV), the speed at which shear waves propagate through tissue [1]. SWV increases with increasing muscle stretch and activation [2], but the physiological mechanisms influencing passive SWV remain unclear. This study investigated whether quantitative MRI (qMRI) parameters, including fat fraction (FF), T2 relaxation time (T2*), and magnetization transfer ratio (MTR), which collectively reflect muscle fat [3], proteoglycan/water [4], and collagen content [5], predict passive SWV in two rotator cuff muscles.

Methods

Fourteen adults (9 females, 5 males; mean age 39.6 ± 16.5 years) underwent MRI of the dominant shoulder using a 3T scanner. Imaging included a multi-echo Dixon sequence to calculate FF and custom fat-suppressed ultra-short echo time (UTE) sequences to derive T2* and MTR. The supraspinatus and infraspinatus muscles were segmented in 3D Slicer, and qMRI parameters were computed using custom Python software. SWV was averaged across three images acquired from each muscle. Separate linear regression models examined the relationship between each qMRI parameter and SWV, along with a combined model with all three qMRI predictors. Interaction terms assessed whether the relationship between qMRI parameters and SWV varied across muscles (Figure 1).

Results

Individual models showed minimal predictive power for FF, MTR, and T2* (all R^2<0.042, p>0.586). In contrast, an interaction model (Figure 1) using standardized predictors and accounting for muscle type explained more than 40% of variance in passive SWV (R^2=0.437, p=0.076). Notably, T2* demonstrated a significant main effect on SWV (β=–

2.93, p=0.004) and a significant T2* × muscle type interaction (β=3.97, p=0.003), indicating muscle-specific relationships between proteoglycan-water content and SWV.

Discussion

Our findings suggest that single qMRI parameters provide limited insight into passive SWV, whereas multivariate models incorporating muscle-specific effects substantially improve explanatory power. The significant influence of T2* and its interaction with muscle type highlights the role of proteoglycan-water content, rather than fat or collagen content, in modulating passive stiffness. Collectively, these results underscore the complexity of interpreting SWE. Expanding these predictive models to include muscle architecture, sex, and age, and further histological validation will enhance the application of SWE in musculoskeletal research.

Images (Optional)

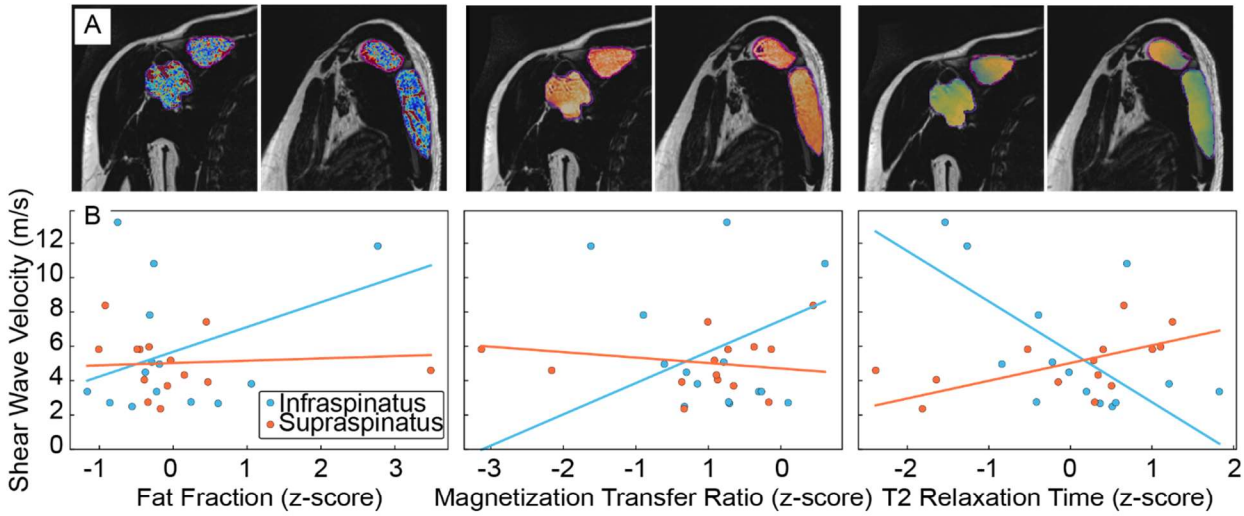

Figure 1: Quantitative MRI parameters exhibit shoulder muscle-specific relationships with shear wave velocity. (A) Fat fraction (left), magnetization transfer ratio (middle), and T2 relaxation time are depicted using heat maps for the supraspinatus and infraspinatus muscles for a representative participant, overlaid on Dixon fat images from the coronal and sagittal planes. (B) Shear wave velocity for the infraspinatus (blue) and supraspinatus (orange) muscles is shown plotted against fat fraction, magnetic transfer ratio, and T2 relaxation time. Individual participant means are shown with filled circles, and linear model results are illustrated with trend lines.

Menopause-Related Effects on Neck-Shoulder Muscle Elasticity and Pain Sensitivity

Ms. Denali Hutzelmann[1], Dr. Whitney Wolff PhD[2], Ms. Colleen Vogel[1], Ms. Savanna Rudy[1], Dr. Caleb Cordes PhD[2], Dr. Joshua Leonardis PhD[2]

[1]University of Illinois at Urbana-Champaign, Urbana, IL, United States. [2]The Ohio State University, Columbus, OH, United States

Introduction

Menopause significantly affects musculoskeletal health through estrogen decline, which alters collagen homeostasis [1] and reduces gamma-aminobutyric acid (GABA) synthesis [2], impacting tissue elasticity and pain sensitivity. Consequently, over 50% of women experience musculoskeletal pain and dysfunction during menopause. Shear wave elastography (SWE) measures tissue elasticity via shear wave velocity (SWV), while pain pressure threshold (PPT) assesses mechanical pain sensitivity. This study investigated how menopausal status influences SWV and PPT in the upper trapezius (UT) and lateral deltoid (LD) and examined their associations with self-reported neck and shoulder pain.

Methods

Twenty-seven participants (15 postmenopausal, 12 premenopausal; 54 shoulders) underwent SWE imaging and PPT testing of the UT and LD. Menopausal status was defined by at least 12 months without menses. Neck and shoulder pain and disability were self-reported using the Shoulder Pain and Disability Index (SPADI) and Neck Disability Index (NDI). Linear models assessed the effects of menopausal status on SWV and PPT and examined the menopause-related relationships among SWV, PPT, and SPADI/NDI scores.

Results

Post-menopausal females showed higher SWV than pre-menopausal females in both the UT (12.7% greater) and LD (10.3% greater), though these differences were not statistically significant (both $p>0.12$). Menopause status significantly affected LD PPT ($p=0.04$), with post-menopausal females exhibiting 23.1% higher PPT, indicating lower pain sensitivity. UT PPT displayed a similar trend (23.8% greater) but was not significant ($p=0.12$). SWV and PPT were unrelated for either muscle ($p>0.42$) or menopausal group ($p>0.15$). LD SWV increased with increasing SPADI score regardless of menopause status ($p=0.049$) and showed a stronger association in pre-menopausal females ($\beta=8.7$, $p=0.019$). No other measure of SWV or PPT related to SPADI or NDI (all $p>0.11$).

Discussion

Post-menopausal females exhibited greater LD PPT, indicating reduced pain sensitivity. They also demonstrated generally higher SWV, though differences were not significant, suggesting limited clinical impact. This suggests reduced pain sensitivity despite increased elasticity in menopause, which possibly reflects altered pain processing. The positive association between LD SWV and SPADI, particularly in pre-menopausal females, suggests tissue elasticity may influence perceived disability. However, the lack of relationships between pain sensitivity and patient-reported outcomes indicates pain sensitivity may not drive functional limitations.

Images (Optional)

Constitutive Parameter Inference in Full Volume Datasets of Intact and Torn Rotator Cuff Tendons

Postdoctoral Research Fellow Carla Nathaly Villacís Núñez PhD[1], Assistant Professor Siddhartha Srivastava PhD[2], Research Scientist Ulrich Scheven PhD[1], Professor Asheesh Bedi MD[1], Professor Krishna Garikipati PhD[3], Professor Ellen Arruda PhD[1]

[1]University of Michigan, Ann Arbor, MI, United States. [2]Auburn University, Auburn, AL, United States. [3]University of Southern California, Los Angeles, CA, United States

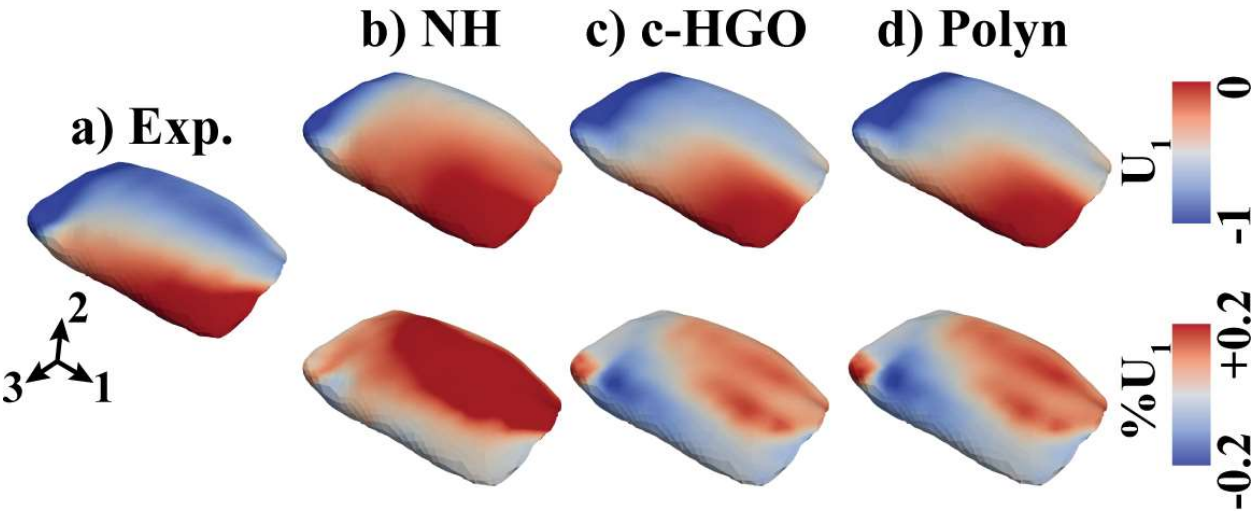
Introduction

Rotator cuff tendons are heterogeneous, anisotropic, and layered tissues prone to tearing, often causing pain and dysfunction. Modelling their complex mechanics is key to predicting tear progression and guiding clinical treatment. In this work, we combine an MRI-based experimental approach [1] with a full-volume inverse method [2] to infer constitutive behavior in an animal model of the rotator cuff. This framework offers a clinically relevant tool for identifying high-risk tears and supporting treatment planning.

Methods

Isolated infraspinatus tendons (n = 12) were cyclically loaded under quasi-uniaxial tension in an MRI-compatible chamber. A custom displacement encoding protocol [2] captured full-volume phase variations. Each tendon was tested in an intact state and after a high-grade bursal-sided tear, at physiologically relevant displacements (1 mm and 2 mm).

Unwrapped phase maps yielded displacement fields, which were smoothed and interpolated to an anatomical mesh. Fiber directions were extracted from high-resolution images. Displacements and fiber maps were input into a variational system identification (VSI) framework with a partial differential equation (PDE) refiner to infer parameters for neo-Hookean (NH), modified Holzapfel-Gasser-Ogden (m-HGO), and polynomial (Polyn) models. Forward predictions were compared to real maps using percentage errors.



Results

The highly non-linear experimental response observed in rotator cuff tendons (Fig. 1-a) was not captured by the NH model (Fig. 1-b). The m-HGO and Polyn models displayed anisotropy, as expected, and were able to capture several experimental features (Fig. 1-c,d) of the torn tendon, such as the sliding behavior between the cut/uncut tissue. Interestingly, the polynomial model had 3 terms only. Error maps showed that the detached tissue band had the largest error magnitudes, surpassing 20% in the NH model.

Discussion

In this work, we inferred constitutive parameters from full volume displacement maps of rotator cuff tendons using a novel inverse characterization framework. Our continuum m-HGO and Polyn models captured key aspects of the torn tendon (delamination), offering potential for improved prediction of tear progression and clinical decision-making.

Age-Related Differences in the Foot's Fat Pad Energetics During Decline, Level, and Incline Walking

Dr. Lauren Williams PhD[1], Mr. Christopher Long[1], Dr. Daniel Davis PhD[1], Dr. Jayishni Maharaj PhD[2], Dr. Jason Franz PhD[3], Dr. Kota Takahashi PhD[1]

[1]University of Utah, Salt Lake City, UT, United States. [2]Griffith University, Brisbane, QLD, Australia. [3]UNC Chapell Hill and NC State University, Chapell Hill, North Caroline, United States

Introduction

Soft tissues of the human foot change with age (e.g., fat pads have altered structure and mechanical properties [1]). When the fat pads cyclically compress, they may absorb and return energy [2] which we suspect may influence mechanical energetics in walking. We tested the effect of age on fat pad energetics using incline/decline walking to systematically alter net energetic demand. We hypothesized that older age and decline walking would increase energy absorbed by the fat pads.

Methods

Eighteen younger [9F; 24.4±3.3 years] and older [9F; 69.8±5.9 years] adults walked barefoot at 1.2 m/s on an instrumented treadmill at three slopes (decline: -5°, level: 0°, and incline: 5°).

To quantify fat pad energy [3], we first calculated total foot power using a unified deformable analysis, representing the energetics of all structures distal to the calcaneus. Next, rotational powers for the midtarsal and metatarsophalangeal joints were summed and assumed to include everything except the fat pads. Thus, we estimated fat pad mechanical power as the difference between total foot power and summed joint power. Lastly, power was integrated to calculate negative (i.e., energy absorbed) and positive (i.e., energy returned) work during two stance subphases: collision and push-off.

Results

Independent of age, decline walking increased fat pad energy absorption and return during collision ($p<0.001$) and incline walking increased fat pad energy absorption during push-off ($p<0.001$). Independent of slope, older adults absorbed more energy during push-off ($p=0.03$) but not collision ($p=0.286$) (Fig.1).

Discussion

We found that decline walking increased fat pad energy absorption during collision, which agrees with previous results examining foot power during sloped walking [4]. Furthermore, our results suggest altered fat pad energetics may partly explain findings of disproportionate foot mechanical energy losses during walking in older adults [5]. These results point to potentially modifiable factors in the human foot that could inform interventions to promote walking performance.

Load-Driven Microstructural Changes in Mouse Articular Cartilage

Ms Sarah-Maud Sombris-Picot[1], Pr Simon Le Floc'h[1], Pr Patrick Cañadas[1], Dr Emeline Perrier Groult[2], Ms Laetitia Hudecek[3], Dr Cristina Cavinato[4]

[1]LMGC, Univ. Montpellier, CNRS, Montpellier, France, France. [2]Institute for Regenerative Medicine & Biotherapy, Univ. Montpellier, INSERM, Montpellier, France, France. [3]INM, Univ. Montpellier, INSERM, Montpellier, France, France. [4]LMGC, Univ. Montpellier, CNRS, Montpellier, Montpellier, France, France

Introduction

Articular cartilage endures complex loads, yet its microstructural response to compression—especially the interaction between chondrocytes and the collagen network—remains incompletely characterized. Despite recent advances in imaging, few studies link three-dimensional microstructure to mechanical loading in intact tissue [1-2]Work supported by the French National Research Agency, ANR-22-CPJ1-0090-01 to CC and ANR-10 INBS-04, 'Investments for the future' to MRI facility. R. This work aims to assess how the murine tibial plateau responds to controlled compression by examining load-induced changes in chondrocyte orientation and collagen organization at high spatial resolution.

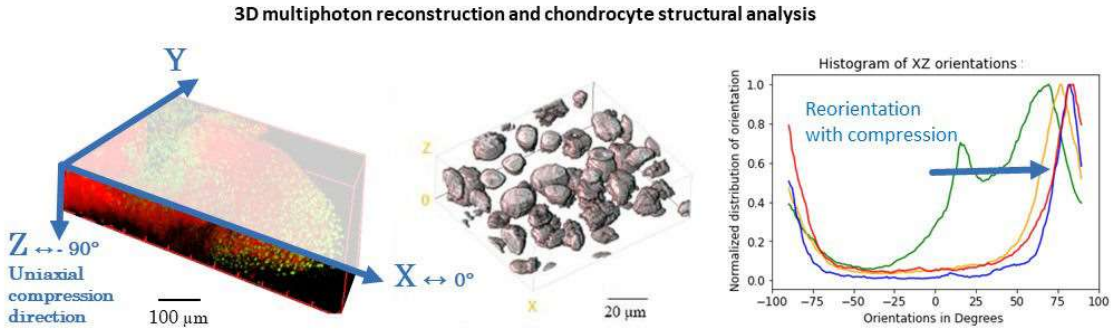
Methods

Tibial plateau samples from 8-week-old male C57BL/6 mice were collected immediately after sacrifice by sectioning approximately 1 mm below the articular surface. Samples were rinsed in phosphate-buffered saline and immersed in a nucleic-acid staining solution before testing.

A custom uniaxial mechanical system was developed to apply three sequential linear compression ramps of 15 µm each. An impermeable 0.2-mm-thick glass coverslip served as the compression platen. Each compression step was held for 5, 10, and 15 minutes, respectively, to allow for comparable stress-relaxation conditions.

To assess local orientation and deformation, 3D high-resolution images were acquired across the full cartilage thickness using a lateral high-resolution camera, optical coherence tomography (OCT), and multiphoton microscopy (MPM). MPM provided second-harmonic generation (collagen) and two-photon fluorescence (chondrocyte nuclei) signals

Results



Multiphoton images revealed a slight, progressive reorientation of chondrocytes following each compression step (Fig.1). A shift toward alignment with the loading direction—

approaching 90°—was also observed. This response appeared consistent with the known heterogeneous organization of articular cartilage, where collagen architecture and cellular arrangement vary across depth. Additional image analyses are ongoing to quantify the observed changes and to compare responses across regions of the tibial plateau.

Discussion

This study demonstrates that articular cartilage exhibits measurable microstructural reorganization under mechanical stress. The observed chondrocyte reorientation suggests load-dependent adaptation mechanisms linked to the local collagen network. Comprehensive 3D analyses and quantitative mapping of local strains are further employed to accurately characterize these reorientation patterns and to elucidate the micromechanical processes that govern cartilage deformation.

Myosin Activator Omecamtiv Mecarbil Dramatically Decreases Power Output in Slow Skeletal Muscle Fibers

Dr. David Lin, Mr. Austin Au, Dr. Bertrand Tanner

Washington State University, Pullman, WA, United States

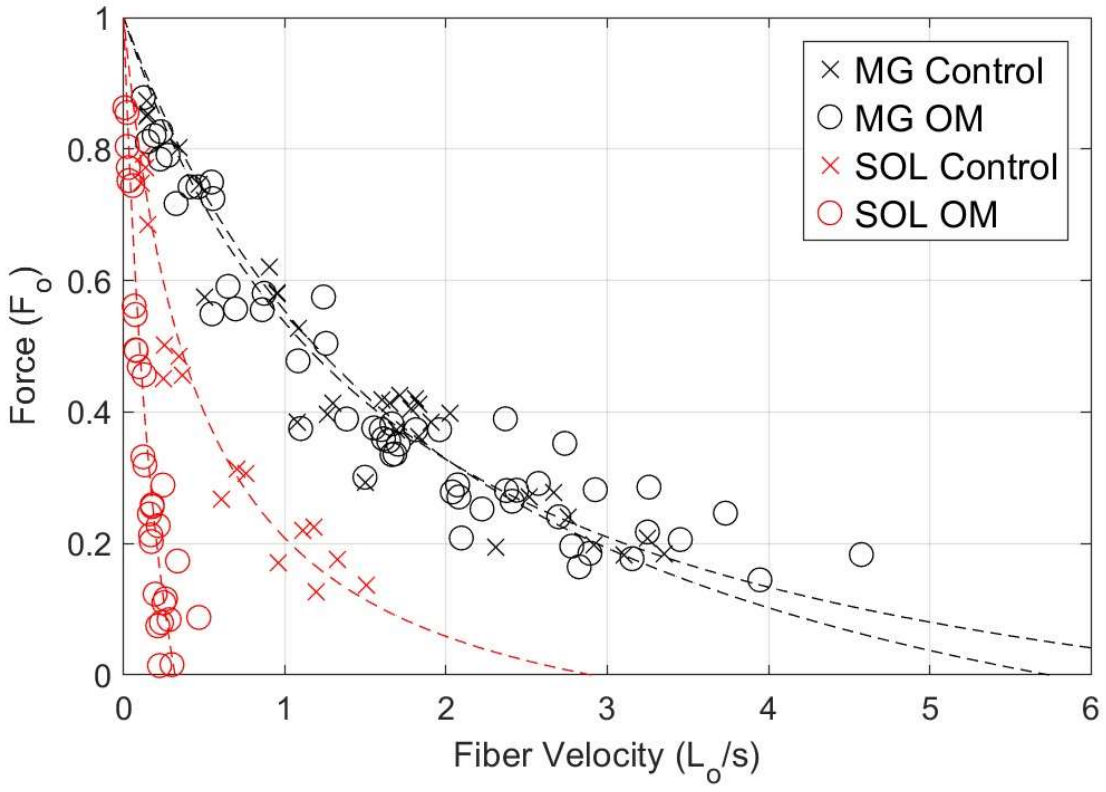
Introduction

Omecamtiv mecarbil (OM) is a myosin activator that was developed to augment cardiac function after heart failure. Although OM was designed to target and activate cardiac-specific ATPase, which enhances cross-bridge formation and increases attachment time, skeletal muscle could be affected due to the similarity of cardiac and skeletal myosins. This study characterizes the effect of OM on the force-velocity (FV) properties of slow and fast skeletal muscle fibers, which has implications for the diaphragm and respiratory function.

Methods

We obtained single muscle fibers from rat medial gastrocnemius (MG; fast fibers) and soleus (SOL; slow fibers) muscles. The fibers were chemically skinned and mounted between a force transducer and motor servo. The bathing solution was exchanged from a low calcium (pCa=8) to a high calcium solution (pCa=4) to activate the fiber. An experimental trial consisted of achieving steady-state isometric force and then imposing an isotonic load within the range of 0.1 to 0.75 F_o (F_o=isometric force). One of two conditions were tested on each fiber, control (no OM) and OM (concentration=0.1 μM), for both MG and SOL fibers. Hill's equation was fit to FV data, and maximal powers were calculated from the fits.

Results



Fast fibers showed minimal difference in the FV curves between the control (n=16) and OM (n=15) fibers (see Figure), and the maximum powers were comparable (0.66 F_0-L_o/s for both; L_o=initial length). Slow fibers showed dramatic differences in the FV curves and maximum powers (0.21 vs 0.05 F_0-L_o/s for control (n=5) vs OM (n=10) fibers, respectively).

Discussion

Only slow skeletal muscle was affected by OM, consistent with cardiac and slow skeletal muscle expressing the same myosin isoforms. Fast muscle fibers did not show any effect,

likely due to OM not binding to fast skeletal myosin. The effect of OM on mechanical output on slow fibers caused a substantial decrease in power of 76%. The functional consequence of OM affecting the power output of skeletal muscles like the diaphragm, which has a high percentage of slow fibers, could contribute to the lack of improvement in exercise capacity seen in OM clinical trials.

Muscle Contractile Properties During Nonsteady-State Activation are Important for Determining the Amount of Energy that Can Be Stored in Tendons

Dr. David Lin, Mr. Austin Au, Dr. Bertrand Tanner

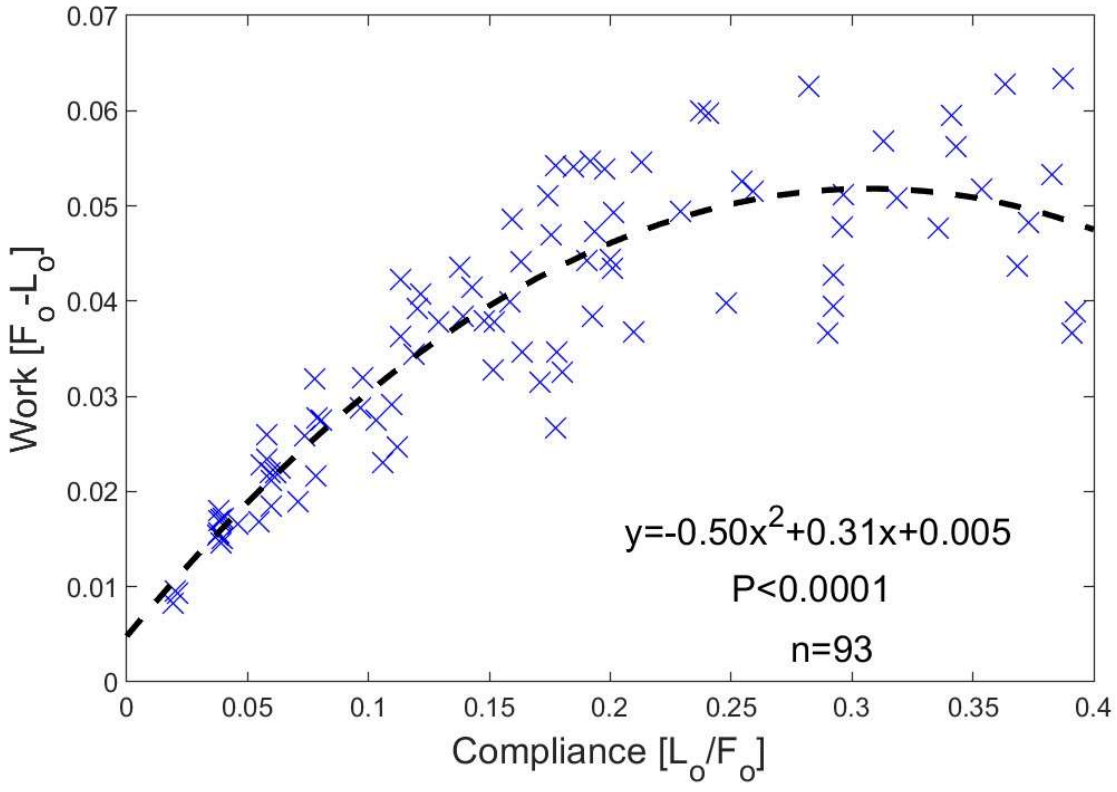
Washington State University, Pullman, WA, United States

Introduction

Tendon compliance is important in ballistic movements like jumping because tendon can store and return energy to augment motor performance. Our objective was to determine the optimal tendon compliance with which muscle can store energy during the initial phase of a jumping task. We also investigated whether the phenomenon of muscle force depression played a role in limiting energy transfer from the muscle to the tendon.

Methods

To test a range of tendon compliance, single muscle fibers were coupled to a servo that physically simulated a virtual tendon via force feedback. Fibers from rat medial gastrocnemius muscles were chemically skinned and mounted between a force transducer and motor servo. The bathing solution was exchanged from a low calcium to a high calcium solution to activate the fiber. During the activation, as the fiber force increased, the fiber shortened against a virtual tendon with linear elasticity such that musculotendon length was isometric. By plotting muscle work done versus tendon compliance, we determined whether there was an optimal compliance for storing energy. We plotted muscle force as functions of muscle length and work done to determine whether force depression, related to muscle work [1], was the main factors affecting muscle work capacity.



Results

The work done by muscle against a linear tendon increased as tendon compliance increased, with a clear optimal value (see Figure). Plots of muscle force versus length showed the linear decrease in force with decreasing sarcomere length, limiting the amount of energy stored in the tendon for higher compliances. The force decrease was much greater than that predicted by a sliding filament based force-length curve. A linear regression of force depression versus work done only explained 7% of the variance.

Discussion

More compliant tendons enabled muscle to store more energy in the tendon, but a limit was reached due to muscle force decreasing with increased shortening. The limitations in muscle force generating capacity were weakly explained by force depression. These results highlight that further investigation of muscle contractile properties under nonsteady activation conditions is needed.

Towards Large-Scale, Automated FE Knee Models: Ligament Calibration and its Impact on Cartilage Mechanics

MSc. Famke Janssen[1], Dr. Ir. Thom Bitter[1], Prof. Dr. Ir. Nico Verdonschot[1,2], Dr. Ir. Dennis Janssen[1]

[1]Radboud university medical center, Nijmegen, Gelderland, Netherlands. [2]University of Twente, Twente, Overijssel, Netherlands

Introduction

Accurate representation of ligament behavior is critical for force-driven, subject-specific finite element (FE) knee models, as ligaments govern joint kinematics and influence cartilage loading. Quantifying cartilage loading in such models is crucial for understanding mechanical factors that may contribute to osteoarthritis. Simplified tibiofemoral models commonly use single-bundle ligament representations, literature-based parameters, and manually placed attachments, which limits mechanical accuracy and scalability for large cohorts. More detailed models add structures such as the patellofemoral joint, popliteus, and capsule but require extensive subject-specific input. For both approaches, manual interventions reduce reproducibility and increase dependence on modeler expertise, while using a single ligament property parameter set limits subject-specificity. This study introduces an automated ligament modeling and calibration framework and evaluates how ligament representation and parameter optimization affect cartilage contact mechanics.

Methods

A Subject-specific FE knee model was generated using a fully automated pipeline from MRI to a complete FE model (i.e., segmentation, mesh generation, and model assembly). Collateral ligaments were represented with three bundles, cruciate ligaments with two bundles. Template-based attachment sites were defined anatomically and transferred via non-rigid mesh morphing. Ligament slack lengths and stiffnesses were calibrated using normative knee laxity values for anterior–posterior and varus–valgus laxity tests at full extension and 90° of flexion. Cartilage contact pressures were evaluated during passive flexion, stance-phase gait, and squat and compared between optimized ligament properties and literature-based parameters [1,2].

Results

Preliminary results indicated that subject-specific ligament calibration substantially lowers cartilage contact pressure distributions compared to literature-based models (Figure 1). Sensitivity to ligament representation increased with flexion angle during both passive and

loaded motions, whereas stance-phase gait showed more moderate effects on cartilage contact pressures.

Discussion

Automated ligament calibration reduces excessive cartilage contact stresses during flexion in subject-specific FE knee models. The workflow enables reproducible, scalable generation of large cohorts, providing a foundation for analyzing cartilage loading and mechanical factors associated with osteoarthritis in a large cohort. Cadaveric validation of laxity response, kinematics, and contact pressures is ongoing. Performance of generalized calibration will also be compared to cadaver-specific laxity optimization.

Biophysical Regulation of Composite Musculoskeletal Tissue Regeneration

Miss Catherine Nguyen M.S., Dr. Cole DeForest Ph.D., Dr. Feini Qu V.M.D, Ph.D.

University of Washington, Seattle, Washington, United States

Introduction

Limb loss affects over 2 million Americans, creating a clinical need for composite musculoskeletal tissue regeneration. To this end, we study the murine digit tip, which regenerates after distal amputation via activated stem/progenitor cells (the "blastema"), but scars after more proximal amputations. While biophysical cues in the extracellular matrix (ECM) are known to modulate various cell behaviors, it remains unclear how the wound's mechanical properties may affect blastema formation and regeneration. To investigate, we quantified ECM stiffness and structure after digit amputation.

Methods

Terminal (P3) and middle (P2) phalanges of male and female 10-week-old C57BL/6 mice were resected with IACUC approval. Bone morphology was quantified via *in vivo* microcomputed tomography at various days post-amputation (DPA). Paraffinized sections of 14 DPA digits were stained with hematoxylin & eosin and picrosirius red. Cryosections of 14 and 21 DPA digits underwent force spectroscopy using an atomic force microscope with a spherical probe ($\varnothing$ = 10.8 μm, k = 0.08 N/m). ECM stiffness was determined via the Hertz model. Significance was determined by two-way ANOVA with Tukey's post-hoc test ($p \leq 0.05$).

Results

Composite musculoskeletal tissue regeneration occurred after P3, but not P2 amputation (Fig. 1). The P3 bone underwent remodeling followed by regrowth, with concomitant changes in length and volume. These changes were absent in the P2 group, which instead formed a fibrotic scar around the stump bone. The scar possessed densely aligned collagen, whereas the blastema exhibited high cell density in regions of low collagen content. The P2 scar was significantly stiffer than the P3 blastema at 14 DPA (3.6 ± 0.6 kPa vs. 1.2 ± 0.1 kPa), a difference that persisted to 21 DPA (4.4 ± 1.1 kPa vs. 1.8 ± 0.7 kPa).

Discussion

Our findings suggest that regeneration depends on the wound's emergent properties, including ECM stiffness and structure. P3 bone regrowth occurred in a compliant matrix with minimal collagen deposition, whereas the dense collagen scar may have physically

inhibited P2 bone outgrowth. A stiffer ECM may also promote a myofibroblast phenotype that perpetuates scar formation. Future work will investigate how altering matrix stiffness affects stem/progenitor cell activation and blastema formation, elucidating potential therapies for musculoskeletal regeneration.

Images (Optional)

Quadriceps Strength and Activation in Healthy Adults Through the Menstrual Cycle

Ms Francesca Belibi, Ms. Emma Sachs, Dr. Skylar Holmes, Dr Emily Kraus, Dr Garry Gold, Dr Carly Jones

Stanford University, Palo Alto, CA, United States

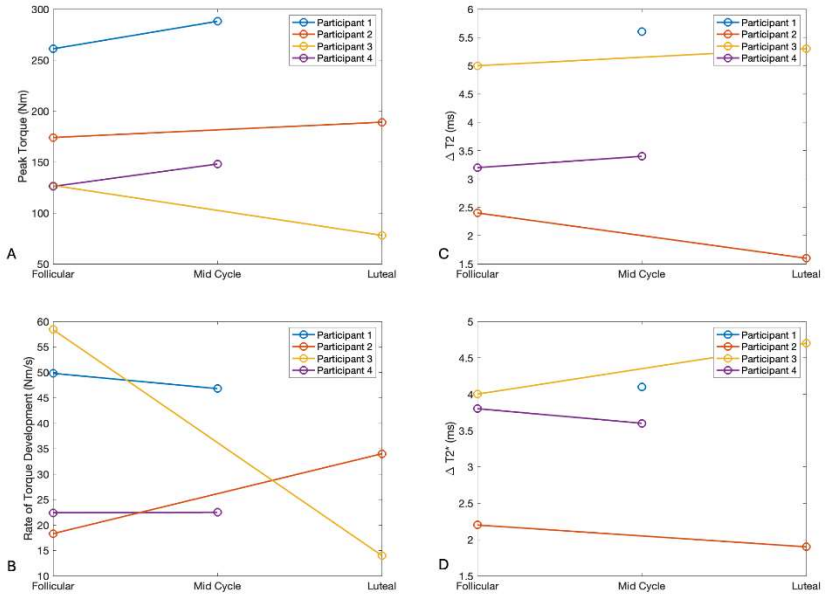
Introduction

The menstrual cycle's impact on athletic performance is a top concern for female athletes. Previous studies have found increased strength, slower muscle recovery, and higher fatiguability mid-cycle; others found no difference. Quantitative MRI (qMRI), in addition to strength testing, may be more sensitive to changes in muscle function than traditional methods. In this abstract, we focused on muscle strength and activation.

Methods

Four naturally menstruating participants completed strength testing and MRI scanning during the follicular phase and one high estrogen (mid-cycle or luteal) phase, determined via cycle tracking. The order of study visits was randomized across participants. Participants were scanned in a 3T MR scanner before and after a wall-sit exercise. The difference from peak to baseline T2/T2* signal, $\boldsymbol{\Delta}$, is related to muscle activation. Quadriceps strength was assessed using an isokinetic dynamometer at 60 degrees of flexion. Participants completed 20 maximum isometric contractions from which measurements of quadriceps peak torque ($\boldsymbol{\tau}$) and rate of torque development (RTD) were obtained. This initial cohort is too small for statistical testing.

Results



Peak torque was slightly higher, and RTD was slightly lower in the mid-cycle compared to the follicular phase. No consistent trend was observed between the follicular and luteal phases, though individual differences in RTD were larger than those observed between the follicular phase and mid-cycle (Figure 1A-B)

Participant 1 had no measure of $\boldsymbol{\Delta}$ T2/T2* for the low estrogen phase due to a hardware malfunction. No consistent trends were observed between follicular, mid-cycle, and luteal phases for $\boldsymbol{\Delta}$ T2/T2* (Figure 1C-D).

Discussion

Our preliminary observations found individual muscle strength and activation variations over the menstrual cycle; however, the conflicting group observations highlight the necessity of hormone testing to gain a better understanding of the menstrual cycle's effects. Future experiments, with a larger cohort, will use urine and saliva-based hormone tracking to confirm cycle phases.

The Role of Achilles Tendinopathy on the Torque-Angle Relationship During Isokinetic Plantar Flexion

Mr. Hidetaka Hayashi, Ms. Corey Whalen, Mr. Michael Hahn

University of Oregon, Eugene, OR, United States

Introduction

Achilles tendinopathy (AT) is a degenerative pathology associated with increased cross-sectional area and decreased stiffness [1]. Previous work showed that a shift in peak torque angle to a more extended position occurs with increasing joint angular velocity during isokinetic knee extension, and that this shift can be attributed to tendon compliance [2]. While it is known that AT alters tendon compliance, the effect of AT on the joint angle-peak torque relationship is unclear. Therefore, the purpose of this study was to elucidate the effect of AT on the joint angle-peak torque relationship during a concentric isokinetic plantar flexion.

Methods

. Five participants with symptoms of AT and 5 healthy age and sex matched controls participated in this study. Participants were positioned on an isokinetic dynamometer with their thigh-trunk angle at 110 degrees (180 degrees = full extension), knee fully extended, and the foot firmly fixed to the footplate. After a warm-up, participants performed 2 sets of 5 maximal concentric plantar flexion contractions at pre-set angular velocities of 30, 60, and 90 deg/sec. Isokinetic torque and angular position data were sampled at 1 kHz. The trial with the highest torque output was used for analysis and was analyzed in the range of -5 degrees (DF) to 15 degrees (PF). A mixed model ANOVA (group x angular velocity) was used to test for the effect of independent variables on the joint position at peak torque.

Results

There was a significant interaction between group and angular velocity ($p < .05$; fig. 1). Simple main effect analysis revealed a main effect of angular velocity, with significant difference between the 30 and 90 deg/sec as well as between the 60 and 90 deg/sec conditions ($p < .05$). There was no main effect of group ($p = .487$).

Discussion

While the effect of angular velocity on the peak torque angle shift towards a more plantar flexed position is consistent with previous findings for the knee extensors, the significant

interaction effect suggests altered velocity-dependent modulation of the torque-angle relationship in individuals with AT.

Region-Dependent Properties of Lamellae Constituents in the Intervertebral Disc: Possible Insights Into Herniation Mechanisms

Dr. Jackie Zehr PhD[1], Dr. Venus Joumaa PhD[2], Dr. Jack Callaghan PhD[3], Dr Walter Herzog PhD[2]

[1]University of Toronto, Toronto, Ontario, Canada. [2]University of Calgary, Calgary, Alberta, Canada. [3]University of Waterloo, Waterloo, Ontario, Canada

Introduction

Intervertebral joint bending is associated with intervertebral disc (IVD) herniations [1]. In an attempt to better understand herniation mechanisms, prior work has examined lamellar mechanics [2-4], yet the specific roles of individual constituents (collagen fibres and the intra-lamellar matrix) remain unclear. This study directly characterized the tensile properties of isolated collagen fibres and the adhesion properties of the intra-lamellar matrix in healthy IVDs.

Methods

IVDs were extracted from the C3C4 spinal level of eight porcine cervical spines. Single lamellae were dissected from the outer 1/3 of the annulus comprising the anterior and posterior regions. From each lamella, two samples were harvested: i) isolated collagen fibre and ii) two adjacent collagen fibres with the matrix that connects them, totalling 32 samples. Two types of mechanical tests were performed: i) isolated collagen fibres were exposed to uniaxial tension; and ii) the intra-lamellar matrix underwent a single lap shear test. The cross-sectional area of all samples was measured, a baseline stress was applied (5 kPa tensile tests, 0.5 kPa shear tests) to remove slack, and samples were strained at 1% per second until failure. The Young's modulus, yield and failure stresses and strains were determined. Regional differences were evaluated using paired and Wilcoxon tests.

Results

In isolated collagen fibres, the Young's modulus and ultimate stress were 45% and 51% greater in the posterior compared to the anterior region, respectively ($p<0.047$). All properties of intra-lamellar matrix adhesion were similar across regions ($p>0.151$). The isolated collagen fibers and intra-lamellar matrix experienced comparable strains at yield (32%) and failure (46%), but the ultimate tensile stress of isolated fibres was approximately five times greater than the intra-lamellar matrix adhesion.

Discussion

Regional variations within and between lamellar constituents likely reflect underlying microstructural differences (e.g., fibril density, orientation, or matrix connectivity), though this remains to be experimentally confirmed. Incorporating these findings into collagen distribution models may provide new insight into early microdamage initiation pathways that precede IVD herniation disorders.

Characterizing Achilles Tendon Non-Uniformity using Cadaveric Simulation and Muscle-Specific Actuation

Dr. Jason Franz[1], Dr. Taija Finni[2], Dr. Raad Khair[2], Dr. William Ledoux[3]

[1]University of North Carolina at Chapel Hill, Chapel Hill, NC, United States. [2]University of Jyväskylä, Jyväskylä, Finland, Finland. [3]VA Puget Sound Health Care System, Seattle, WA, United States

Introduction

The Achilles tendon is comprised of subtendons arising from individual triceps surae muscles. Ultrasound techniques used to characterize subtendon structure-function relations are limited by anatomical and theoretical assumptions. We used cadaveric simulation and muscle-specific actuation in the robotic gait simulator (RGS) to test those assumptions.

Methods

A cadaveric specimen was transected approximately 15 cm proximal to the malleoli. The Achilles tendon was separated into gastrocnemius (medial and lateral, GAS) and soleus (SOL) compartments ("subtendons"). These two subtendons were sutured to nylon straps in series with load cells and linear tendon actuators. We tested the specimen on the RGS. With the ankle specimen in a neutral position, the RGS simulated three isometric fixed-end contractions, prescribed as symmetrical (loading/unloading) ramp tests from rest: (1) SOL 200 N + GAS 200 N; (2) SOL 400 N + GAS 0 N; and (3) SOL 0 N + GAS 400 N. We recorded cine B-mode images of the Achilles free tendon, analyzed using speckle tracking to resolve localized tendon tissue displacements and longitudinal strain, which we averaged over superficial (50%) and deep (50%) regions thought to correspond to the GAS and SOL subtendons, respectively.

Results

All three of the following discoveries were unexpected based solely on simple anatomical assumptions (Fig. 1). First, despite constant total force, peak tendon tissue displacements were largest when that force was distributed equally between the GAS and SOL. Second, tendon non-uniformity (i.e., the difference between superficial and deep tendon tissue displacements) was largest when the applied muscle forces were distributed equally between the GAS and SOL. Finally, positive strain in the superficial (or deep) tendon was largest when the SOL (or GAS) was actuated independently.

Discussion

The triceps surae muscle-subtendon units do not behave as simple linear actuators. Thus, capturing anatomical heterogeneity in the Achilles tendon—for example through recent MRI advancements [1] or combined ultrasound/electrical stimulations protocols [2]—is paramount in the design and conduct of any future study designed to understand the complex interaction between calf muscle forces and Achilles subtendon deformation.

Influence of Collagen Fiber Strain on the Development of the Shear Mechanical Properties of the Superficial Region of Cartilage

Ms. Kangxin Wang, Dr. Jill Middendorf

Johns Hopkins University, Baltimore, Maryland, United States

Introduction

The superficial region of articular cartilage protects the joint from damage but remains difficult to recreate or repair, so understanding how the cartilage develops may inform future repair strategies. During maturation, unorganized collagen in the superficial region becomes aligned collagen fibers, increasing shear stiffness. Previous work has linked physiologically relevant cyclic shear loading and collagen fiber stretch to changes in fiber orientation and alterations in tissue mechanics[1,2]. However, these prior works focused on mature cartilage or hydrogels. Our study investigated how the superficial shear mechanics of immature cartilage change with collagen fiber stretch under cyclic shear loads.

Methods

Thirteen fetal bovine articular cartilage cylinders were assigned to simple shear (N = 5) or shear with 15% global compression (N = 8). These loads were chosen to induce a wide range of fiber strains (Fig. A). All samples underwent 3% global cyclic shear for 8h followed by 12h of relaxation. Horizontal and vertical photobleached lines in the superficial region tracked compressive and shear strains, while shear stress was measured. Shear stress-strain curves were obtained at 0, 4, and 8 hours and after relaxation. Collagen fiber stretch was calculated from measured tissue strains for fiber orientations between 0° and 90°.

Results

Both groups (simple shear and 15% compression) showed decreased shear modulus with loading time (Fig. B). Partial recovery was observed after relaxation in the 15% compression group, and no recovery was observed in the simple shear group. In the 15% compression group, toe and effective shear modulus decreased during loading and recovered to their 4h values after relaxation (Fig. C).

Discussion

The tensile strain in collagen fibers under simple shear and the lack of tensile fiber strain under 15% compression most likely contribute to the differences in shear mechanical recovery. This relationship between collagen fiber tensile strain and changes in shear mechanics is consistent with work in other tissues[3,4]. These findings shed light on the mechanisms of superficial region development in immature cartilage and may guide repair strategies for the cartilage.

Images (Optional)

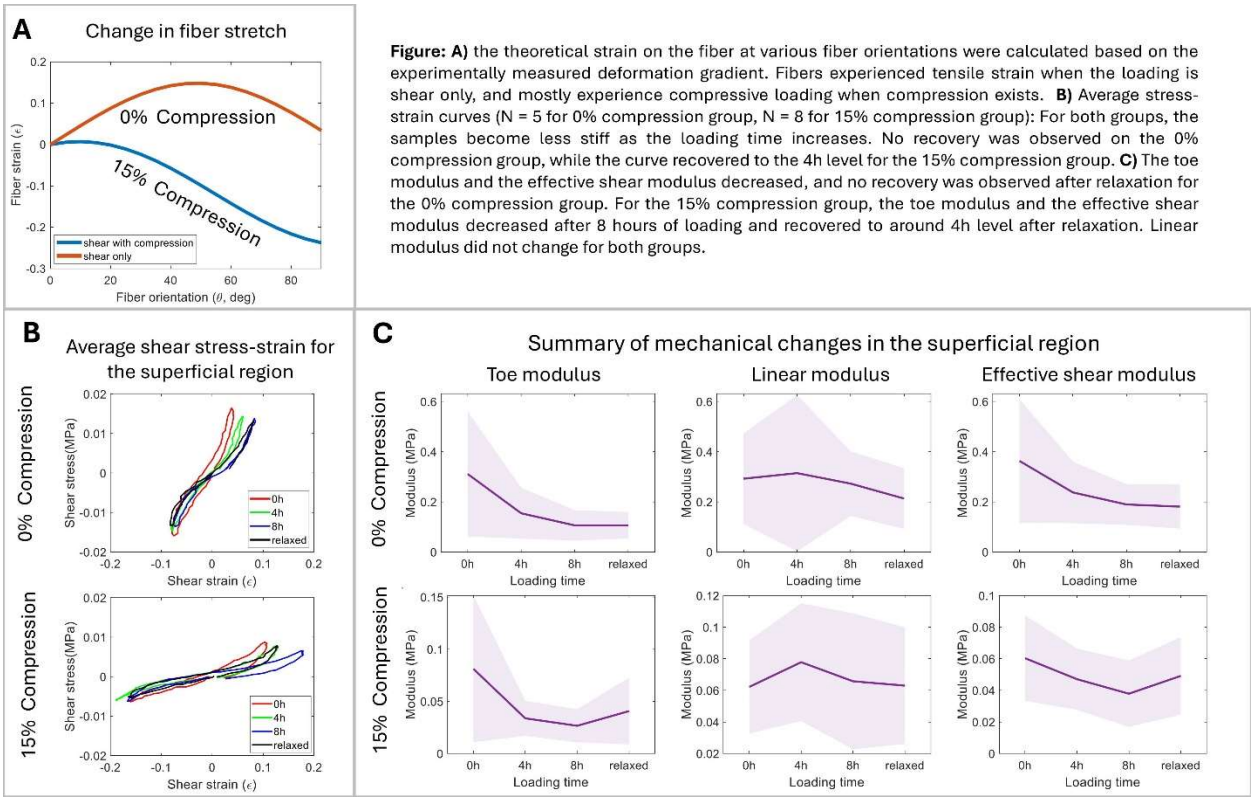

Figure: A) the theoretical strain on the fiber at various fiber orientations were calculated based on the experimentally measured deformation gradient. Fibers experienced tensile strain when the loading is shear only, and mostly experience compressive loading when compression exists. **B)** Average stress-strain curves (N = 5 for 0% compression group, N = 8 for 15% compression group): For both groups, the samples become less stiff as the loading time increases. No recovery was observed on the 0% compression group, while the curve recovered to the 4h level for the 15% compression group. **C)** The toe modulus and the effective shear modulus decreased, and no recovery was observed after relaxation for the 0% compression group. For the 15% compression group, the toe modulus and the effective shear modulus decreased after 8 hours of loading and recovered to around 4h level after relaxation. Linear modulus did not change for both groups.

Cartilage Redox Responds Consistently to Tensile and Compressive Loading

Postdoctoral Research Associate Jingyi Wang, Associate Professor Corinne Henak

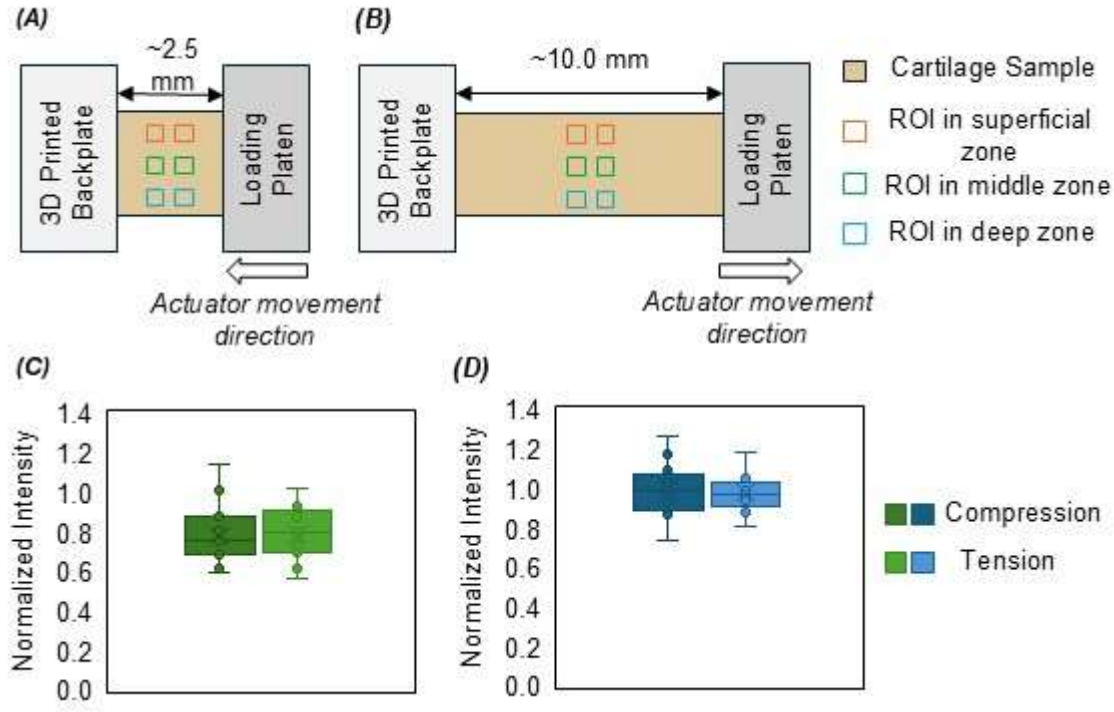
University of Wisconsin - Madison, Madison, WI, United States

Introduction

Articular cartilage experiences complex mechanical loading *in vivo*. Although compression is the most studied loading mode, cartilage also undergoes other modes[1,2]. Tensile loading can induce various biologic responses[1,3,4]. Redox balance, the balance between the production and elimination of oxidants, is crucial for cartilage health[5-7]. Its mechanobiological response is therefore of interest. Optical redox imaging (ORI) can evaluate cartilage redox balance and is responsive to both compressive[8] and tensive loading[9]. However, it remains unclear if cartilage redox responds the same way to compression and tension, leaving a gap in understanding of mode-specific cartilage mechanobiology and making interpretation of results from tensile studies challenging. Hence, this study aims to test the hypothesis that sub-failure compression and tension cause the same response in cartilage ORI metrics.

Methods

Samples were cut from full-thickness porcine patella cartilage. Cut dimensions were ~2.5 mm x 3 mm or ~10 mm x 0.5 mm for compression and tension tests, respectively (N = 5 for each). Mechanical loading was done on a custom-built microscope-top loading device. An actuator was programmed to move at ±0.1 s^{-1} to ±0.3 strain and return to the original position. Regions of interest (ROIs) were defined in the superficial, middle and deep zones (Fig. 1A and 1B), and images were taken before and after loading in green and DAPI channels. Post-loading intensity was normalized to that of the corresponding zone from the pre-loading image. Unpaired student t-test was performed to compare the normalized intensity of compression and tension groups.



Results

No significant difference was found between compression and tension in both channels (Fig 1C and 1D).

Discussion

This study showed that acute response of cartilage redox to sub-failure compression and tension is consistent. The result advances the understanding of cartilage redox mechanobiology and highlights the potential to use various loading modes when designing *in vitro* cartilage loading models. Nevertheless, further studies are needed before making a more specific conclusion, as the achieved loading parameters could differ for each group due to backplate deformation. In addition, cultured chondrocytes demonstrate distinct responses to cyclic compression and tension[10], implying the subtle and complex nature of cartilage mechanobiology.

Contraction-Mode Dependent Muscle Adaptations to Eccentric, Concentric, and Isometric Training in Rats

Ms Kathryn Chapman, Ms Amelia Rilling, Dr Alexander M Zero PhD, Mr Maxum A.K Stratford, Ms Alexandra Q Kirkup, Dr Geoffrey A Power PhD

Univeristy of Guelph, Guelph, Ontario, Canada

Introduction

In response to resistance training, skeletal muscle exhibits distinct mechanical and morphological adaptations depending on whether training consists of eccentric, concentric, or isometric contractions. Across separate investigations, species, and muscle groups, eccentric loading appears to increase torque production across a range of muscle lengths, while concentric training tends to preferentially improve power, and isometric training often yields joint-angle–specific strength gains. However, it remains unclear whether these contraction types differentially contribute to performance improvements when training demands are matched in the same study and population. Therefore, we examined mechanical adaptations following 6 weeks of eccentric, concentric or isometric training in young male rats.

Methods

Male Sprague-Dawley rats (n=18; 14-17 weeks; 360-565g) were randomly assigned to 6 weeks of unilateral plantar-flexor training on a dynamometer involving either eccentric, concentric, or isometric contractions (n=6/group) 3 days/week. Peak isometric torque across 3 joint angles (70°, 80°, 90°) was assessed pre- and post-training. Eccentric contractions were performed through an ankle angle range of motion of 110-70° at 40-80°/s with muscle activation (i.e., electrical stimulation) set to ~60-70% of maximal isometric torque. Meanwhile the concentric group performed contractions in the opposite range of motion (70-110° motion) at 40-80°/s, and activation/stimulation set to 100% of maximal isometric torque measures on that training day. Isometric training involved 1500ms maximal contractions at a 70° ankle angle. Across all training modes, there was progressive increases in repetitions and sets.

Results

Isometric torque increased following training for all groups ($P<0.05$). There was no joint angle, or training group × angle interaction (both $P>0.05$). However, there was an effect of group ($P<0.05$), such that the isometric group had the largest magnitude increase in torque

production (~30%) as compared with both the eccentric (~15%), and concentric (~11%) groups which increased similarly.

Discussion

All three training protocols increased isometric peak torque independent of joint angle; however, the greatest increase was observed following isometric training at a long muscle length.

Voltage-induced Demineralization Behavior of Cortical Bone in Physiological Saline

Associate Professor Kazuhiro Fujisaki, Mr. Rinto Hashiguchi, Professor Kazuhiko Sasagawa, Assistant Professor Kotaro Miura

Hirosaki University, Hirosaki, Aomori, Japan

Introduction

Bone tissue is a composite material mainly consisting of apatite and collagen. The crystalline structure of apatite provides hardness and stiffness to the tissue. It has been confirmed that the impact toughness of cortical bone can be modified through a localized demineralization treatment. Although demineralization of bone tissue is commonly performed using chelating agents such as ethylenediaminetetraacetic acid solution, precise control over the treated area is difficult with liquid supply methods. We proposed an electrical stimulation-based demineralization method for bone tissue. This study investigated the characteristics of the demineralization process and explored effective treatment conditions using a voltage application system.

Methods

Cortical bone samples were prepared from a bovine femoral bone. Plate-shaped specimens were fabricated using a low-speed wheel saw under wet conditions. The specimens were then immersed in a physiological saline, with Ti electrodes attached. Experiments were conducted using both a constant direct current (DC) voltage of 10 V and an alternating current (AC) square wave voltage of ±10 V at various frequencies (15, 50, 150, 300, and 1k Hz).

Results

Demineralization behavior was observed at the electrode contact areas under both DC (anode side) and AC conditions. Apatite deposition was also observed under both conditions. A frequency dependence was confirmed; specifically, 150 Hz showed the highest reaction rate compared to other AC conditions. The demineralization progressed from the specimen surfaces, which was recognized during microscopic observation of the cross-section of the specimens.

Discussion

The electric application method allowed for easy control of the demineralization area, suggesting its potential applicability under biological conditions. The observed frequency dependence could be induced by the gas generation behavior at the surface. Gas generation decreased under higher frequency conditions. However, higher frequency may also reduce the reaction rates of apatite dissolution and deposition. The optimal condition was likely provided by the balance of these contradictory factors. Since localized demineralization is effective in improving the mechanical characteristics of cortical bone, this electric method is expected to be used in the clinical field.

Quantification of Equine Tendon Loading During Locomotion with a Wearable Sensor

Ms. Lindsay Rehme[1], Mr. Fisher Adkisson[1], Dr. Annette McCoy[2], Dr. Alex Reiter[1]

[1]Saint Louis University, Saint Louis, Missouri, United States. [2]University of Illinois at Urbana-Champaign, Champaign, Illinois, United States

Introduction

Tendinopathies are a primary cause of lameness and decreased performance in athletic horses, particularly the superficial digital flexor tendon (SDFT).[1] Clinical evaluation relies on lameness assessment and ultrasonographic imaging; however, these methods lack sensitivity for detecting subtle biomechanical abnormalities. Recent work highlights the need for improved techniques to diagnosis and monitor injuries.[1,2] To address these challenges, novel techniques are needed to provide real-time, sensitive measurements of tendon loading. A tensiometer, previously developed for humans, can track the speed of propagating vibrations in tendon to quantify loading.3 The purpose of this study was to assess the capacity of tensiometry to capture the expected tendon loading patterns of equine during locomotion.

Methods

A healthy 8-year-old female equine (Arabian) completed treadmill locomotion under four conditions while a tensiometer recorded wave speed in the SDFT (Fig. 1A). The forelimb SDFT was assessed during level walking (1.5 m/s), incline (~4°) walking, and level trotting (4 m/s), and the hindlimb SDFT during level walking. Data were collected and processed in MATLAB to time normalize gait cycles and extract peak tendon wave speeds. Differences between conditions were analyzed using descriptive statistics.

Results

In the forelimb SDFT, incline walking induced a small increase in wave speed of ~8 m/s in the second loading peak during stance (Fig. 1A) compared to level walking. Peak wave speed increased from 103±5 m/s during level walking to 141±9 m/s during trotting (Fig. 1B). Hindlimb SDFT peak wave speed during level walking was notably lower than the forelimb by ~57 m/s (Fig. 1C).

Discussion

Tensiometry captured expected loading patterns during equine locomotion. Differences between conditions were consistent with previous studies. Forelimb ground reaction forces have been shown to increase with locomotion speed[4] similar to how wave

speed increased in this study. Furthermore, equines bear ~60% of their weight with their forelimbs compared to ~40% in the hindlimbs,[4] and wave speed magnitudes in the SDFT were similarly split between limbs. These findings demonstrate the potential of tensiometry to monitor equine tendon loading.

Anterior Cruciate Ligament Size is Associated with Timing of Puberty Onset in the Skeletally Immature Porcine Knee Joint

Ms. Margaret Easson[1,2], Dr. Jacob Thompson[1,2], Dr. Sandra Shultz[3], Dr. Lauren Schnabel[1], Dr. Jeffrey Spang[4], Dr. Matthew Fisher[1,2]

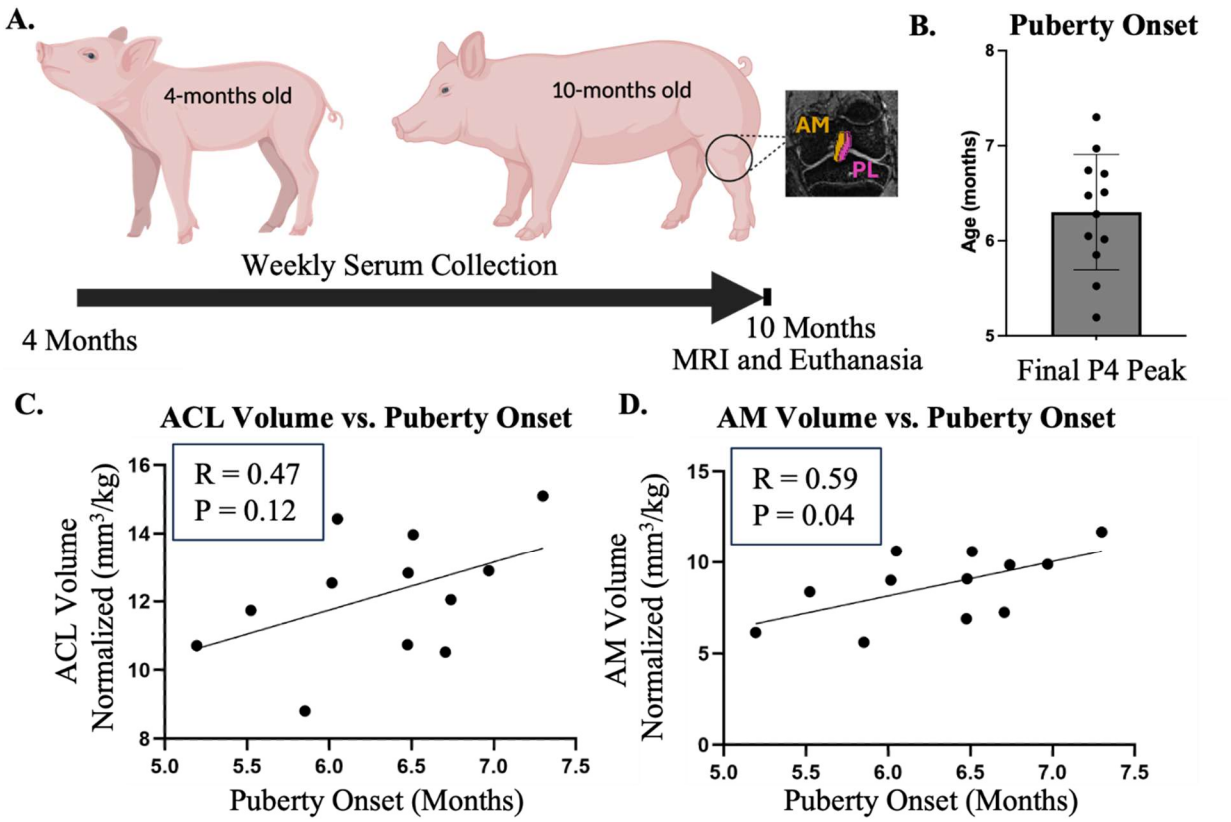
[1]North Carolina State University, Raleigh, North Carolina, United States. [2]University of North Carolina- Chapel Hill, Chapel Hill, North Carolina, United States. [3]University of North Carolin at Greensboro, Greensboro, North Carolina, United States. [4]Wake Forest University School of Medicine, Winston-Salem, North Carolina, United States

Introduction

Anterior cruciate ligament (ACL) injuries are rising, with over 200,000 cases annually in the U.S. Adolescent females are 3-4 times more likely than males to sustain an ACL tear. Puberty involves hormonal and physiological changes that may influence injury risk. The relationship between puberty timing, early hormone exposure, and ACL development is not well understood. This study examines associations between puberty timing, sex hormones, and ACL morphology and function using a pig model.

Methods

Twelve female Yucatan minipigs were monitored from pre-puberty to mid-adolescence (4–10 months old). Serum was collected weekly, increasing to three times weekly before MRI and euthanasia. Body weight was recorded biweekly. Progesterone (P4) and estradiol (E2) were measured from serum. At 10 months, MRI scans were used to manually segment the ACL and its anteromedial (AM) and posterolateral (PL) bundles to determine volume and cross-sectional area. Associations between puberty onset, sex hormones, and ACL morphology were assessed using linear regression.



Results

Puberty onset, defined by the first progesterone peak, occurred at an average age of 6.3±0.6 months(Fig. 1B). Earlier puberty onset was moderately associated with greater final weight (R=-0.62). Later onset was moderately associated with larger ACL and bundle volumes (normalized to final weight)(Fig 1C-D). Preliminary findings also suggest associations between the final progesterone peak, body weight, and ACL size(R=0.66). Ongoing work is exploring relationships among puberty onset, hormone levels, and ACL and knee mechanics and function.

Discussion

This study shows that earlier puberty onset is linked to higher body weight and ACL size, but when normalized to weight, earlier onset corresponds to smaller ACLs. These results align with literature showing that girls who reach menarche earlier often have greater weight and BMI. Human studies have linked smaller ACL size with higher injury risk, and current data suggests that pubertal timing influences ACL size. In ongoing work, a larger set of animals as well as biomechanical and biochemical changes in the ACL will be assessed. This will allow for a comprehensive analysis on how the timing of puberty onset can impact ACL morphology and function throughout maturation.

A Low-Cost Biaxial Testing Set-Up to Evaluate Pregnancy-Related Changes in Birth Canal Material Properties

Dr Mariana Masteling PhD[1], Ms Xinfei Shen BS[1], Dr Noah Pearson PhD[2,3], Dr Christopher Hong MD[1], Dr Jon Estrada PhD[1], Dr John DeLancey MD[1], Dr James Ashton-Miller PhD[1]

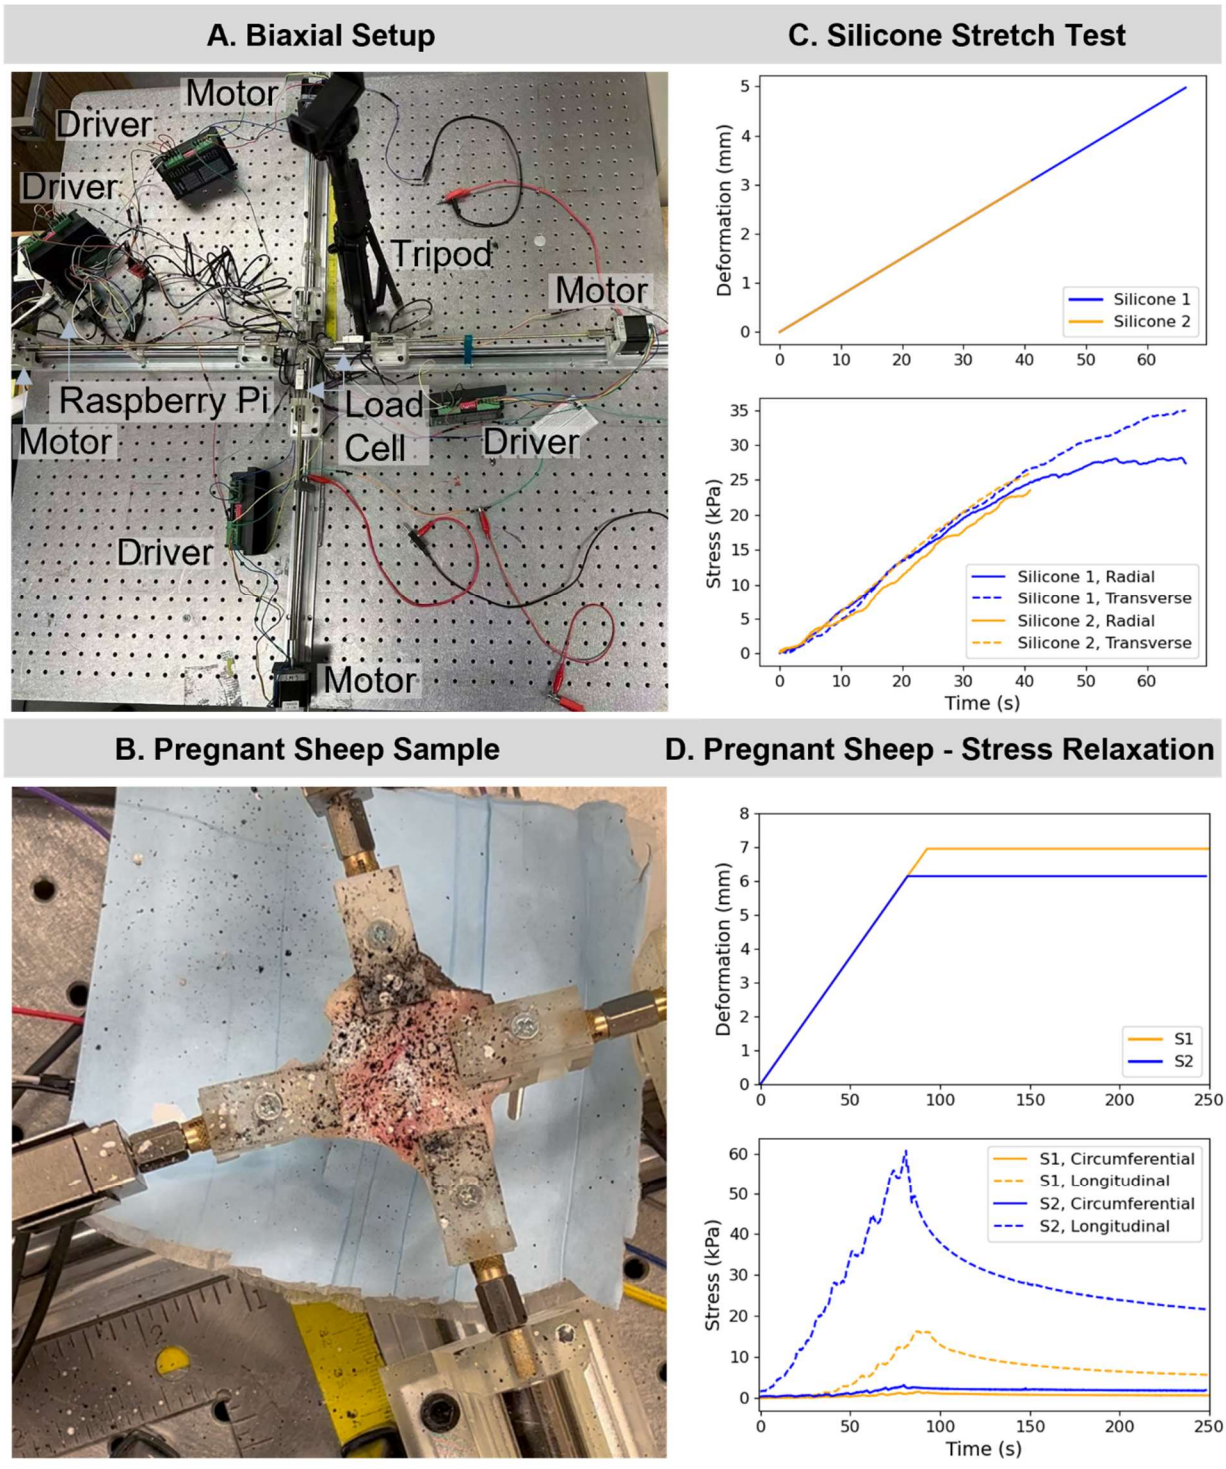
[1]University of Michigan, Ann Arbor, MI, United States. [2]Bloom Surgical, Inc, Salt Lake City, UT, United States. [3]University of Utah, Salt Lake City, UT, United States

Introduction

Pregnancy induces remarkable changes to the birth canal tissues, whose biaxial properties are unstudied. Biaxial testing is the gold standard for soft tissue mechanical characterization, however, commercially available instruments are expensive and lack flexibility. To address these issues, we developed a low-cost, portable and customizable biaxial testing system using commercially available and custom 3D printed components.

Methods

Our biaxial testing system uses a modular, cost-effective design composed of five components: (i) four linear rods, each equipped with a stepper motor and motor driver mounted via custom 3D printed supports (~$200); (ii) two load cells attached using 3D printed supports ($120); (iii) custom grips with independent clamping units connected by a screw to accommodate varying sample thickness; (iv) a Raspberry Pi 5 to control the stepper motors and record load cell readings ($120); (v) a tripod ($15) that is perpendicular to the testing area for digital image correlation (DIC) using a smartphone camera. The system offers variable strain rate, travel range of 300 mm and load capacity up to 65 N (Figure 1A), with a total cost of ~$450.



Results

Two Ecoflex 00-30 silicone samples (30x30x5 mm) were stretched biaxially at a constant rate (0.075 mm/s) to a deformation of 5 mm in both axes. The stress response shows elastic behavior in both radial and transverse directions (Figure 1C). Two birth canal samples (~20x20x6 mm), lateral to the vagina, were harvested from the same term-pregnant sheep euthanized for other studies. These tissues were tested biaxially at a constant rate (0.075 mm/s) for ~90 s followed by ~160 s relaxation period (Figure 1B, 1D). As expected, there are significant differences in the longitudinal and circumferential (up to 23x higher stress) direction in these tissues' response to stress-relaxation.

Discussion

This custom low-cost biaxial testing setup can accurately evaluate both elastic and viscoelastic materials, representing a first step for the characterization of the biaxial properties of the remarkable pregnancy-related changes in birth canal material properties. This system is portable, customizable to accommodate different motors and load cells, as well as, adjusting the angle between axis, to accurately simulate the biological stretches seen during birth.

Ground Reaction Forces and Biomechanical Differences Among Runners with Calf Pain Compartment Syndrome

Ms. Maryanne Anderson Lee, Dr. Ryan Nixon

University of Florida, Gainesville, Florida, United States

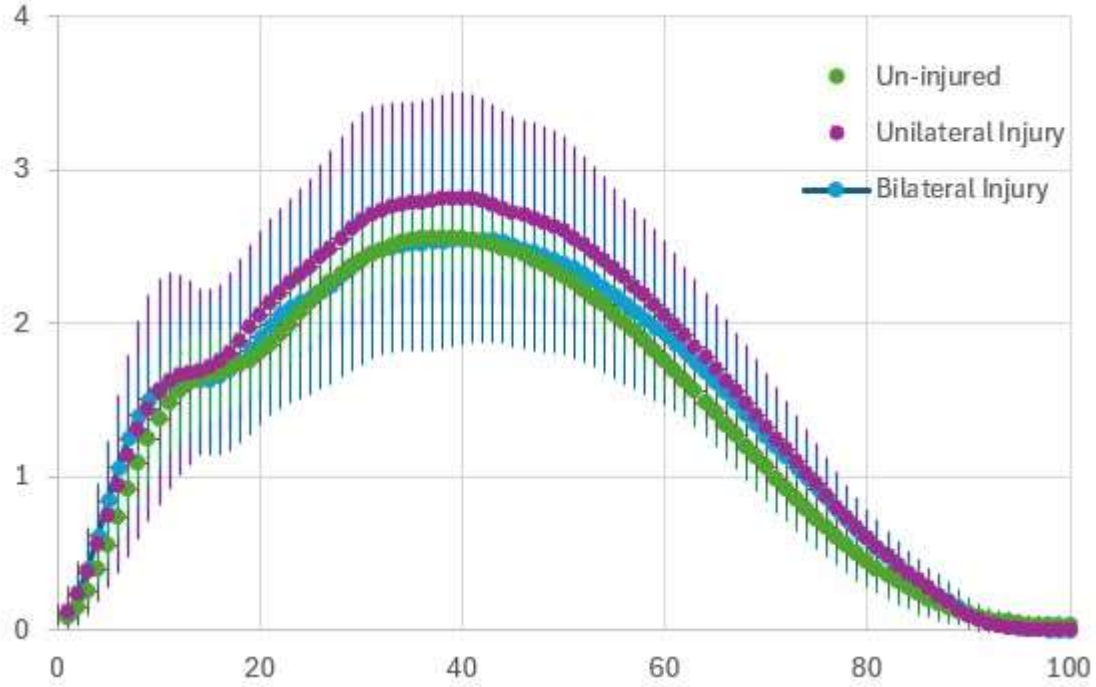
Introduction

Running is one of the most popular sports globally; however, running comes with a plethora of potential running-related injuries (RRI). Although there has been extensive research about the relation between ground reaction forces (GRFs), biomechanics, and injuries; there has not been comprehensive research into runners with Calf Pain Compartment Syndrome (CPCS) and how they biomechanically differ from non-injured runners. We aim to discover the biomechanical differences and differences in GRF components in runners with CPCS.

Methods

44 runners participated in the study and ran on an instrumented treadmill at self-selected speeds. Runners were categorized by injury status (CPCS or non-injured), foot strike (rearfoot or midfoot), and sex. To characterize signals obtained in more detail we developed an advanced waveform analysis that analyzes the collected GRFs and kinematic data (Nixon et al., 2025; Nixon et al., 2025). We tested whether CPCS runners would demonstrate differing or improved kinematics compared to non-injured runners.

Results



We normalized and frame-averaged unfiltered, data for RRI subsets of runners with CPCS to case-matched, non-injured runners. 59% of the non-injured runners ran at faster speeds and 77% ran more miles weekly compared to CPCS runners.

Discussion

Compared to non-injured runners, CPCS had shorter stance times and anterior-posterior GRFs (braking) for CPCS were higher on the right side (r = .38). Anterior-posterior GRFs (propulsion) were higher on the left (r = .46) and right side (r = .43) for runners with CPCS, showing moderate correlation. CPCS runners displayed higher maximum lateral force magnitude on the right side (r = .50), with there being a strong correlation, but lower maximum lateral force time on the right side (r = -.40). There was moderate correlation between CPCS and maximum load rate magnitude on the left (r = .41) and right side (r = .34), with runners with CPCS displaying higher maximum load rate magnitudes compared

with non-injured runners. On the other hand, runners with CPCS showed lower minimum load rate magnitude on the left (r = -.37) and right side (r = -.34). Runners with CPCS showed lower minimum load rate time on the left side (r = -.43) and right side (r=-.31).

Muscle Strength, Power, and Physical Performance Associations with Volumetric Bone Mineral Density in Older Adults of the Study of Muscle, Mobility and Aging

Graduate Student Mason Shaffer[1], Dr. Nina Heilmann[1], Graduate Student Diana Madrid[1], Dr. Stephen Kritchevsky[1], Dr. Denise Houston[1], Dr. Fang-Chi Hsu[1], Dr. Shirley Bluethmann[1], Dr. Leon Lenchik[2], Dr. Jane Cauley[3], Dr. Elsa Strotmeyer[3], Dr. Peggy Cawthon[4], Dr. Ashley Weaver[1]

[1]Wake Forest University School of Medicine, Winston-Salem, North Carolina, United States. [2]Stanford University, Stanford, California, United States. [3]University of Pittsburgh, Pittsburgh, Pennsylvania, United States. [4]University of California San Francisco, San Francisco, California, United States

Introduction

Muscle and bone interactions are fundamental to movement, with forces generated by muscle contractions influencing bone remodeling. We investigated muscle strength and physical performance associations to hip/spine volumetric bone mineral density (vBMD) in older adults. We hypothesized men and women with lower muscle strength, power and physical performance would have lower vBMD.

Methods

Computed tomography (CT) scans were obtained for 320 Study of Muscle, Mobility and Aging (SOMMA) participants (86% white, BMI 27.8±4.4, ages 75.8±4.9) including a Mindways phantom for vBMD calibration. Total hip cortical and trabecular vBMD (each left/right average) and spine trabecular vBMD (L1-L4 average) were measured in mg/cm^3 using QCTPro software. A handheld dynamometer measured grip strength (kg). Leg power and strength was measured by a Keiser A420 leg press machine. Specific power ($Watts/mm^2$) was computed as leg power divided by mid-thigh muscle area from CT. Timed physical performance tests included usual-pace 4-meter walk (m/sec), usual-pace 400-meter walk (m/sec), and 5 chair sit-to-stands (sec) without utilizing arms. Sex-stratified linear regression models for men (n=140) and women (n=180) associated function/performance measures with vBMD, adjusting for age, race, BMI, education, mid-thigh subcutaneous adipose tissue area, smoking status, alcoholic drinks per week, moderate-to-vigorous physical activity, step count, fall history, multimorbidity index, arthritis, hypertension, back pain, leg pain, and osteoporosis medication.

Results

In men, faster 400-m gait speed and quicker sit-to-stand performance were associated with higher hip and spine trabecular vBMD ($p<0.03$). In women, higher leg strength was associated with higher trabecular spine vBMD ($p=0.02$), but stronger grip was associated with lower cortical hip vBMD ($p=0.04$).

Discussion

Better physical performance in men, but not leg strength or power, was associated with higher trabecular hip and spine vBMD. Higher leg strength in women, not power or physical performance, was associated with higher spine vBMD. The negative association between grip strength and cortical hip vBMD suggests upper extremity strength does not translate to higher vBMD in lower extremities in women. Muscle strength and performance associations to vBMD in older adults appear to differ by sex, body region (weight bearing vs non-weight bearing), and bone compartment (trabecular vs. cortical).

Bone Adaptation in Response to Ovariectomy and/or Hemiparetic Stroke

Graduate Student Matthew Hart BS, MS

University of Michigan, Ann Arbor, MI, United States

Introduction

Estrogen deficiency and stroke-induced motor impairment, independently, can adversely affect bone morphology and consequently reduce cortical bone strength, but their combined effects remain undefined. Ovariectomy, a model of post-menopausal estrogen loss, alters mineral composition, and weakens mechanical performance (Goulet et al. 2011 (https://doi.org/10.1007/s00223-010-9457-x). Stroke can add further cortical deterioration in affected limbs through disuse, inflammation, and elevated osteoclast activity. The current study examines how ovariectomy and stroke separately and/or together affect cortical bone morphology and mechanical properties in rat femora and tibiae.

Methods

Female Sprague Dawley rats underwent bilateral ovariectomy (Steele & Bennett, 2011 https://doi.org/10.1053/j.jepm.2011.04.008) or sham surgery at 10 wk, followed by hemiparetic stroke (McDonald et al., 2021 https://doi.org/10.1177/15459683211005019) or shamstroke surgery at 14 wk. Animals were euthanized at 30 wk, and femora and tibiae were harvested and frozen. Femora were tested in 3-point bending with a 10 N preload and 0.5 mm/s displacement to failure. Tibiae were potted with 10 mm gauge length and twisted to failure at 0.5°/s. Stiffness, maximal load, and maximal torque were calculated. Biomechanical data were analyzed using parametric Three-Way Factorial ANOVA and LME models. Due to low sample numbers, ANOVA effect sizes were adjusted for bias by calculating ω^2, which accounts for σ^2 and DOF.

Results

Models revealed a medium effect for femoral work-to-failure (ω^2=0.1149), small effects for femoral stiffness (ω^2=0.0100), and tibial work to failure (ω^2=0.0364). Cohen's d comparisons showed small effects of OVX on stiffness (d=0.246) and small stroke-related effects on stiffness (d=0.344). Figure 1A depicts bending stiffness, while figures 1B and 1C show torsional and bending work-to-failure data across groups.

Discussion

This study builds on research of Goulet et al. (2011, https://doi.org/10.1007/s00223-010-9457-x) by extending OVX-related osteoblast changes and incorporating the added complexity of hemiparetic stroke. This work demonstrates statistical approaches that provide a foundation for current methods and analyses and establishes a robust methodological and statistical foundation for future biomechanical analyses, including a-priori power.

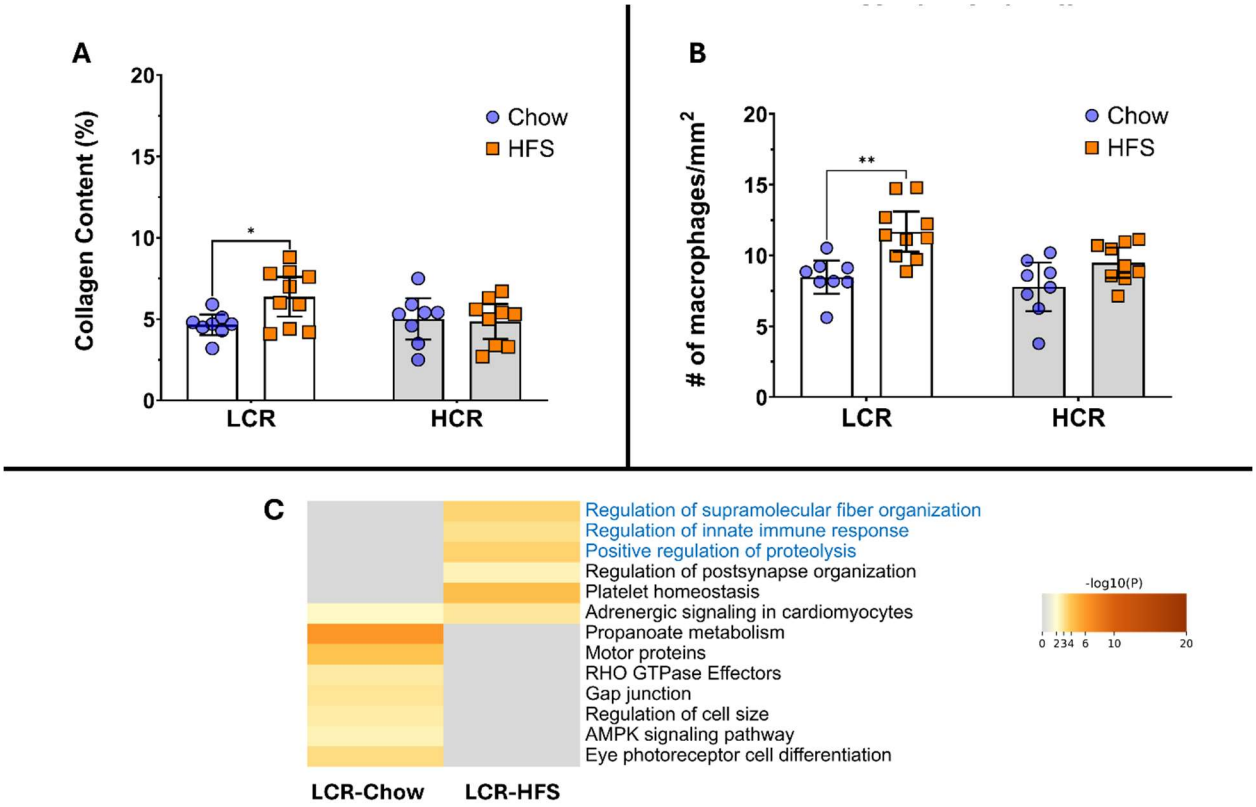
[3]Departamento de Kinesiología, Escuela de Ciencias de la Salud, Pontificia Universidad Católica de Chile, Santiago, Región Metropolitana, Chile. [4]Department of Physiology and Pharmacology, The University of Toledo, Toledo, Ohio, United States

Introduction

Obesity and its related comorbidities often lead to reduced mobility, sedentary behavior, and musculoskeletal degeneration [1]. Obesity is also associated with altered muscle integrity, including fat infiltration, inflammation, and fibrosis [2]. We previously found that muscles composed primarily of slow-twitch, high–aerobic capacity fibers were protected, whereas fast-twitch, low–aerobic capacity muscles degenerated within days of exposure to a high fat/high sucrose (HFS) diet in Sprague Dawley rats [2]. Aerobic capacity is also crucial in regulating metabolic stress in the presence of an obesity-inducing diet [3]. Therefore, the purpose of this study was to investigate the effect of an HFS diet on skeletal muscle structural integrity in rats with inherently diverse aerobic capacity.

Methods

Thirty-five 25-week-old N:NIH male rats selectively bred for high (HCR) or low (LCR) running capacity were fed either an HFS or standard chow diet (CD) for 12 weeks, resulting in four groups (HCR-CD, n=10; HCR-HFS, n=9; LCR-CD, n=8; LCR-HFS, n=8). Vastus lateralis (VL) and soleus (Sol) muscles were collected for histology and proteomics. 10 µm mid-belly sections were used to quantify fibrosis (Picrosirius), fat infiltration (Oil-Red-O), and type 1 inflammatory macrophages (CD68 histochemistry). Shotgun mass spectrometry–based proteomics was performed to identify biomarkers and pathways related to inflammation and fibrosis.



Results

In VL, collagen (p=0.03) and macrophage content (p=0.001) were increased in LCR-HFS compared to LCR-CD (Fig 1A, 1B), while fat infiltration was higher (p=0.02) in HCR-HFS versus HCR-CD. No differences in fibrosis, macrophage number, or fat infiltration were observed in Sol between diet groups. Quantitative proteomics of VL muscle in LCR-HFS revealed an upregulation of proteins associated with the innate immune response. (Fig 1C).

Discussion

Under metabolic stress, the immune response triggers myofibroblasts and fibro-adipogenic progenitors responsible for remodeling the extracellular matrix, increasing collagen crosslinking, and perimysium/ endomysium thickening, changes that may alter muscle stiffness and mechanics [4]. Our findings suggest that VL fibrosis in LCR rats may be driven by local, diet-induced inflammation, whereas high aerobic capacity in the HCR rats mitigates HFS-induced damage in fast-twitch muscle.

Force-Frequency Relationships of Pelvic Floor Muscles from Non-, Mid-, and Late-Pregnant Rats

Dr. Megan Routzong Ph.D.[1,2], Ms. Melissa Vu B.S.[2], Dr. Marianna Alperin M.D., M.S.[2,3]

[1]UT Southwestern Medical Center, Dallas, TX, United States. [2]University of California, San Diego, La Jolla, CA, United States. [3]Sanford Consortium for Regenerative Medicine, La Jolla, CA, United States

Introduction

Vaginal birth is the greatest epidemiologic risk fact factor for pelvic floor disorders due to injury sustained by pelvic soft tissues, including the pelvic floor muscles. However, not all women sustain birth injury. With the goal of elucidating drivers of injury susceptibility, we need to understand how pregnancy alters pelvic floor muscle function. In this study, we evaluated pelvic floor (pubocaudalis, PC) and tibialis anterior (TA, non-pelvic control) muscles from non-pregnant, mid-pregnant, and late-pregnant rats to determine how pregnancy alters their force-frequency relationships.

Methods

Whole PC and TA muscles were procured from 3-month-old female non-pregnant (and nulligravid), mid-pregnant (~day 12), and late-pregnant (~day 20) Sprague-Dawley rats, leaving the proximal ends attached to their respective bones. Samples were placed in a tissue bath (oxygenated Kreb's Ringer solution, pH=7.3, 37°C). Sutures were used to secure the proximal end to a clamp and the distal end to the force transducer's lever arm (Aurora Scientific, 300C). The following force-frequency data were obtained at each sample's optimal muscle length: 1Hz, 10Hz, 25Hz, 50Hz, 75Hz, 100Hz, 150Hz, and 200Hz with 2-minute rest periods and peak active force recorded for each stimulation. A sigmoidal function was fit to obtain parameters representing steepness/slope and frequency needed to reach half the maximum force (half-frequency). These parameters and forces at 1Hz and 200Hz were compared between muscles and pregnancy stages via two-way mixed MANOVA with multiple comparisons post hoc.

Results

Six non-pregnant, 3 mid-pregnant, and 3 late-pregnant animals were included in this analysis. Half-frequency and 1Hz force were significantly larger in TA muscles ($p=0.003$ and 0.046, respectively, Figure 1 top). Meanwhile, the slope factor was impacted by pregnancy ($p=0.047$, Figure 1 bottom), with curves from mid-pregnant animals being significantly steeper than those from non-pregnant animals specifically ($p=0.038$).

Discussion

This data demonstrates that pregnancy impacts skeletal muscle contractility, noted by a downward shift in mid-pregnant force-frequency curves. Though non-pregnant PC and TA curves differed, the comparable impact of pregnancy on their active mechanical behavior is indicative of global skeletal muscle remodeling during early- and mid-gestation with similarities between non- and late-pregnant data suggesting recovery of muscle function before the onset of parturition.

Images (Optional)

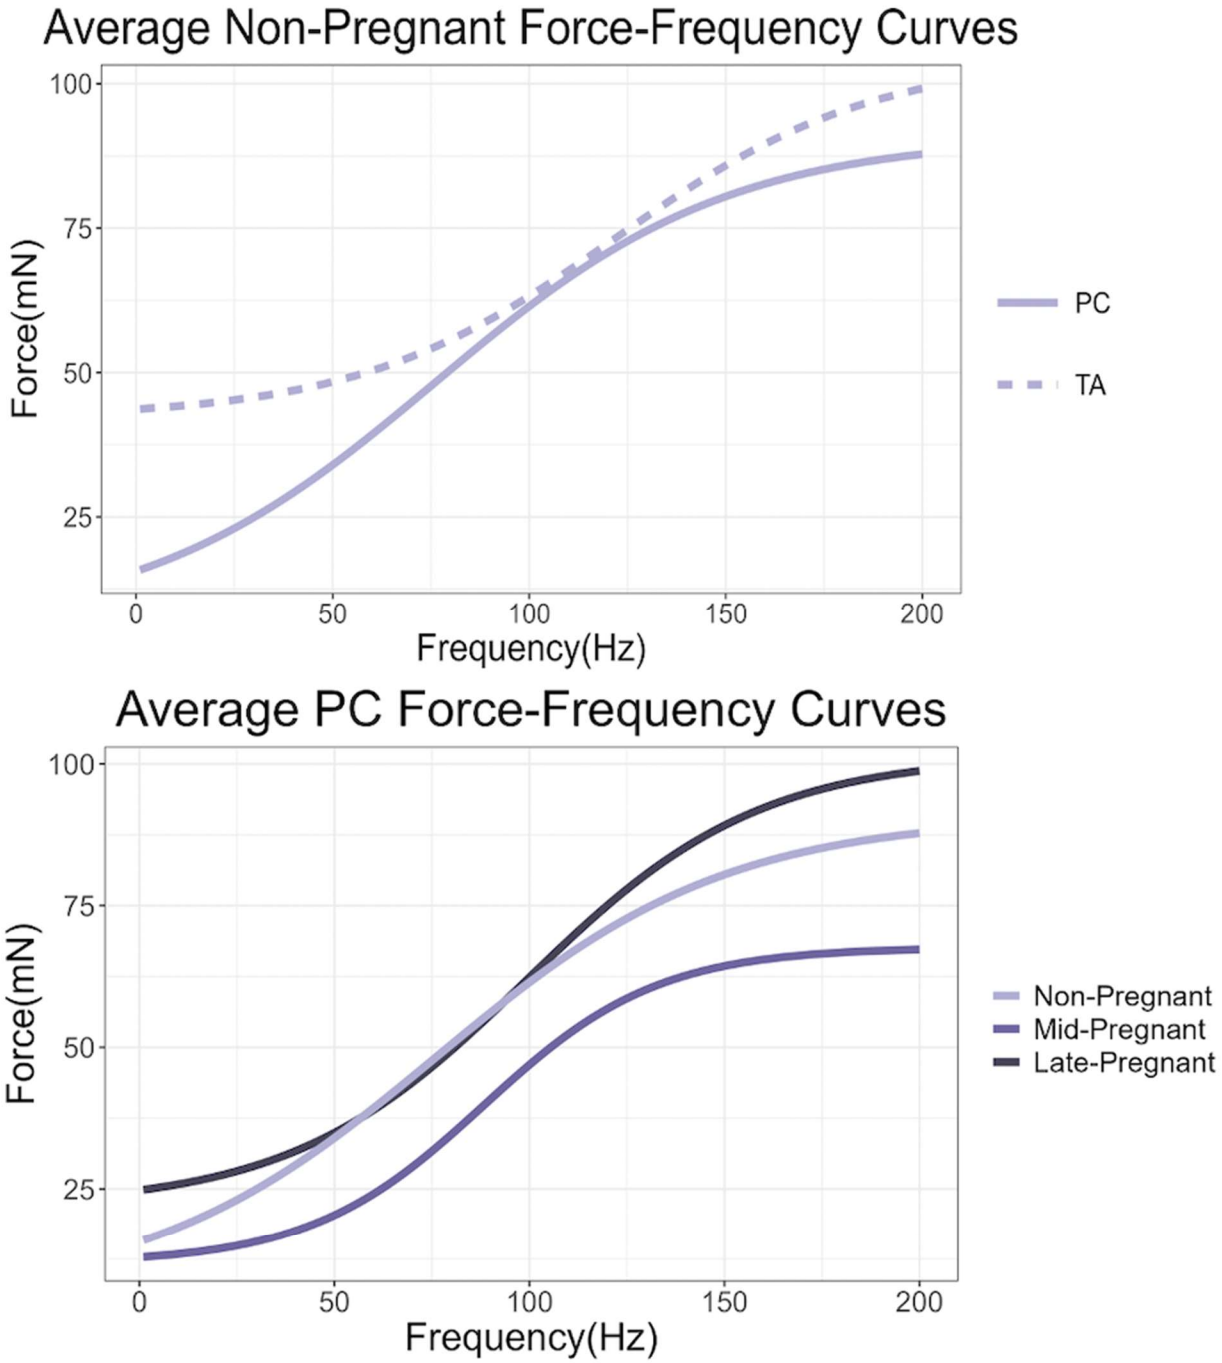

Figure 1: Top) Average force-frequency curves for PC (solid) and TA (dashed) samples from non-pregnant animals demonstrating higher TA forces at low frequencies and a rightward shift in the curve's inflection point (i.e., a higher half-frequency). Bottom) Average force-frequency curves for PC samples from non-pregnant (lighter purple), mid-pregnant (purple), and late pregnant (darker purple) animals demonstrating that the mid-pregnant data are the most distinct.

Absence of Integrins α1β1, α2β1 and α11β1 Affects the Structural and Mechanical Properties of Murine Bones

Dr. Miriam Weyers[1], Mr. Davin Kumpf[1,2], Ms. Maren Dreiner[1], Ms. Yvonne Sponer[1], Ms. Daniela Mählich[1], Dr. Beate Eckes[3], Prof. Dr. Anja Niehoff[1,2]

[2]Cologne Center for Musculoskeletal Biomechanics, Medical Faculty, University of Cologne, Cologne, North Rhine-Westphalia, Germany. [3]Translational Matrix Biology, Medical Faculty, University of Cologne, Cologne, North Rhine-Westphalia, Germany

Introduction

Integrins are transmembrane proteins that transmit mechanical stimuli between the extracellular matrix (ECM) and the cell. To coordinate interactions between bone cells and the ECM, the integrins α1β1, α2β1 and α11β1 bind to type I collagen (Col I). Previous studies using knockout the β1 subunit or double-knockouts of α2 and α11 subunit demonstrated that loss of these integrins impaired bone architecture and resulted in severe low bone mass and systemic dwarfism [1, 2]. In the present study, we investigated the effects of a triple knockout of the integrins α1β1, α2β1 and α11β1 on the structural and mechanical properties of femoral bone tissue in mice.

Methods

Bone properties were analyzed in femora of fifteen one-year-old female and male wildtype C57BL/6N (WT; N = 9) and triple-knockout (TKO; N = 6) mice [3] using µCT (SCANCO) and 3-point bending tests (Zwick). To assess the ECM immunohistochemical staining for Col I was performed in the femoral cortex. Group differences were evaluated using the unpaired non-parametric Mann–Whitney U-test.

Results

Femora of TKO mice were significantly shorter, and their tissue area was markedly reduced compared to WT controls. TKO mice further exhibited significantly reduced cortical thickness and cortical area, along with significantly lower marrow area. No significant differences were observed in trabecular bone structure between groups. The maximal breaking force was significantly reduced, whereas maximal strain stress was significantly increased in TKO compared to WT mice. The absence of collagen binding integrins in TKO did not affect the localization or intensity of Col I in the femoral cortical ECM.

Discussion

Consistent with findings in α1β1 and α11β1 double-knockout animals, the deficiency of integrins α1β1, α2β1 and α11β1 adversely affected the structural and mechanical properties of the femoral cortex. The absence of differences in type I collagen staining intensity may be attributable to the advanced age of the mice. Currently, we study younger animals to exclude age-related confounding effects.

Evaluating Rigid and Deformable Transformations for Quantifying Cranial Vault Growth in Rats

Dr. Mostafa Mohamed, Dr. Michael Baggley, Ms. Kiana Zhu, Dr. Tsolmonbaatar Khurelbaatar, Dr. Mehrdad Palizi, Dr. Samer Adeeb, Dr. Dan L. Romanyk, Dr. Lindsey Westover

University of Alberta, Edmonton, AB, Canada

Introduction

Traditional morphometrics use anatomical landmarks to study growth[1]. Alternatively, statistical shape modelling (SSM) uses 3D representations to capture anatomical variation, but requires accurate mesh alignment and underlying transformations[2]. This investigation developed a 3D morphometric pipeline to analyze rat cranial vault growth and compared two Coherent Point Drift (CPD) approaches: rigid-scaling and deformable transformation.

Methods

Four Sprague–Dawley rats (2F, 2M; age 7 weeks) underwent two in-vivo CT scans separated by two weeks (voxel size 8.9 µm, Bruker Skyscan 1176, AUP00003759 under UA ACUC). Images were segmented in Materialise MIMICS, downsampled to 17.8 µm, and the domain was trimmed in Geomagic Design X using landmark-based offsets. Longitudinal changes were quantified by registering earlier to later timepoints with CPD using rigid-scaling and deformable pipelines developed on Python. Pipeline performance was evaluated on meshes subjected to prescribed transformations and in mapping the timepoints.

Results

Under prescribed transformations, both CPD methods achieved high accuracy (average RMSE < 0.05 mm). When applied to longitudinal data, only the deformable CPD produced near-complete alignment between the moving (earlier timepoint) and reference meshes (**Figure 1A**). The RMSE using rigid and deformable workflows to map the timepoints was 0.11+/-0.02 mm and 0.05+/-0.01 mm, respectively. Vector plots showed that rigid CPD failed to capture the expected flattening and elongation behavior, whereas deformable CPD captured this behaviour (**Figure 1B**). Contour plots of the anterior–posterior displacement component demonstrated directional growth about a neutral axis near the midpoint of the sagittal suture, with movement occurring in opposite directions on either side (**Figure 1C)**.

Discussion

Cranial growth is a complex process that may not adequately represented by uniform scaling alone. These findings support the use of non-rigid CPD, which minimized error between transformed and reference meshes and produced growth vectors that are more aligned with biological expectations, including elongation/flattening, and bidirectional anterior–posterior growth. While the current pipeline shows promise in capturing global cranial growth, displacements near sutures are small and approach the error bound. Future work should focus on reducing this error, and expanding the sample size before fully implementing SSM.

Images (Optional)

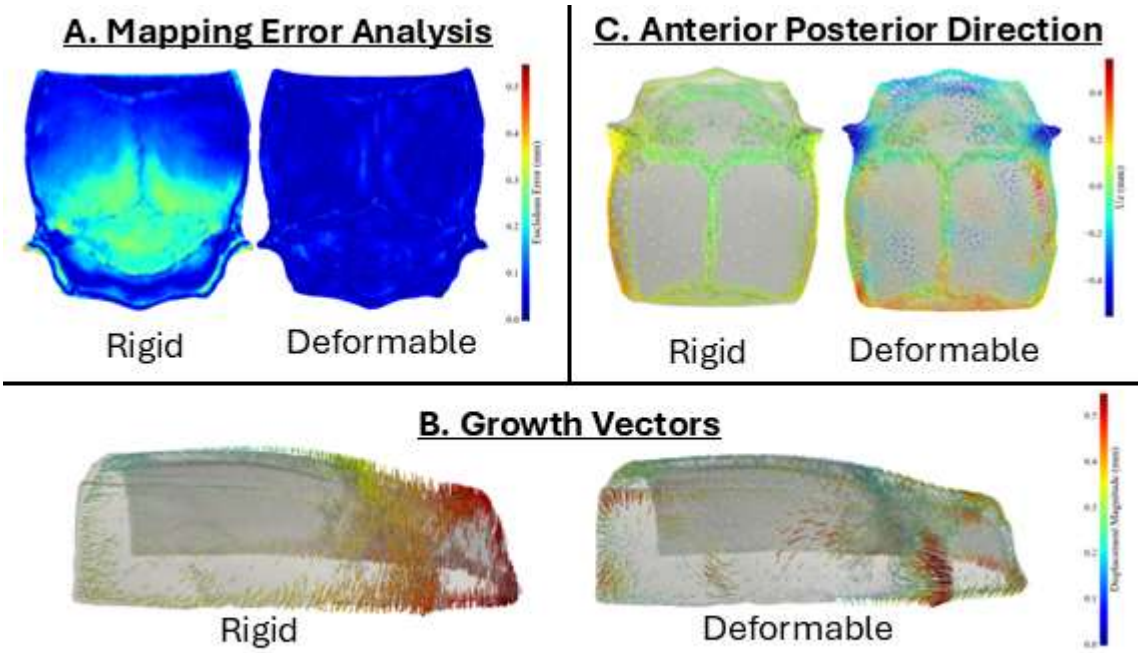

Figure 1: A. Deformable CPD achieves lower error when mapping the two time points, **B.** better represents the expected elongation and flattening behaviour, **C.** and shows more biologically relevant anterior–posterior movement.

Stribeck Analysis Reveals Differences in Friction Behavior of Cartilage from Femoral and Humeral Head

Mr. Nathan Briard

Cornell University, Ithaca, NY, United States

Introduction

Ball-and-socket joints provide a wide range of motion, support body weight, while sustaining varying normal loads and contact speeds that differ from other joints. These joints, located at femoral and humeral heads, are covered with cartilage that differ in thickness across regions yet maintain low friction. However, the lubrication modes of these joints and whether regional differences affect their coefficients of friction remain unclear. The Stribeck framework provides a way to characterize lubrication by relating friction to viscosity, sliding speed, thickness, and normal load. This study aims to define the lubrication modes of femoral and humeral head cartilage within the Stribeck framework and to determine whether regional variations influence frictional behavior.

Methods

A total of 16 samples per donor (20-30 years) for 3-donors with full-thickness cartilage (4mm diameter) were obtained from four regions of femoral and humeral heads. Custom cartilage on glass was used to characterize frictional behavior of 9 speeds from 0.1-10 mm/s. Samples were tested in 3 dextran solutions of viscosities (0, 9, and 23%), and friction coefficients were averaged after equilibrium.

Results

The data was well described by the Stribeck curve for both femoral head and humeral head (R^2=0.82) (**Fig.1A**). The fit coefficient showed different modes of lubrication for the two different cartilages; the femoral cartilage had lower boundary friction coefficient and greater minimum friction coefficient and transition number (**Fig.1B**). However, regional variation within femoral head cartilage revealed superior and anterior regions having similar modes of lubrication as do inferior and posterior regions (**Fig.1C**). The humeral head had similar modes of lubrication as femoral head, except superior region had higher boundary friction coefficient and transition number (**Fig.1D**).

Discussion

This study is the first to examine the tribological behavior of young, healthy human ball-and-socket cartilage using the Stribeck framework. It revealed inherent differences between the two joint cartilages; humeral head cartilage exhibited roughly twice the boundary friction coefficient of femoral cartilage but had a friction minimum an order of magnitude lower and transitioned more rapidly. These findings clarify how friction varies across femoral and humeral heads, providing essential insight for designing viscosupplements and developing strategies to protect joints from osteoarthritis.

Images (Optional)

Determining the Combined Effects of Menopause and Stroke on Skeletal Muscle Function and Weakness

Ms. Nicole A. Conquergood, Dr. Stephanie A. Ross, Dr. Walter Herzog

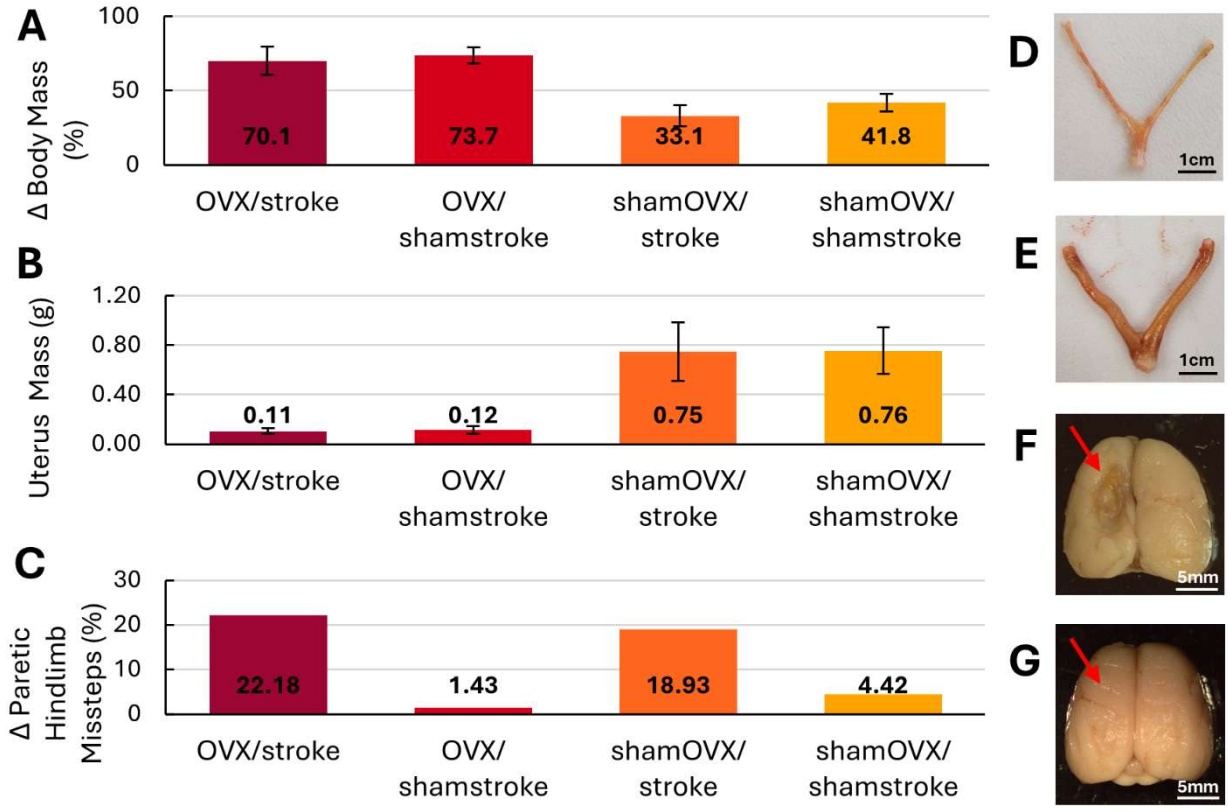
University of Calgary, Calgary, Alberta, Canada

Introduction

Menopause is linked to reduced skeletal muscle strength [1], but the mechanisms are unclear. Post-menopausal women are at increased stroke risk [2], which independently reduces muscle mass and strength [3], and experience greater post-stroke mobility deficits than men [4]. However, the combined impact of menopause and stroke on skeletal muscle has not been directly examined. Therefore, this study aimed to develop a combined menopause-stroke animal model to investigate muscle mechanisms that may contribute to mobility deficits in post-menopausal stroke survivors.

Methods

Ten-week-old female Sprague-Dawley rats underwent either bilateral ovariectomy (OVX) to induce menopause or sham surgery (shamOVX). Four weeks later, photothrombotic stroke was induced in some OVX and shamOVX animals [5]. Remaining animals received a sham stroke, creating four groups: OVX/stroke (n = 13), OVX/shamstroke (n = 9), shamOVX/stroke (n = 12), shamOVX/shamstroke (n = 9). Motor function was assessed using a misstep protocol [5]. Animals were euthanized 4 months post-stroke, corresponding to the chronic phase of stroke [6].



Results

Twenty weeks post-OVX, OVX animals gained 71.9±7.7% of their baseline body mass, compared to 37.2±7.9% in shamOVX animals ($p < 0.001$, Figure 1A). Uterus mass was 85% lower in the OVX animals than in sham animals (0.11±0.03 g vs. 0.75±0.21 g, $p < 0.001$, Figure 1B, example OVX/shamOVX uteri images in Figure 1D-E, respectively). Stroke animals showed an increase in paretic hindlimb missteps compared to shamstroke (20.6±14.3% vs. 2.9±8.2%, $p = 0.006$, Figure 1C, example stroke/shamstroke brain images in Figure 1F-G, respectively).

Discussion

Body and uterus mass changes confirm that the OVX was successful [1]. We also found an increase in paretic hindlimb missteps for stroke animals, consistent with previous studies [5], which suggests successful stroke induction. Therefore, the combined OVX/stroke model was successful and can be used for further analysis on post-stroke skeletal muscle adaptations following menopause.

Achilles Tendon Biomechanical Properties during Physiologically Representative Loads

Mr Nisal Jayaneththi, Dr Hans Gray, Prof Peter Lee

The University of Melbourne, Melbourne, Victoria, Australia

Introduction

The current study aimed to analyse the effects of different physiologically representative loads on Achilles tendon failure and how damage accumulates in different regions. We implemented a cyclic loading experiment on cadaveric specimens and used digital image correlation to measure surface strains.

Methods

Four Achilles tendons from three female donors (88.8 ± 2.89 years, 60.0 ± 9.2kg) were mounted to a tensile testing machine.

A spectrum simulating a single basketball game - where Achilles injuries are common - was constructed - 332 cycles of jogging (0.92 BW at 1.35Hz), 380 cycles of running (1.30 BW at 1.43Hz), 442 cycles of sprinting (2.24 BW at 2.33Hz) and 26 cycles of unilateral jumping and landing (1.13 BW for jumping and 1.21 BW for landing at 0.658Hz).

Activities were split equally over two blocks within the spectrum, except for jumping. Loads were scaled down from literature data based on donor age, sex, and the assumption that donors were not athletes. The spectrum was repeated until failure, where possible.

Two synchronised cameras recorded the deformation of a speckle pattern on the surface of the tendons for the duration of the experiment. Cycles were recorded intermittently: every 15th cycle for jogging, every 9th for running, every 5th for sprinting, and every 5th for jumping.

Data was processed using a digital image correlation software (VIC-3D, Correlated Solutions, SC, USA). Longitudinal strain was extracted across the tendon, and within subregions of the tendon: the insertion, midsubstance and the proximal region. Hysteresis loop areas and secant stiffnesses were calculated for each recorded cycle in each region and activity tested, and averaged across specimens.

Results

Throughout each activity, the hysteresis area and stiffness remain relatively unchanged between cycles (Figure 1). However, it appears that the insertion of the tendon has a lower stiffness on average compared to the midsubstance and proximal regions for all activities.

Discussion

This study is ongoing, and further statistical analysis is required to draw conclusions regarding the data collected. We anticipate that the results will help us understand the way tendon strains develop during cyclic loading, which will inform methods of injury prevention.

Effects of Dynamic Load, Wrist Posture, and Venous Occlusion on Carpal Tunnel Tissue Motion in Females

Miss Noelle Donatelli H.B.Sc.Kin, Dr Peter Keir PhD

McMaster University, Hamilton, Ontario, Canada

Introduction

Carpal tunnel syndrome (CTS) has been linked to altered tendon-subsynovial connective tissue (SSCT) motion. Mechanical loading, venous congestion, wrist posture, and aging influence tendon-SSCT motion, yet their combined effects across adulthood are unclear. This study examined the effects of load, venous occlusion, wrist posture, and age on tendon and SSCT excursion during cyclic single finger motion in women.

Methods

Women aged 17-80 years completed eight randomized conditions, each repeated twice, crossing two levels of force (0 N, 2 N), wrist posture (neutral, 20° flexion), and brachial venous occlusion using a blood pressure cuff (none, 80% diastolic). In each condition, participants performed 12 isolated middle-finger flexion-extension cycles at 0.75 Hz while colour Doppler ultrasound captured tendon and SSCT motion (GE Vivid Q, 12L-RS). Tissue displacement and velocity were extracted for the middle 8 cycles to quantify tendon-SSCT gliding using two metrics. Shear strain index (SSI) reflects the percentage difference between tendon and SSCT excursion where higher values indicate greater tendon-SSCT relative motion. Maximum velocity ratio (MVR) expresses SSCT peak velocity relative to tendon peak velocity.

Results

Preliminary analyses show that younger women had similar relative tendon–SSCT motion across conditions while the older group had greater SSCT displacement, and SSI, in the no force, neutral wrist condition. Wrist flexion increased excursion in the young participants but reduced SSCT displacement in the older group. Blood flow reduction (occlusion) produced little change in younger adults but reduced SSCT velocity in the older group. Similar results were found for the loaded condition, with increased relative tendon-SSCT motion in the older group. The effect was even greater in the combined wrist flexion, finger force, and reduced blood flow condition with the highest SSI and lowest MVR.

Discussion

Younger women appeared less reactive to the experimental conditions than older women. Posture, load, and venous occlusion had mild effects in younger women but acted to reduce SSCT motion in older women. These early findings suggest aging heightens tissue sensitivity to mechanical stress and vascular compromise, increasing relative tendon-SSCT motion and shear in the carpal tunnel.

Bone mechanoregulation is not altered by disease severity in adults with OI at distal tibia

Mr. Pedram Akhlaghi[1,2], Dr. Seyedmahdi Hosseinitabatabaei[1,2,3], Dr. Frank Rauch1[1,4], Dr. Bettina Willie[1,2,3,5]

[1]Shriners Hospital for Children, Research Center, Montreal, Quebec, Canada. [2]Faculty of Dental Medicine and Oral Health Sciences, McGill University, Montreal, Quebec, Canada. [3]Department of Bioengineering, McGill University, Montreal, Quebec, Canada. [4]Department of Pediatrics, McGill University, Montreal, Quebec, Canada. [5]Department of Biomedical Engineering, McGill University, Montreal, Quebec, Canada

Introduction

Osteogenesis imperfecta (OI) is an osteodysplasia which leads to bone fragility, recurrent fractures, and bone deformities. The most common types of OI, differ considerably in disease severity, with Type I being the least severe, type IV being moderate, and type III being most severe. Time-lapse high-resolution peripheral quantitative computed tomography (HR-pQCT) has emerged as a noninvasive method to assess bone formation and resorption. We combined timelapse HR-pQCT with finite element (FE) modeling to study local mechanoregulation (strain energy density [SED]) that drives bone formation and resorption, and to investigate the role of OI severity (type I vs type III or IV) on bone mechanoregulation.

Methods

Thirty-two tibial HR-pQCT scans of female adults with OI type I (N=19), and III or IV (N=13), were analyzed using timelapse and micro-FE analyses at baseline and in the absence of a placebo group, at one year after receiving a low dose of setrusumab (2 mg/kg), a sclerostin neutralizing antibody (Fig.1 A,B). First, 3D image registration was performed to register the scans at baseline and month-12 and then timelapse HR-pQCT were computed using Scanco's image processing language. The SED was calculated using micro-FE analysis at baseline. A surface-based projection method was developed to project timelapse-identified (re)modeling events onto the bone surface. The (re)modeling events were registered to the corresponding local SED fields at the bone surface. Conditional probability curves for formation, resorption, and quiescence as functions of local SED were calculated and compared across disease severity (OI type).

Results

Our results showed that after one-year of follow-up, bone had the highest conditional probability (around 90%) to be quiescent (unchanged) in both high-SED and low-SED regions, regardless of OI type (Fig.1 C). However, bone formation increased and bone resorption decreased moderately as SED magnitudes rose for both OI groups.

Discussion

Our data suggests that mechanoregulation in OI is not dependent on OI disease severity, (type I vs type III or IV) and largely quiescent. These findings correspond to prior observations that show smaller long bone circumference in people with OI, regardless of OI severity.

Images (Optional)

Activation and Force-Dependent Contributions to Short-Range Stiffness of Cat Soleus Muscles: Insights From System Identification of Viscoelasticity

Dr. Ridhi Sahani[1,2], Research Assistant Professor Daniel Ludvig[1,2], Professor Eric Perreault[1,2], Mr. Richard Casler[3], Professor Kiisa Nishikawa[4]

[1]Northwestern University, Chicago, Illinois, United States. [2]Shirley Ryan AbilityLab, Chicago, Illinois, United States. [3]Massachusetts Institute of Technology, Cambridge, Massachusetts, United States. [4]Northern Arizona University, Flagstaff, Arizona, United States

Introduction

Muscle short range stiffness (SRS) provides stability and is assumed to result from stretching bound cross-bridges. [1,2] Titin acts as a tunable viscoelastic spring in active muscles, [3] but its activation and force-dependent contributions to SRS are typically overlooked. We used system identification to compare viscoelastic properties of cat soleus muscle-tendon-units (MTUs) in response to length perturbations at matched levels of passive and active force. We hypothesized that force-dependent viscoelastic properties contribute to the short-range force response, suggesting a role for titin in SRS.

Methods

The soleus MTUs of anesthetized cats (n=4, 2M 2F) were stretched (~2% L_o at ~4 L_o/s) while passive and active forces were between 25-100% of optimal force (**Fig. 1A**). SRS was calculated with a linear fit to the initial force response (~2ms). The contribution of viscous forces after the initial SRS was determined as $\%F_{viscous}=(F_{peak}-F_{end})/F_{end}$. Single input-single output system identification was used to find the spring constants and damping coefficients using time-series data from the ramp stretch experiments, with muscle length as the input and muscle force as the output. (**Fig. 1B**).

Results

$\%F_{viscous}$ was greater in active than passive MTUs ($p=0.017$), increasing with active force ($p<0.0001$) but decreasing with passive force ($p=0.011$; **Fig. 1C**). Passive and active MTUs were fit by a Kelvin-Voigt element in series with a spring (average $R^2=0.986$). Stiffness (k1) was greater in passive than active MTUs ($p<0.048$) and increased with passive force ($p<0.017$; **Fig.1D**). Although not significantly different, damping (b1) was greater in passive (0.31-33.73 N/mm^2) than active MTUs (0.015-0.16 N/mm^2; **Fig 1E**). Series spring stiffness (k2) increased with passive ($p<0.0029$) and active ($p<0.042$) force and corresponded well with SRS ($R^2=0.69$; **Fig 1F**).

Discussion

While SRS increased with both passive and active forces, resistance to stretch was primarily elastic in passive muscles but primarily viscous in active muscles. Our results demonstrate activation and force-dependent viscoelastic contributions to SRS, suggesting a role for titin. Further research is needed to distinguish between cross-bridges and titin as potential mechanisms.

The Effects of Growth-Period Exercise on Adult Body and Muscle Composition

Dr. Derek J. Jurestovsky, Mr. Roberto Castro Jr., Dr. Ana Carla C. Salamunes, Dr Stephen J. Piazza, Dr. Jonas Rubenson

The Pennsylvania State University, State College, PA, United States

Introduction

Physical inactivity is linked to chronic diseases, morbidity and even mortality. However, physiological effects of childhood exercise on adult physical activity remain unclear. Previous data from our lab show, in an animal model (fowl), that uphill treadmill training throughout growth (1yr) results in a greater peak aerobic capacity after 12 months of training and that this adaptation is retained even following a 6-month non-exercise washout period [1]. Here, we explore how growth-period exercise impacts long-term body and muscle composition into adulthood and whether this may be associated with long-term adaptations to exercise capacity.

Methods

Sixty-two one-day old animals were randomly assigned to a sedentary control group (CON; N = 31) or an exercise training group (EXE; N = 31). EXE underwent uphill (6 deg) treadmill training 30 min/day, 5 days/wk from age 2 wks until 12 months (skeletally mature). CON received no training. At 12 months, subsets of animals from each group were euthanized for body composition (DXA) and muscle architecture analyses of the iliotibialis lateralis pars postacetabularis (ILPO), a key muscle used to power uphill running [2]. The remaining animals of both CON and EXE were transferred to large pens where they underwent a 6-month non-exercise washout period. After the washout period birds were euthanized for the same analyses. (The protocol used the same animals as in [1]).

Results

EXE exhibited lower body mass and a lower body fat percentage at both 12- and 18-month timepoints ($p<0.05$). Preliminary data indicate no significant differences in ILPO density (hydrostatic weighing) at 18 mo. Measurements on PCSA, optimal fiber length, pennation angle, sarcomere lengths, and tendon properties are currently underway.

Discussion

Early life exercise led to lasting differences in body composition with EXE being leaner even after a prolonged period of inactivity. Body composition may be a contributing factor to long-term effects of growth-period exercise on metabolic capacity. Preliminary data show no differences in ILPO density between groups. Additional analyses of muscle architecture are underway to further evaluate long term musculoskeletal adaptations.

The Articular surface is the primary site of changes in shear mechanics and composition in all stages of OA

Mr Salman Matan[1], Dr. Camila Carballo[2], MD Sabrina Strickland[2], MD Andreas Gomoll[2], MD Scott Rodeo[2], Dr. Itai Cohen[1], Dr. Lawrence Bonassar[1]

[1]Cornell University, Ithaca, NY, United States. [2]Hospital for Special Surgery, NYC, NY, United States

Introduction

: Osteoarthritis (OA) is chronic disease affecting around 500 million individuals. During OA development, ECM (collagen and aggrecan) is gradually depleted, beginning at the surface, progressing to deeper zones, and eventually exposing bone. However, little is known about how matrix depletion affects depth-dependent shear mechanics of OA human cartilage. We hypothesize that OA cartilage's mechanical and compositional changes are primarily localized at the surface. This study aims to determine how depth-dependent local compositional changes influence microscale mechanics.

Methods

A total of 13 healthy and 6 OA samples were obtained as operating room discard after IRB approval and patient consent. Healthy donors were 14-28 and 69-73 years for OA donors. Outerbridge and OARSI scoring were performed. Depth-dependent shear mechanics were measured after 15% compression and 1% peak shear strain. FT-IR and biochemical assays were utilized to study ECM composition.

Results

The shear modulus of OA was significantly lowered, and the notable difference was larger at the surface by a factor of 20, while samples remained lower throughout tissue depth compared to healthy (**Fig.1A**). The first 200μm were highlighted to demonstrate approximately 2-orders of magnitude differences in shear modulus. Healthy cartilage showed higher stiffness than OA, both in the shear-min and plateau (**Fig.1B-C**). Compositional analysis supported mechanical findings, showing collagen content decreased 4-fold within the first 200μm but remained around 3-fold throughout tissue depth compared to healthy (**Fig.1D**). Both shear min (surface) and shear plateau (deep

zone) showed strong correlation (R^2= 0.70 and R^2= 0.21, respectively) with collagen concentration (**Fig.1E**).

Discussion

This is the first study to examine depth-dependent shear mechanics on all stages of OA, showing large differences in the modulus is concentrated at the surface. The shear mechanics of OA cartilage are governed by compositional changes and are more sensitive to collagen than aggrecan, with a small decrease in collagen concentration causing an order of magnitude decrease in modulus. Future therapeutics need to stabilize the cartilage surface to stop the progression of the disease.

Collagen Fibre Volume Fraction in Healthy and Degenerated Articular Cartilage: Insights from Mixture Theory

Dr. Kotaybah Hashlamoun, Dr. Ziad Abusara, Dr. Walter Herzog, Dr. Salvatore Federico

University of Calgary, Calgary, AB, Canada

Dr. Kotaybah Hashlamoun

Introduction

Articular cartilage is a complex, multi-phasic, multi-constituent tissue, providing nearly frictionless contact and stress distribution in diarthrodial joints. Osteoarthritis (OA) is a degenerative disease that reduces the cartilage's ability to withstand physiological loading. OA-degenerated cartilage is characterised by a reduced elastic modulus (E). Thus, E can be used as an indicator of cartilage health.

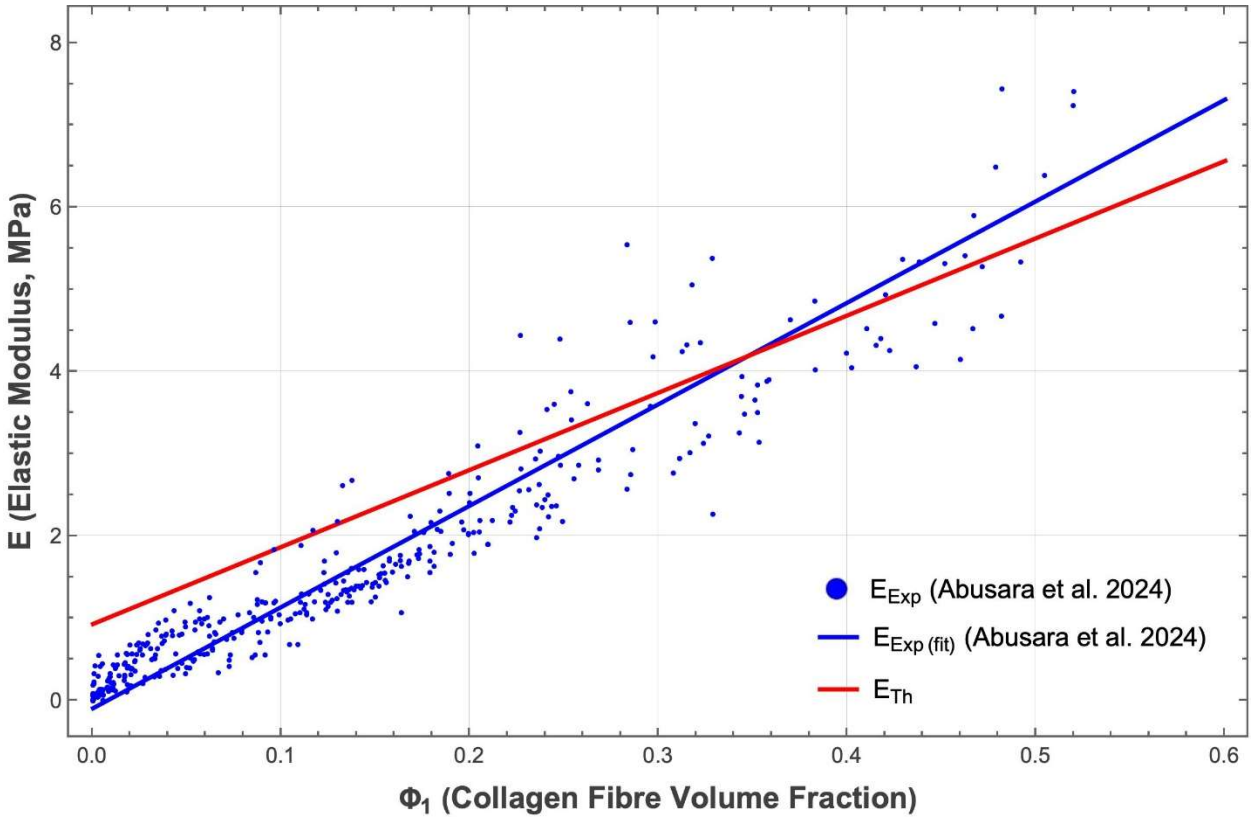
Recently, Abusara et al. [1] explored the possibility of relying entirely on imaging as an alternative to mechanical testing in assessing the tissue's health. While the correlation between cell viability and E was poor, the correlation between collagen fibre volumetric fraction in the superficial zone and E was strong and nearly linear. This suggests that collagen fibre fraction may be a direct indicator of cartilage health.

The purpose of this work was to determine whether such linear relationship between E and fibre fraction can be predicted via an established microstructural model.

Methods

The solid phase of articular cartilage was modelled as an elastic composite comprised of proteoglycans (isotropic Holmes-Mow energy) and collagen fibres (isotropic Holmes-Mow energy plus an anisotropic term) [2]. A confined compression test in the direction of tissue thickness was simulated numerically. The fibre fraction was varied between 0.1 and 0.6, while the proteoglycan fraction remained fixed at 0.1.

Results



The figure shows a linear relationship between the experimental and the theoretical elastic moduli and the fibre fraction, for a value of nominal strain of 0.1, as in [1]. The ratio

between the theoretical to experimental slopes obtained for the lines describing the moduli against collagen volume fraction was about 0.76.

Discussion

The effect of fibre fraction on the elastic modulus, found experimentally, can be re-reinforced by established structural models, further supporting the reliability of using fibre fraction as an indicator of early OA. These preliminary results motivate the development of a biphasic cartilage model that can be used to investigate systematically the effect of fibre volumetric fraction on cartilage mechanical properties, and by association cartilage health, without the need for extensive experimental testing.

The Component of Synovial Fluid which Protects Cartilage from Fatigue Failure Under Cyclical Compression is Present in Fetal Bovine Serum

Mr. Justin Weiss, Mr. Haoyu Zhang, Ms. Sarah Deiters, Dr. Clark Hung, Dr. Gerard Ateshian

Columbia University, New York, NY, United States

Introduction

Synovial Fluid (SF) is conventionally thought to protect articular cartilage through lubrication. However, SF's friction-reducing effect is modest, with interstitial fluid pressurization providing the dominant effect [1]. Recent studies demonstrated that, compared to phosphate-buffered saline (PBS), SF delays cartilage fatigue failure under cyclical compression, which presents as middle-zone (MZ) delamination [2-3]. Zhang et al. showed SF protects cartilage even with no sliding, indicating a non-lubrication mechanism [2]. The SF constituents responsible for this protection remain unknown. SF consists of an ultrafiltrate of serum mixed with hyaluronan and lubricin. In [2], samples were not pre-incubated, yet protection emerged within 100 minutes, implicating low–molecular-weight constituents as the responsible factors. Because hyaluronan's large molar mass (10 MDa) and lubricin's strong surface binding prevent transport to the MZ, we hypothesize that the protective component of SF is also present in fetal bovine serum (FBS).

Methods

Cylindrical cartilage plugs (12 mm) were harvested from immature bovine femoral condyles (n=4), sectioned from the deep zone to 1.79±0.26 mm thickness, and stored in PBS. Samples were assigned to PBS (n=4), FBS (n=4), or 25% FBS in PBS (n=3). Following [2], plugs were submerged in 15 mL of fluid and subjected to a prescribed cyclical compression of 54 N at 2 Hz. Tests ended at 12,000 cycles (100 minutes) upon gross visual damage or continued to 36,000 cycles.

Results

All PBS samples showed gross damage by 12,000 cycles (Figure 1). No FBS or 25% FBS samples exhibited damage, even after 36,000 cycles, as assessed from surface roughness measurements.

Discussion

The SF component that protects cartilage against fatigue failure is also present in FBS and is independent of SF's high viscosity. SF's protection reduces in 25% dilutions [2-3], whereas 25% FBS retained full efficacy, suggesting the target component exists in FBS at

higher concentrations. These findings exclude hyaluronan and lubricin as candidates and instead point to low-molecular-weight constituents present in both fluids, and capable of diffusing from the articular surface to the MZ within 100 minutes.

Age-Related Decline in Impact Strength and Its Association With Collagen-Related Bone Quality in Bovine Single Trabeculae

Prof. Satoshi Yamada, Mr. Shoei Miyamoto, Ms. Mari Kasai, Ms. Miyu Kobayashi

Hokkaido University, Sapporo, Hokkaido, Japan

Introduction

Osteoporotic fragility fractures typically arise from low-energy impacts, including falls, and frequently occur in regions enriched with cancellous bone. To better understand cancellous bone behavior under impact loading, strength must be assessed at the trabecular scale. However, the impact strength of trabeculae and its underlying determinants remain unclear. This study hypothesizes that dynamic strength is associated with collagen-related bone quality and aims to compare trabecular impact strength across two bovine age groups while identifying collagen-related contributions.

Methods

Single trabeculae were harvested from mature (2 years old; n = 21) and aged (15–18 years old; n = 31) bovine femurs and shaped into cantilevered specimens. Static elastic modulus was determined using micro-cantilever bending. Impact strength was evaluated using a customized Izod-based pendulum device, calculated as fracture energy divided by the mean cross-sectional area at the fracture site. Fracture modes were classified as complete, hinge, or partial breaks. Microfocus X-ray computed tomography (micro-CT) scans were taken before and after the impact test in order to observe the specimen shape and tissue mineral density. Raman spectroscopy (785-nm laser) was performed at each fracture surface of partially broken specimens to assess crystal and molecular features.

Results

In both age groups, specimens with partial breaks displayed significantly higher impact strength than those with complete or hinge breaks. Among partially broken specimens, impact strength was significantly lower in the aged group (5.9 ± 2.2 kJ/m^2) compared with the mature trabeculae (9.6 ± 4.1 kJ/m^2) ($P < 0.05$). Neither micro-CT–derived tissue mineral density nor static elastic modulus showed significant age-related differences. The hydroxyproline-to-proline ratio, reflecting collagen molecular stability, did not differ between age groups but exhibited a significant positive correlation with impact strength ($r = 0.47$, $P < 0.05$).

Discussion

Single-trabecula impact strength varied widely, yet its upper limit declined with age. This reduction appears unrelated to bone mineral density or static elastic modulus. The observed correlation with the hydroxyproline-to-proline ratio indicates that the structural state of collagen molecules contributes to the velocity-dependent strength of trabeculae. Future studies are warranted to elucidate the complex mechanisms underlying age-related strength decline.

[3]Faculty of Animal Bioscience, University of Guelph Guelph, Guelph, Ontario, Canada. [4]Division of Biological Sciences, University of Montana, Missoula, Montana, United States

Introduction

Fetal movements generate stresses necessary for normal skeletal formation. Studies in chick and mouse models show that elimination of movements by muscle paralysis disrupts joint development and weakens bone structure. However, the specific effects of more or less embryonic movement (EM) on bone structure and strength have not been examined. This study aims for the first time, to quantify embryonic movements *in ovo* and compare bone outcomes after hatch in chicks that exhibit more EM compared to those that move less. In particular, we measured tibiotarsus bone mineral density, microarchitecture, bone turnover markers, and muscles mass at hatch.

Methods

A total of 73 fertile eggs were incubated and hatched under commercial conditions at the University of Guelph. Eggs represented two genetic strains (white-feathered and brown-feathered) and both sexes. EM was measured on day 15 and 18 using a portable digital egg monitor for a duration of one minute, and the number of EM was recorded. We then performed multivariable regression analysis to assess the influence of changes in movement between 15 and 18, sex and strain on bone outcomes. One day after hatch, chicks were euthanized, and blood and bone and muscles were collected. Micro-CT was performed on the left tibiotarsus, P1NP levels were measured in the blood serum using ELISA, and leg muscle weights were recorded.

Results

Sex, genetic strain, and EM (Fig. 1A) were significant predictors of metaphyseal trabecular bone volume fraction (Tb_BV/TV) ($p < 0.05$). Higher EM, brown-feathered strain, and female

sex were each associated with increased Tb.BV/TV. Genetic strain was also a significant predictor of diaphyseal total area (Tt_Ar), with brown-feathered chicks exhibiting greater Tt_Ar (Fig. 1B). EM demonstrated a positive association with Tt_Ar as well (p = 0.095). ANOVA results did not show significant difference in P1NP levels and leg muscle in different sexes, genetic strains, or movement status.

Discussion

Our results indicate EM, sex, and genetic strain modulate trabecular and cortical bone mass. Studies are ongoing to determine how long the effect of EM persists into the juvenile period, since bone fractures in chickens, especially egg laying hens are a major animal welfare concern.

Images (Optional)

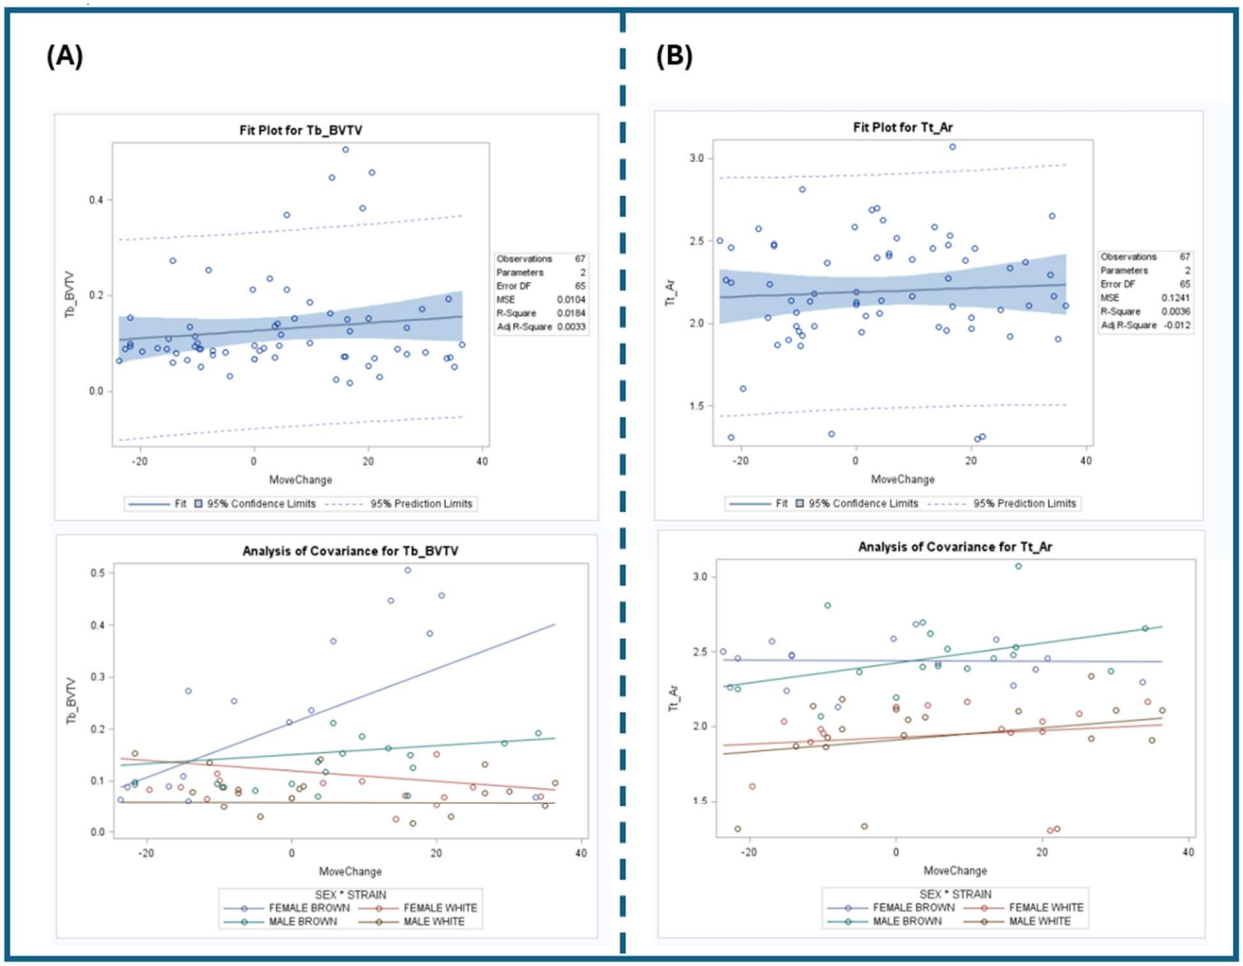

Figure 1: Univariable (top row) and ANCOVA (bottom row) regression plots for trabecular bone volume fraction (Tb_BV/TV) (A) and total area (Tt_Ar) (B); sex, strain, movement change (MoveChange = EM18 – EM 15) are significant predictors of the Tb_BV/TV. In addition, movement change is a positive indicator of Tt_Ar.

A Longitudinal High-Resolution Peripheral Quantitative Computed Tomography Investigation of Tibial Bone Adaptation in Response to Marathon Training

Ms. Shannon Hugard, Mr. Zak Kindl MS, Dr. Michael Hahn

University of Oregon, Eugene, OR, United States

Introduction

Load-bearing bone continuously adapts to changes in mechanical demands. For this reason, weight-bearing exercise is recommended as a strategy for increasing bone strength and preventing osteoporosis. Running is one of the most popular forms of weight-bearing exercise globally. However, the efficacy of running as an exercise intervention for increasing bone strength has yet to be prospectively evaluated using high-resolution peripheral quantitative computed tomography (HR-pQCT). HR-pQCT measures of tibial density and strength are predicative of subsequent fracture risk [1]. Therefore, the objective of this study is to perform a longitudinal HR-pQCT investigation of the time course and magnitude of tibial bone adaptation in response to marathon training.

Methods

Novice marathon runners aged 19-26 (n=9, 3M/6F) performed 16 weeks of structured marathon training. This is a preliminary subset of an ongoing study with a projected sample size of 28. Marathon training increased progressively in volume and intensity through week 14, followed by a 2-week intensity reduction (taper) period. HR-pQCT scans of the tibial metaphysis were collected at baseline and every 2-4 weeks throughout training. Changes in metrics of tibial bone density, geometry, and microstructure were quantified with the manufacturer-supplied software. Changes in compressive failure load and stiffness were estimated using microfinite element analysis. Linear mixed-effects models were used to assess the effect of marathon training time on each HR-pQCT metric of bone adaptation.

Results

Preliminary results showed non-significant trends of increasing total bone volumetric mineral density (Tt.vBMD; $p=0.07$), failure load ($p=0.10$), and stiffness ($p=0.10$) with marathon training time. On average, participant Tt.vBMD increased 0.8% ± 1.16% after 16 weeks of marathon training. Notably, Tt.vBMD decreased at week 14 for most participants before increasing again at week 16 (Figure 1).

Discussion

Peak bone mineral density (BMD) is typically achieved by age 30. Every 1% increase in peak BMD is estimated to delay osteoporosis onset by more than 1 year [2]. Additional participant data are needed to investigate the preliminary trends of tibial density and strength increases with running training time.

Effect of the Degree of Achilles Tendon Twist on Three-Dimensional Force Transmission: A Finite Element Analysis

Dr. Shota Enomoto[1], Dr. Kohta Ito[2]

[1]Okayama University, Okayama, Okayama, Japan. [2]National Institute of Advanced Industrial Science and Technology (AIST), Koto-Ku, Tokyo, Japan

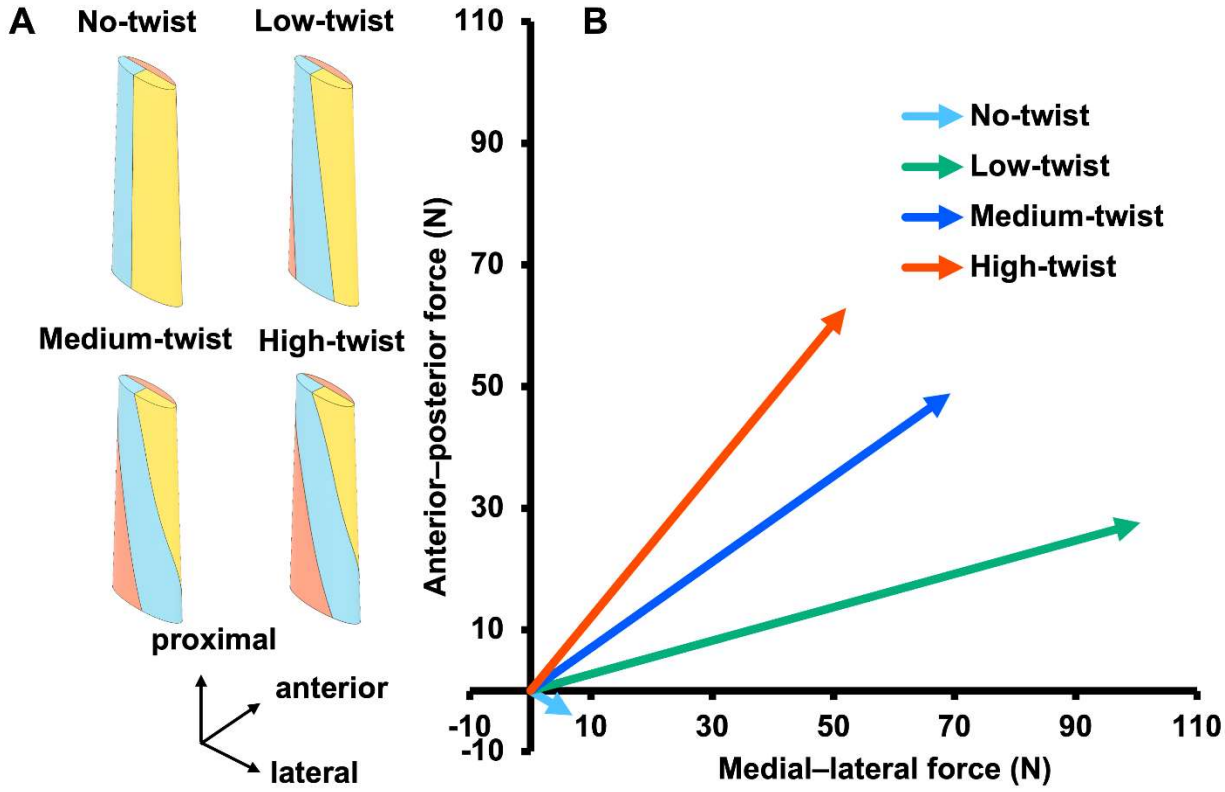
Introduction

The Achilles tendon (AT) is composed of three subtendons arising from the lateral (LG) and medial (MG) heads of the gastrocnemius and from the soleus muscle (SOL), and these subtendons twist around each other [1]. To date, the relationship between the twisted structure and the tendon's function of transmitting tensile forces has remained unclear. We aimed to estimate how the degree of AT twist affects three-dimensional transmitted forces at the distal end of the tendon using finite element analysis.

Methods

We created four finite element models of the AT varying the degree of twist (no-, low-, medium-, and high-twist models) (Figure A). A tensile force of 2000 N was applied to the proximal surface. We allocated the total force to each subtendon according to the relative force-generating contributions of the triceps surae reported in a previous study [2]. The forces applied to the LG-, MG-, and SOL-derived subtendons were 200 N, 500 N, and 1300 N, respectively. The interfaces between subtendons were modeled as frictionless contacts. The nodes on the distal surface were fully fixed and the nodes on the proximal surface were allowed to translate only in the proximal-distal direction. Three-dimensional forces exerted on the distal nodes were calculated, including proximal–distal, medial–lateral, and anterior–posterior components.

Results



All models exhibited the same proximal-directed force of 2000 N at the distal surface. In addition, the twisted models clearly exhibited horizontal forces directed anterolaterally (Figure B). Furthermore, as the degree of twist increased, the force vectors in the horizontal plane shifted to point more anteriorly.

Discussion

Our results indicate that the uniaxial contractile force generated by the triceps surae may be transformed into triaxial tensile forces by the twisted AT structure. Although the directions of these forces vary depending on the degree of twist, they fundamentally tend

to displace the posterior calcaneus in an anterolateral direction, which might play a role in the mechanical interactions that facilitate efficient locomotion.

Sarcomere Lengths in Paretic Muscle Affected by Chronic Stroke in Rats

Dr. Stephanie Ross, Ms. Sydney Dorscher, Dr. Timothy Leonard, Dr. Walter Herzog

University of Calgary, Calgary, Alberta, Canada

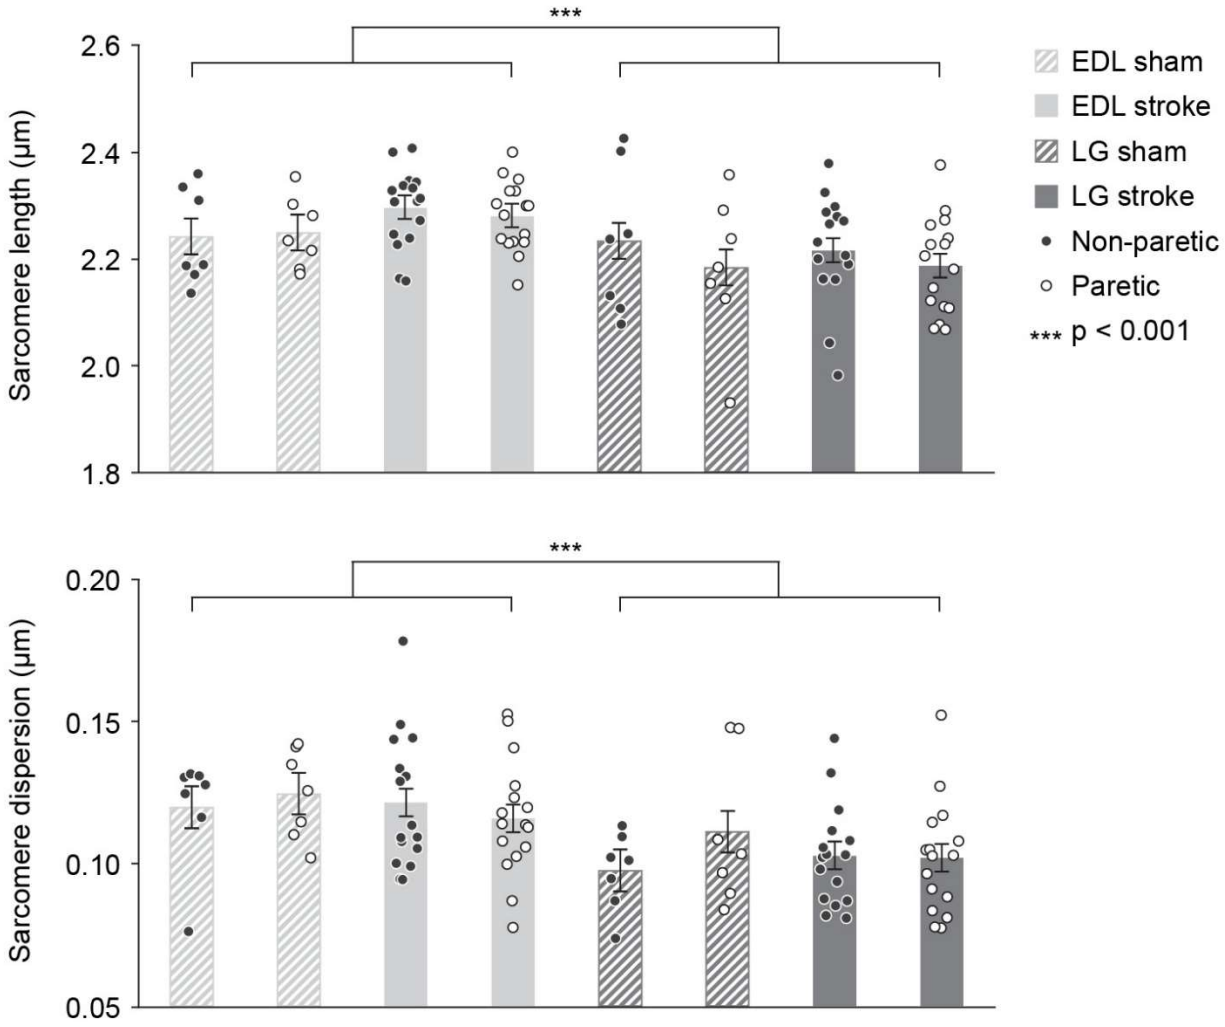
Introduction

Stroke is a leading cause of mobility impairment in adulthood, yet the mechanisms underlying these impairments at the muscle level are poorly understood. In children with cerebral palsy, which similarly results from white matter lesions and leads to muscle paresis or weakness on the affected side of the body, reduced force production is thought to be partly due to excessively long sarcomere lengths that limit cross-bridge binding [1]. Measures of sarcomere length using microendoscopy in adults with stroke have shown no difference between paretic and non-paretic sides [2]; however, microendoscopy is a newer approach with limited validation. Therefore, the purpose of this study was to measure differences in sarcomere length between paretic and non-paretic muscle more directly using laser diffraction in a rat model of stroke.

Methods

We induced hemiparetic (n=16) and sham (n=7) stroke using photothrombosis in Sprague-Dawley rats. Eighteen weeks following surgery, corresponding to the chronic phase of stroke, we euthanized the animals and harvested their tissues. We measured sarcomere length and dispersion, a measure of variability in sarcomere length, using laser diffraction [3] of fascicles isolated from the lateral gastrocnemius (LG) and extensor digitorum longus (EDL) muscles fixed at knee and ankle angles of 90 degrees. To examine differences between groups, muscles, and sides of the body, we used a linear mixed model in R, with rat included as a random effect.

Results



We found a statistically significant difference in least-squares mean sarcomere length and dispersion between the LG and EDL ($p<0.001$), but not between paretic and non-paretic sides or between sham and stroke groups (Figure 1).

Discussion

Our results support previous findings in humans [2] indicating that sarcomere length is unaffected by stroke. This contrasts measures of muscle affected by cerebral palsy and suggests that post-lesion growth may drive the development of elongated sarcomere lengths in paretic muscle, an effect not present in adult stroke. Although we found a

significant difference between the LG and EDL, this likely reflects differences in relative length at the selected joint angles.

The Effect of Speed and Incline on Force Sharing Between the Medial Gastrocnemius and Plantaris Muscles of Sheep During Treadmill Gait

Dr. Stephanie Ross[1], Mr. Florian Schumacher[2], Mr. Esthevan Machado[1], Mr. Andrew Sawatsky[1], Dr. Timothy Leonard[1], Mr. Keiji Hopfner[1], Dr. W. Michael Scott[1], Dr. Walter Herzog[1]

[1]University of Calgary, Calgary, Alberta, Canada. [2]ETH Zurich, Zurich, Zurich, Switzerland

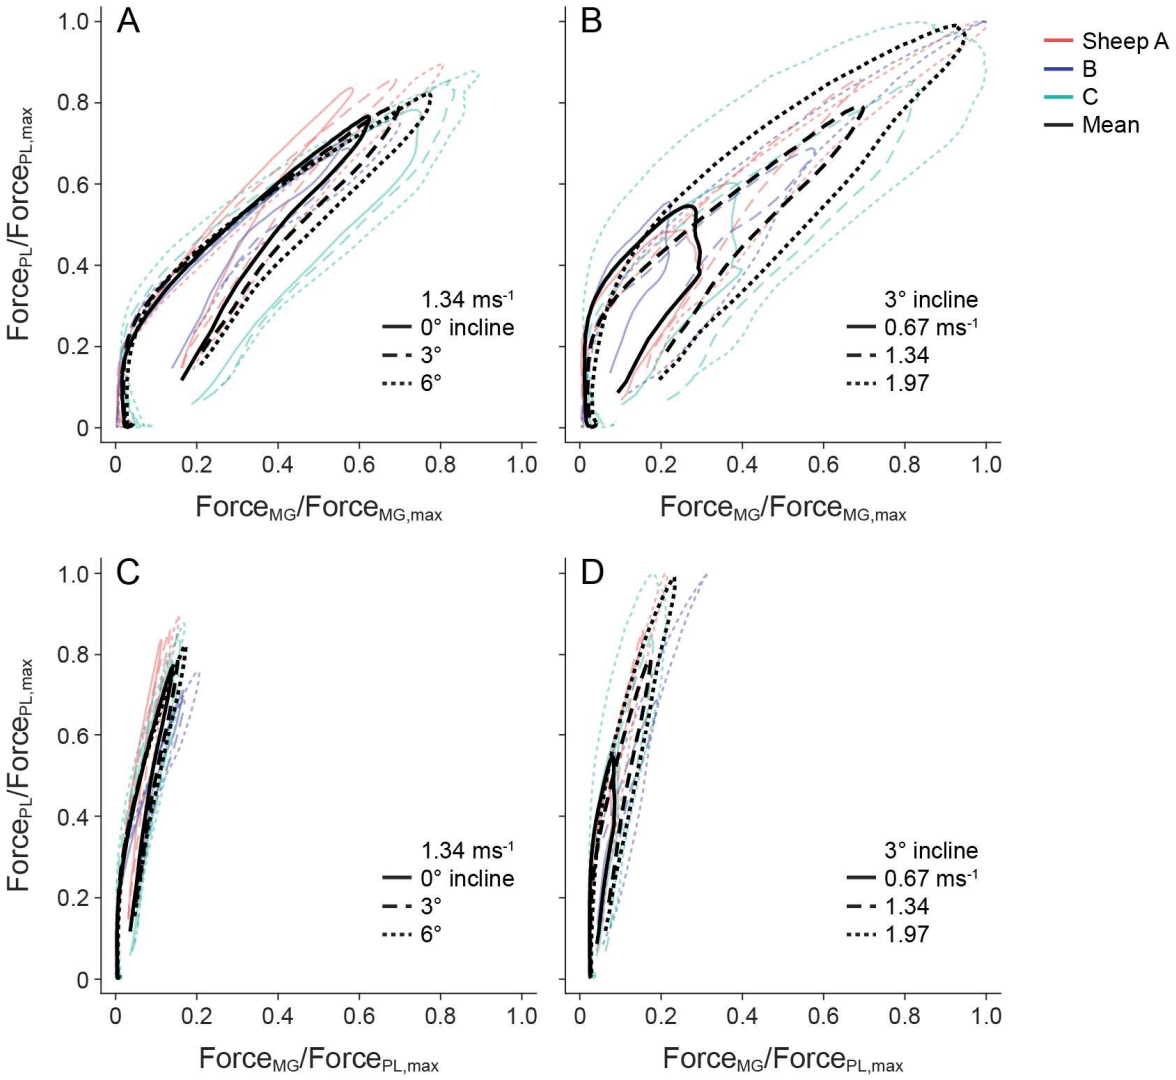
Introduction

Multiple muscles cross each joint, allowing numerous ways to distribute force to produce the same joint moment during gait. Previous work in cats has shown that force sharing across the plantarflexors depends on task demand, with the plantaris (PL) and medial gastrocnemius (MG) both contributing more force with increasing speed and incline, whereas the soleus contributes nearly the same force across conditions [1]. Because cats may be optimized for high-speed chases when hunting prey, it is unclear to what extent these force sharing patterns persist in other species less specialized for speed. To address this gap, we examined force sharing between the PL and MG of sheep during treadmill gait to determine whether the patterns observed in cats persist in a species with slower typical gait speeds.

Methods

We measured PL and MG forces *in vivo* in five Île-de-France sheep using buckle force transducers implanted on the isolated distal tendons. During testing, sheep walked and trotted on a treadmill at speeds and inclines ranging from 0.67 to 1.97 m/s and 0 to 6 degrees. Details of the methods can be found elsewhere [2]. Following testing, we euthanized the sheep and calibrated the force transducers. We analyzed forces from ten consecutive steady-state steps and determined the stance phase of each step from videos of the trials.

Results



Preliminary results (n=3) indicate that PL and MG forces during stance both proportionately increased with increasing speed and incline (Figure 1A,B). PL force was substantially larger than MG force across all sheep and conditions (Figure 1C,D).

Discussion

The proportional increases in PL and MG force with increasing speed and incline are consistent with previous findings in cats [1]. Our PL forces relative to MG are much larger

than those reported in cats [1], rats [3], and wallabies [4] during gait. This may be because some studies [1,4] measured the combined force of the gastrocnemius complex, whereas we measured the isolated MG force. In other cases [3], this difference may reflect muscle design differences dictated by body morphology or locomotor specialization.

Associations between Sound Limb Total Support Moment and Femoral Cartilage Thickness in those with Traumatic Lower-Limb Amputation

Dr. Steven Garcia[1], Ms Nikou Nikoumanesh[2], Ms Shraddha Suddhir[2], Dr. Lindsay Hannigan[2]

[1]Jackie and Gene Autry Orthopedic Center, Childrens Hospital of Los Angelesotion Analyi, Los Angeles, CA, United States. [2]Department of Physical Therapy, University of Illinois, Chicago, Chicago, IL, United States

Introduction

Introduction: Individuals with lower-limb amputation (LLA) develop knee osteoarthritis (OA) at high rates likely due to overreliance on the sound limb for support and mobility. Limited research has directly evaluated associations between sound limb loading and cartilage health in those with LLA. The total support moment (TSM) is linked with knee-OA progression in non-amputee groups and functionally represents lower-limb inter-joint kinetic coordination for support. Here, we evaluated associations between the TSM and ankle, knee and hip contributions to the TSM in individuals with traumatic LLA.

Methods

Methods: Ten persons with LLA (7:Transtibial, 3:Transfemoral, Age:50.3±15.8 yrs, BMI:27.1±5.9, Time Post-LLA:17.5±14.1 yrs) completed treadmill gait biomechanical assessments and femoral cartilage US. Gait biomechanics were evaluated at preferred speed and kinematic and kinetic data were filtered at 6 and 12Hz. Loading metrics included the 1st and 2nd peak TSM (TSM1, TSM2) and individual joint contributions to the TSM. Femoral cartilage US images were captured in the sound limb at the trochlea and medial femoral condyle (MFC). Cartilage thickness from three images was averaged for analysis. Pearson's *r* was used to evaluate correlations between TSM, joint contributions and cartilage thickness.

Results

Results: Greater second peak TSM2 was moderately associated with thicker MFC thickness in superior (r=0.71,p=0.03) and central regions (r=0.73,p=0.03). Moderate associations between TSM2 were observed in medial trochlear cartilage (r=0.61) and inferior MFC regions (r=0.62) but were not significant (p=0.08). Greater knee contributions to the TSM2 were associated with thinner medial femoral cartilage in superior (r=0.74,p=0.02), central (r=0.77,p=0.02) and inferior regions (r=0.74,p=0.02). No associations between TSM1 or other joint contributions were observed (p>0.05).

Discussion

Discussion: We found larger TSM2 and reduced knee contributions to TSM2 were correlated with thicker sound limb MFC. Sufficient limb extensor moments, reflected by TSM2, are important for mobility and also contribute to late stance knee compressive loads and thus may help preserve cartilage health. During late stance, limb extension is driven by ankle and hip extensor moments and thus higher knee contributions to TSM may reflect an inefficient gait pattern. Future work is needed to confirm the longitudinal link between the TSM and sound limb cartilage health after LLA.

Images (Optional)

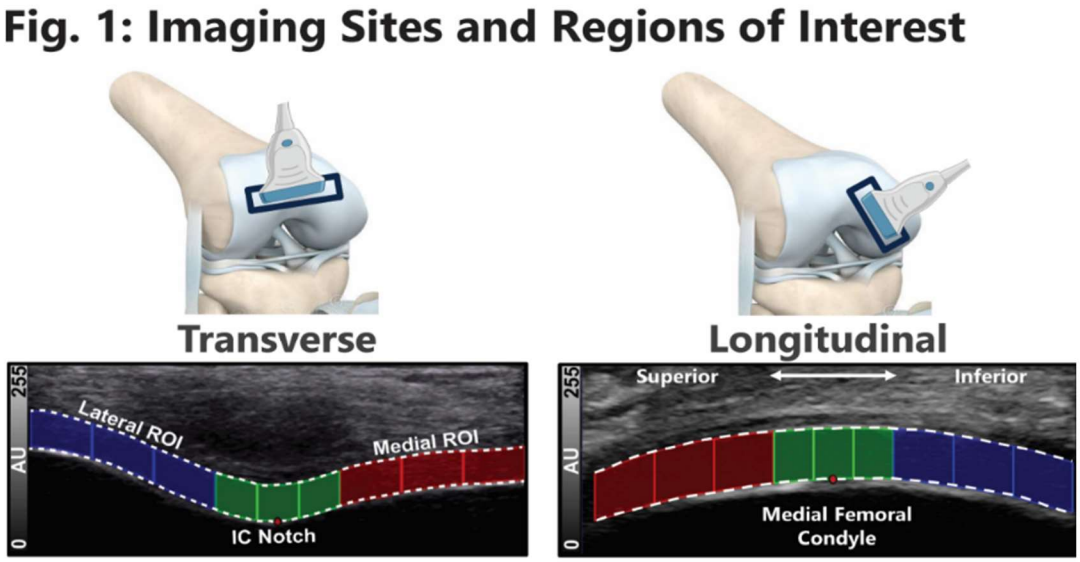

Figure 1: US Images Sites for Femoral Cartilage. Transverse View: Trochlea. Longitudinal View: Medial Femoral Cartilage (MFC). Cartilage thickness was evaluated as the minimum Euclidean distance between superficial and deep cartilage borders across all pixels in each ROI.

Modeling Physiological Tasks and their Impact on Cartilage Deformation and Recovery: A Robotically Controlled Joint Simulator

Mr. Tejus Surendran, Dr. Axel Moore

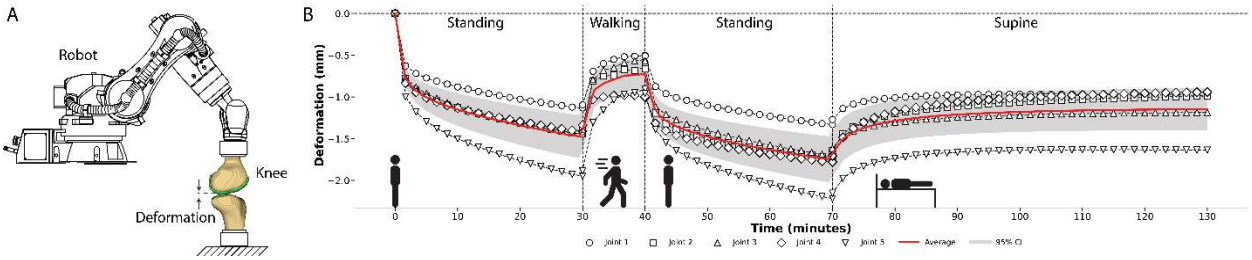
Carnegie Mellon University, Pittsburgh, PA, United States

Introduction

Articular cartilage functions as the joint's biological bearing, supporting load and enabling low-friction motion through poroelastic fluid pressurization. Prior work has shown that this fluid pressure limits compressive deformation; however, due to the permeable nature of cartilage there is a depressurization and a consequential increase in compressive deformation. How cartilage maintains and recovers this pressure during physiological task remains unclear. While traditional ex vivo models offer excellent experimental control and direct access to the cartilage interface, they typically use sub-physiological loads and speeds, non-native contacts, and altered boundary conditions. On the other hand, in vivo studies capture physiological relevance but experience inter-subject variability, limited control, and low measurement resolution. To bridge this gap, we apply near-physiological joint dynamics to cadaveric knees while simultaneously measuring cartilage deformation. We hypothesized that replicating native joint loading in cadaveric joints that preserve native contacts and boundary conditions would produce physiological deformations.

Methods

Five adolescent female Duroc pig stifle joints were dissected, preserving collateral and cruciate ligaments and menisci. Femoral and tibial shafts were potted in polymethyl-methacrylate and mounted in a 6-DOF robotic system (**Fig 1A**) that provided control of joint kinematics and kinetics. In each joint we simulated a series of tasks: Standing 1 (30 min), Walking (10 min, ASTM F3141), Standing 2 (30 min), and Supine (60 min). Cartilage deformation measured as a change in the position of the end effector of the robot once it achieved a target load of −245 N along the superior-inferior axis.



Results

Simulated standing produced compressive cartilage deformation (negative values indicate compression) with similar patterns in both Standing 1&2 (**Fig 1B**). During Standing 1, deformation increased to an average of −1.5 mm. Walking recovered 0.8 mm (51%) of deformation after 10 minutes. Following Standing 2, the compressive deformation increased to −1.8 mm. Simulating 60 min of lying supine led to a mean recovery of 0.60 mm.

Discussion

In this ex vivo cadaveric model, we observed time- and task-dependent changes in superior–inferior joint displacement consistent with cartilage deformation and recovery. The results demonstrate that simulated standing produces time-dependent compressive deformation, whereas simulated walking and lying supine promote time-dependent recovery.

Lucas Lu[2], Dr. Robert Mauck[5], Dr. Lin Han[1]

[1]Drexel University, Philadelphia, PA, United States. [2]University of Delaware, Newark, NJ, United States. [3]University of South Florida, Tampa, FL, United States. [4]Thomas Jefferson University, Philadelphia, PA, United States. [5]University of Pennsylvania, Philadelphia, PA, United States

Introduction

Effective regeneration of cartilage is limited by our incomplete understanding of molecular activities that regulate the integrity of its extracellular matrix (ECM). Cartilage ECM, a hydrated collagen II–aggrecan composite, undergoes dynamic turnover during both normal homeostasis and disease-associated remodeling. This study aims to elucidate the role for decorin, a small proteoglycan, in mediating the retention and stability of nascent aggrecan within the ECM.

Methods

Femoral head cartilage explants from 3-week-old wild-type C57BL/6 mice were labeled with GAL to tag nascent proteoglycans via click chemistry. Explants were stimulated with IL-1β for 8 days to elicit chondrocyte catabolism, with both pre- and post-treatment of exogenous decorin (before/after IL-1β), followed by the quantification of nascent proteoglycans retained in explants versus release to media. Surface plasmon resonance (SPR) was applied to measure the effects of decorin on aggrecan and collagen II binding affinities. AFM-nanoindentation was applied to test the effects of decorin on the modulus of proteoglycan-depleted cartilage. Significance of treatment effects were assessed by one-way ANOVA followed by Tukey–Kramer post hoc multiple comparison ($\alpha = 0.05$).

Results

Pre-treatment of decorin before the onset of IL-1β attenuated the release of nascent aggrecan caused by IL-1β, but such effects were absent for post-treatment (Fig. 1a). Meanwhile, SPR showed that decorin enhanced the binding affinities among aggrecan and collagen II pairs (Fig. 1b). Furthermore, AFM-nanoindentation showed that infiltration of decorin stiffened the collagen II fibrillar network of proteoglycan-depleted murine cartilage (Fig. 1c).

Discussion

This study identifies decorin as a crucial regulator of dynamic cartilage matrix turnover, particularly in the retention of newly synthesized aggrecan. Specifically, the partial rescue of IL-β-elicited nascent proteoglycan release by decorin pre-treatment highlights the potential of decorin as a therapeutic for osteoarthritis intervention. We attribute this role to its biophysical function in stabilizing aggrecan–aggrecan, aggrecan–collagen II, collagen II–collagen II integration. In turn, such effects strengthen the collagen II fibril network, and therefore its capability of confining the entrapped aggrecan networks. Our ongoing studies are further interrogating the mechanisms and delivery of decorin-based therapeutics.

Low-Dosage Temporal Effects of Botulinum Neurotoxin on Whole Skeletal Muscle's Passive Mechanical Properties

Mr. Timothy McGinley M.S., Dr. Albino Schifino Ph.D., Dr. Benjamin Binder-Markey PT, DPT, Ph.D.

Drexel University, Philadelphia, PA, United States

Introduction

Botulinum neurotoxin (BoNT) is used to reduce spasticity and resulting increased muscle resistance following neurological injuries. However, in chronic stroke patients, long-term BoNT injections are linked to increased passive muscle stresses. Yet, the temporal development of these BoNT-related increases in passive muscle mechanics remains unclear. Within this study, we aim to characterize the temporal timeline over a year of a clinically relevant low-dose injection.

Methods

Passive mechanical characteristics were collected from the lateral gastrocnemius (LG) of C57BL6 mice. Animals received an intramuscular injection of a clinically relevant low dose of 1 U/kg BoNT in their left LG. The contralateral LG was used as the control. 40 mice (20 male & 20 female) were separated into 4 groups: 1-month, 3-month, 6-month, and 12-months post-injection. Force was measured with a 5N force transducer while lengthened in 5% step increments from 0% - 30% strain. Samples were weighed and mass ratio (BoNT/Control) was compared to 1.0. Stress was calculated using the animal's PCSA. The passive stress-strain data were fit to non-linear regression models and compared using linear mixed methods.

Results

Mass ratios were significantly less than one at 1 & 3 months, but recovered by 6 months (Fig.1A). Normalized stress-strain curves indicated that BoNT-injected samples exhibited significantly higher stresses by 1-month post-injection that lasted to at least 6 months. Yet, by 12-months post-injection, muscle stresses are not significantly different between BoNT and control muscles (Fig. 1B).

Discussion

BoNT caused alterations in passive muscle mechanics, with elevated stresses persisting up to 6 months post-injection. Early atrophy is evident from muscle loss, though after muscle mass recovers and the stresses increase, indicate ECM remodeling beyond BoNT's

three-month active phase. These findings highlight that a single low dose of BoNT leads to changes that potentially resolve over time.

Understanding the temporal effects of BoNT is critical for optimizing treatment. Increased passive stresses following treatment may impair functional outcomes and rehabilitation efficacy following injections. Insights from this study provide a foundation for developing dosing protocols that minimize adverse effects.

Energy Consumption After Active Stretch in Single Skinned Muscle Fibres

Miss Torri Heiser BSc, Dr. Venus Joumaa PhD, Dr. Walter Herzog PhD

University of Calgary, Calgary, Alberta, Canada

Introduction

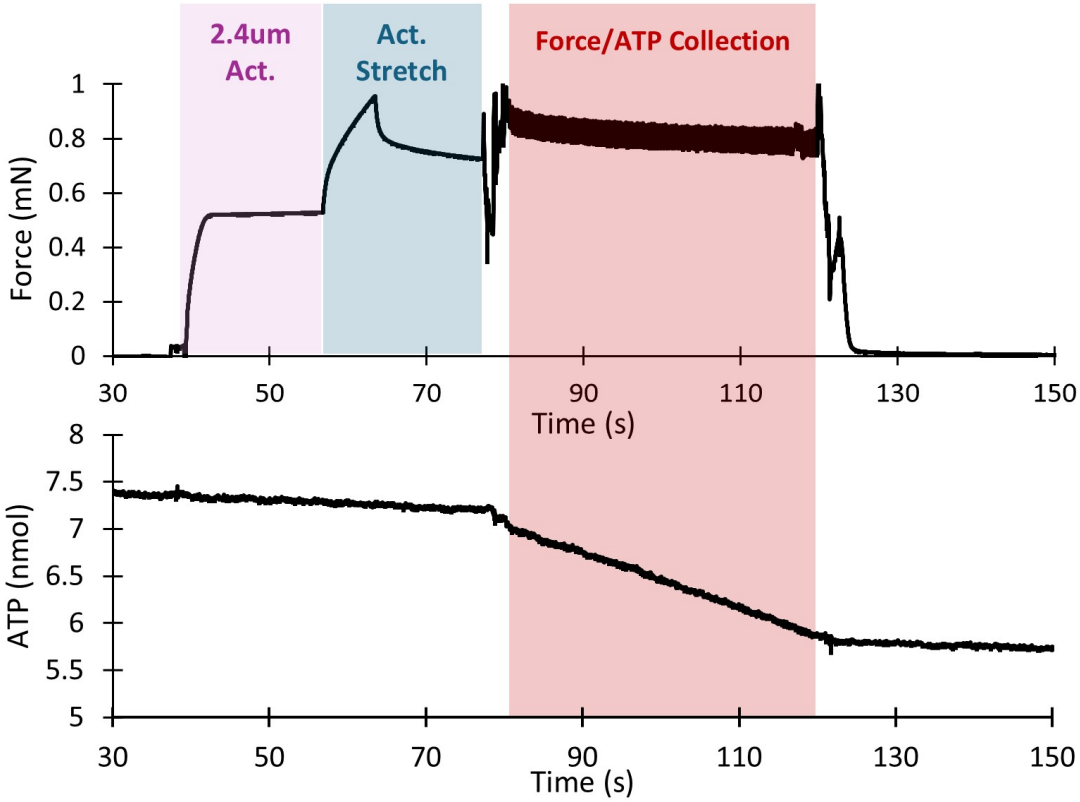
The isometric force produced at steady-state following active stretching is greater than a purely isometric contraction at the same final muscle length and level of activation. This muscle property has been observed at all structural levels and is referred to as residual force enhancement (rFE) [1]. There is increasing evidence that the passive element, titin, may contribute to rFE [1]. If so, rFE would occur with little or no increase in energy cost (ATP consumption). However, there is minimal systematic work that has measured ATP consumption simultaneously with force following active stretch in muscles [2].

The purpose of this study was to gain insight into the mechanism of rFE by measuring ATP consumption simultaneously with force at steady-state after active stretch and the corresponding isometric reference contractions in muscle fibres.

Methods

A newly developed system (1415A, Aurora Scientific) based on de Tombe and Stienen [3] allowed us to measure the rate of ATP consumption simultaneously with force in the steady-state region following purely isometric and active stretch contractions in skinned rabbit psoas muscle fibres. The purely isometric contractions were performed at an average sarcomere length (SL) of 3.2μm. In the active stretch trials, fibres were actively stretched from an average SL of 2.4μm to 3.2μm and held at this length until steady-state force was achieved.

Results



To date, our results show an average rFE of 11±0.4%. The rate of ATP consumption per unit of force was 20% lower following active stretch compared to the purely isometric reference contraction.

Discussion

From our knowledge, this is the first study to record ATP consumption simultaneously with force in rFE. The reduced ATP consumption per unit of force in rFE compared to the corresponding isometric state supports the idea that the extra force in rFE originates from a

passive element and not from increased cross-bridge activity. Titin-calcium and titin-actin interactions have been suggested to occur upon muscle activation and stretch, resulting in an increase in titin stiffness and thus, rFE without a corresponding increase in ATP consumption.

Why Is the Triceps Surae Muscles Pennate? A Predictive Simulation Study

Dr. Torstein Dæhlin[1], Dr. Stephanie Ross[2], Dr. Nilima Nigam[1], Dr. Friedl De Groote[3], Dr. James Wakeling[1]

[1]Simon Fraser University, Burnaby, BC, Canada. [2]University of Calgary, Calgary, AB, Canada. [3]KU Leuven, Leuven, Flemish Brabant, Belgium

Introduction

Metabolic cost of transport (COT) is one selection pressure purported to drive evolution of the human locomotor system. Mechanical work performed by the triceps surae muscles has a strong influence on COT during running [1]. These muscles are pennate, affecting their force-length-velocity characteristics [2]. Therefore, their pennation may influence how efficiently these muscles perform mechanical work. While most locomotor muscles are pennate, it remains unclear whether pennate muscles are advantageous for reducing COT. The purpose of this study was to investigate whether triceps surae pennation influences COT and joint work during the stance phase of running.

Methods

The influence of triceps surae pennation on COT and joint work during running was investigated using a predictive musculoskeletal simulation software (PredSim), and a previously validated musculoskeletal model. Soleus, medial gastrocnemius, and lateral gastrocnemius pennation angles were scaled to 0 to 200% of those of the nominal musculoskeletal model (25.0°, 17.0°, and 8.0°, respectively) in 50% increments. Simulations were generated for 2.5, 3.0, 3.5, 4.0, and 4.5 m/s running. Optimal fibre and tendon slack lengths were scaled to offset the influence of pennation on the muscles' operating length.

Results

COT was highest with the largest pennation angles and smallest when pennation angles were zero (Fig 1). Less positive and negative ankle plantar flexor work was performed when pennation angles were larger than those of the nominal model (Fig 1). The decrease in ankle plantar flexor work was accompanied by an increase in positive and negative work performed at the knee and hip (Fig 1).

Discussion

Our results predict that COT would be lower with non-pennated versus pennated triceps surae muscles. This suggests that another selection pressure may have driven the evolution of triceps surae pennation. Nonetheless, pennation angles equal to or less than those of the nominal model only minimally increase COT and have little influence on lower extremity joint work. As our model does not capture all factors influencing COT or other selection pressures, there may be further undiscovered benefits to having pennated muscles.

Impact of Distinct Loading Configurations on Extracellular Matrix Structure and Function in Fibroblast-Seeded Collagen Scaffolds

Mr. Amevi Semodji[1], Ms. Dalia DeLaCruz[1], Dr. Xinzhu Pu[1], Dr. Anamaria Zavala[1], Dr. Sean Howard[1], Ms. Shaughnessy Murphy[2], Dr. Gunes Uzer[1], Dr. Julia Oxford[1], Dr. Trevor Lujan[1]

[1]Boise State University, Boise, Idaho, United States. [2]Boise High School, Boise, Idaho, United States

Introduction

Fibroblast activity in soft tissues is highly regulated by mechanical cues within their 3D extracellular matrix (ECM). However, optimal loading conditions (e.g., tension, compression, biaxial) that best promote ECM repair and remodeling by fibroblasts remain unclear due to limited direct comparisons. We developed a new experimental approach that delivers equivalent mechanical energy to 3D cell-seeded constructs under distinct loading configurations [1]. Our study objective was to evaluate how loading configuration influences ECM structure and mechanical function in 3D fibroblast-seeded collagen scaffolds.

Methods

Collagen scaffolds were seeded with mouse fibroblasts (3T3) and stimulated using our custom bioreactor at a targeted energy of 40 J/m^3 (8 h/day, 7 days) [1]. Three loading configurations were investigated (n=5/group): uniaxial tension (TO), uniaxial compression (CO), and biaxial tension-compression (TC), with an additional unstimulated control group (UC). Stiffness changes were assessed using Dynamic Mechanical Analysis, cell density was assessed using confocal microscopy, and RNA and proteins were extracted using modified TRIzol and RIPA protocols, respectively. ECM gene expression was quantified by qPCR, and protein profiles and gene ontology (GO) enrichment by mass spectrometry.

Results

Dynamic moduli significantly increased after stimulation (tensile for TO, compressive for CO, and both for TC) (**Fig. 1A**). TC displayed the highest cell density (**Fig. 1B**), while CO produced the greatest ECM expression (**Fig. 1C**) and amount of most structural proteins although the differences were not significant (**Fig. 1D**). The GO analysis revealed similar differential representation in most ECM-related terms between groups (**Fig. 1E**).

Discussion

Mechanical stimulation was applied at a target energy to fibroblast-collagen constructs in three loading configurations. TC resulted in better mechanical and cell density outcomes but showed weaker ECM gene and protein responses than CO and TO. The combined loading induced the highest distortion energy, which positively and strongly correlated with cellular and mechanical changes, suggesting that shape-changing deformations enhance cellular and mechanical outcomes. Such correlations could not be established for ECM protein expression and production, likely because fibroblasts tend to produce less during their active division phase. Future work will investigate longer stimulation periods to capture ECM responses beyond early growth phases.

Modelling Tendons as a Fibre-Reinforced Poroelastic Material

Miss Zoe Godard, Professor Sarah Waters, Professor Derek Moulton

University of Oxford, Oxford, Oxfordshire, United Kingdom

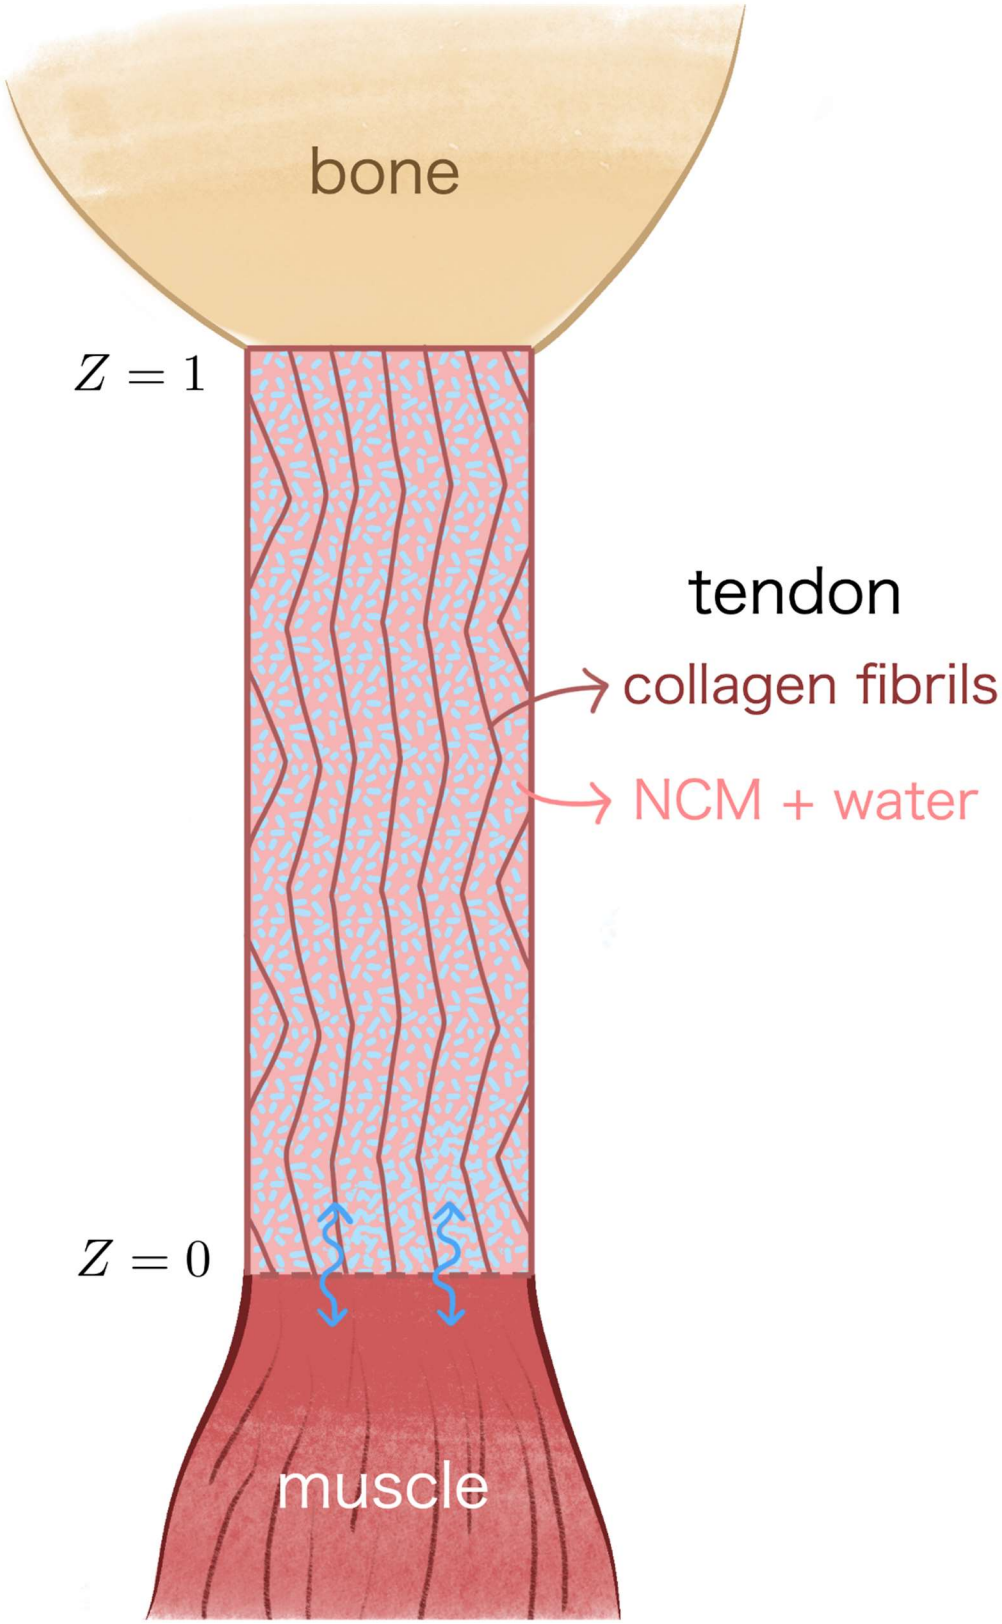
Introduction

Tendons are connective soft tissues between muscle and bone. Tendinopathy is a common musculoskeletal disease, characterised by a range of physiological and structural changes, the underlying mechanics of which are still not well understood. Our aim is to build a mathematical model for tendons to tease out the key mechanisms that support tendon function and how they are affected by damage.

Methods

Tendons undergo large deformations and are made up of 55-70% water and a collagen-heavy solid matrix; to capture this we employ a non-linear poroelastic framework to capture the bulk mechanics of the tissue, assuming Darcy flow through the pores of the solid skeleton, and a solid constitutive law which assumes the solid is primarily formed of crimped collagen fibrils that only bear load once fully taut, embedded in a soft isotropic background matrix. The bone boundary is rigid and impermeable and the muscle boundary is permeable, where a stress is also imposed. Damage may be introduced into the model by weakening or breaking fibrils. The model is parameterised using published human tendon data.

Results



The objective of our study is to gain mechanistic insight into the interaction between constitutive components of tendon, namely the crimped collagen fibrils, the porous background matrix and fluid flow under static or dynamic loading conditions and potential damage. We reveal how the inclusion of fluid flow through the porous matrix, which introduces an inherent timescale, results in asymmetries between the dynamics of loading and unloading. We also investigate how damage to the fibrils affects the response to loading, and compare this to our previous study which neglected fibrils.

Discussion

The model provides us with access to quantitative measures of spatial and temporal stress and strain fields, as well as fluid flux, enabling us to predict where damage might occur.

Additionally, by prescribing regions of damage we can determine the impact of tendinopathies on the resulting tendon behaviour. The simplicity of this model provides us with a clear mechanistic understanding of the interplay between tendon damage and behaviour, motivating further clinical and biomechanical testing, and may serve as a guide to more complex models.

The Effect of Firefighters' Turnout Gear on Mobility Limitations and Task Performance: Preliminary Data

Ms. Arianna Eyre, Mr. John D. Tebbetts MS, Mr. Kuanting Chen MS, CSCS, Dr. Jennifer M. Yentes PhD

Texas A&M University, College Station, Texas, United States

Introduction

Turnout gear (TG) is the personal protective equipment worn by firefighters. Due to the inherent nature of firefighting, TG is
often bulky and heavy, causing restricted movements and increased physical taxation. Understanding how TG affectsfirefighters' movements in occupational settings is imperative for improving gear design and developing training strategies to mitigate negative movement impacts. Therefore, this study aimed
to investigate how TG affected firefighters' range of
motion (ROM)and firefighting task performance.

Methods

Sixteen males (1.8±0.1m, 97.7±15.7kg, service years: 17.3±9.9 yrs) and
four females (1.7±0.1m, 97.7±9.4kg, service years: 11.8±10.9 yrs) completed two tasks with their own TG (geared) and station wear (baseline). Task 1: single-joint, active, maximal ROM movements; Task 2: firefighting circuit including ladder maneuver, victim rescue, hose manipulation, and forcible entry. Whole body kinematics were captured using Xsens inertial measurement units. Subsequent joint angles and segment angular accelerations were computed for both conditions. Changes in ROM during Task 1 were extracted. For Task 2, completion times and movement quality (i.e., root-mean-square segment angular acceleration) were computed. To assess the impact
of TG, preliminary data from 10 firefighters' geared and baseline conditions were compared using descriptive statistics.

Results

When completing Task 1, TG reduced mean shoulder flexion by 19.4±10.0°, shoulder abduction by 38.1±20.2°, elbow flexion by 8.6±8.3°, hip flexion by 16.6±8.7°, knee flexion by 4.8±3.2°, and neck extension by 11.4±11.5° compared to
baseline. During Task 2, compared to baseline, TG increased time to completion and reduced movement quality across all tasks (Table 1). Future work will include ROM during firefighting tasks.

Discussion

As reduced ROM was evident during geared single-joint, active, maximal ROM movements, these same biomechanical limitations may exist during firefighting tasks. Firefighting performance decline (i.e., increased time and decreased quality) may be partially driven by these biomechanical limitations. Due to inherent bulkiness, a degree of ROM limitation will likely be present in TG, limiting TG modifiability. Functional mobility training may help overcome these limitations. Moreover, lack of gear fit is a common complaint. Firefighters may benefit from improved processes for TG measurement, tailoring gear to their anthropometrics.

The Comparison of Two Virtual Reality Systems on Muscle Activity and Posture During Computer Tasks at Sit and Stand Workstations

Mr. Cameron Lang MSc[1], Dr. Michael Holmes PhD[1], Dr. Garrick Forman PhD[1], Dr. Jack Callaghan PhD[2], Ms Jessa Davidson MSc[2]

[1]Brock University, St. Catharines, Ontario, Canada. [2]University of Waterloo, Waterloo, Ontario, Canada

Introduction

Advances in technology (including design, resolution, and computing power) have allowed traditional computer work to be possible with Virtual Reality (VR) headsets. Previous research demonstrated that VR headsets are more responsive and easier to use compared to traditional computers. However, research on the physical demands of these devices on office workers is lacking, and the full potential of these technologies remains underexplored. The purpose of this study is to quantify the physical demands of immersive technologies during computer tasks.

Methods

Five individuals (3M/2F; 24.8±1.9 years) completed two 60-minute sessions using the Meta Quest 3 (MQ) or Apple Vision Pro (AVP). Muscle activity was measured using surface electromyography on 16 muscles of the upper extremity. Kinematics were measured using motion capture, with reflective markers placed bilaterally on the upper extremities, head and thorax. Trunk lateral bend and flexion/extension angles were measured using triaxial accelerometers along the spine (C7, T12, L1). To simulate office work, alternating 5-minute blocks of typing and text editing were completed for 30 minutes while sitting and standing, with both VR headsets and a physical keyboard. Muscle activity and kinematics were analyzed using APDFs (10th, 50th, 90th percentiles). Performance measures for the typing and editing tasks were also analyzed.

Results

Preliminary results show greater flexor digitorum (FD) and cervical extensor (CE) muscle activity while seated (FD: 26.8±0.8 %MVC; CE: 12.3±1.8 %MVC) compared to standing (FD: 22.1±2.1 %MVC; CE: 10.6±1.5 %MVC), with no difference between the AVP and MQ. Neck flexion angles were greater when using the MQ (15.2±1.2^0) compared to AVP (13.2±1.2^0), with no differences between sit and stand conditions. AVP demonstrated greater accuracy in typing tasks (AVP: 92.1±1.9%; MQ: 86.8±4.8%).

Discussion

Our preliminary findings are consistent with previous literature, showing a decrease in upper-limb muscle activity during typing tasks when standing vs. sitting. Increased neck flexion while using the MQ may be a result of lower visibility of external devices (i.e., keyboard), which may affect performance. A larger sample size is required before the true physical demands of VR use in office work are completely understood.

Effects of Turbans on the Biomechanical Effectiveness of Industrial Protective Headwear: Impact Attenuation and Retention Perspectives

Ms. Claudia M. Graham MHK, Dr. Andrew C. Laing PhD

University of Waterloo, Waterloo, Ontario, Canada

Introduction

Numerous religious and cultural practices incorporate head coverings. Despite their potential to influence the biomechanical effectiveness of protective headwear products, research in this domain is limited [1,2]. In some occupational settings/jurisdictions, industrial protective headwear (i.e. hardhats) is required. This study investigated the effects of turbans on industrial hardhat performance from two biomechanical perspectives: retention and impact attenuation.

Methods

Physical test methods were adapted from CSA standards [3]. Turban conditions included a magnesium headform (K1A) either bare or covered by two Dumalla-style turbans (T1=smaller, T2=larger). Tests were performed on a representative hardhat model certified by [3]. Retention: Hardhats were secured on the headform or turban. An instrumented hook/cable was secured to the hardhat's anterior brim and a vertically-oriented load was applied. Peak force to cause helmet decoupling (45° displacement) was recorded. Impact: A vertical drop tower and headform impacted the hardhats across turban conditions at crown, anterior, and lateral locations (energies of 55J, 30J, 30J, respectively). Peak resultant acceleration (g_{max}) was extracted from a triaxial accelerometer at the headform's centre of mass.

Results

Retention: Compared to the bare headform, the force required to cause hardhat retention failure was 39.7% and 32.8% lower in the large ($p=0.040$) and small turban ($p=0.057$) conditions, respectively. Impact: For lateral impacts, g_{max} was significantly greater in the bare (110.8(5.7)g, CV:9%) compared to small turban (69.5(2.3)g, CV: 7%) and large turban (62.8(11.8)g, CV:33%) conditions ($p<0.001$), and coefficient of variability was more than three-fold greater in the large turban condition.

Discussion

From a broad safety perspective, wearing a turban underneath an industrial hardhat may improve impact attenuation for some impact scenarios, but also decreases the force required to cause retention failure. Overall, adding turban materials on top of a headform created uncertainty regarding the source of impact attenuation, increased across-trial variability, and influenced hardhat positioning on the headform. Accordingly, while inclusive design for industrial hardhats is desirable, incorporating religious headwear within physical test systems is not recommended from a biomechanics perspective.

Using Optical Marker Tracking for the Determination of Relative Movement Between Exoskeleton and Human

Dr. David Scherb, Prof. Robert Weidner

TU Bergakademie Freiberg, Freiberg, Saxony, Germany

Introduction

Musculoskeletal simulation is increasingly being used in the design process of support systems, like exoskeletons. Especially, the insight into resulting biomechanical effects allows a more straightlined design. However, for the performance of the designed exoskeleton, the recreation of the interface between exoskeleton and human is crucial. One major aspect of the interface is the biological soft tissue. Due to its compression during force transmission, relative movement between exoskeleton and human body occurs, influencing the support behaviour of the exoskeleton. However, this compliant behaviour of biological soft tissue is currently not sufficiently depicted in musculoskeletal simulation. Thus, a novel method for simulating the behaviour of biological soft tissue under the effect of exoskeleton support using spring-damper-elements should be developed. For this method, the parameters for stiffness and damping are elemental.

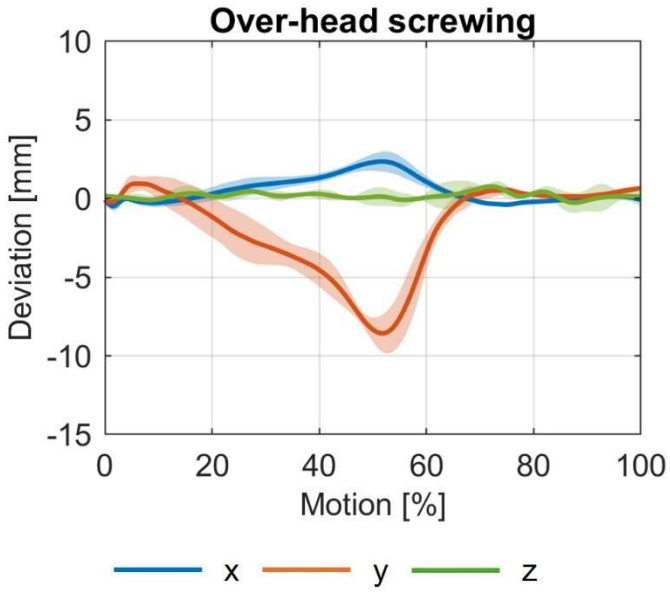
Methods

To derive these parameters, a study was conducted with participants executing over-head screwing and lifting a box over-head while wearing different shoulder exoskeletons. The participants were attached with markers at anatomical landmarkers due to the Vicon Plug-in-Gait model and additional markers at the exoskeleton to allow the derivation of the movement of exoskeletons and body segments individually and relative to each other (Figure 1a).

Results

The results show that relative movement occurs between exoskeleton and human body segment, i.e., arm. Especially, at the highest angles of the executed tasks, the highest magnitude of deviation appears (Figure 1b). Furthermore, an influence due to participant classifications (age, gender…) is identified.

Discussion



The influence of the participant classification is explained by the dependent appearance and distribution of biological soft tissue and its components (skin, muscle, adipose tissue) from these parameters. The course of the captured relative movement between human body and exoskeleton is accordingly traceable and plausible. In addition, the deviation depends on the exoskeleton and the incorporated joint kinematics. However, the magnitude can be arguable. During the calibration of the Vicon software, a discrepancy of up to 1 cm is considered as fine. Thus, some details of the occurring effects could be missed by marker tracking. In future, more accurate capturing methods (e.g. fluoroscopy) should be used to provide further insights into these promising results.

Visual Cues and Physical Literacy Influence Perceived Reach Affordances in Manual Materials Handling

Mr. Dean Stewart, Dr. Olu Awosoga PhD, Dr. Hardeep Ryait PhD, Dr. Jon Doan PhD

University of Lethbridge, Lethbridge, Alberta, Canada

Introduction

Work-related musculoskeletal diseases (WR-MSDs) are common in manual materials handling (MMH) as increased musculoskeletal demands elevate injury risk. Affordance thresholds (ATs), the distances a worker feels they can safely reach, may shift when visual cues alter perceived limits. Physical literacy (PL), awareness of one's body and movement capability, may influence what is perceived as safe. This study examines whether directional visual cues (left, right, none) influence height-normalized affordances (AT/H) across reach-distance groups and whether PL moderates the likelihood of selecting conservative or higher-risk reach distances.

Methods

Sixty-three adults completed a single lateral MMH task under a randomized visual cue: Left (n=20), none (n=20), right (n=23). After a scripted briefing, participants set their safe lateral reach distance (AT), which was normalized to height (AT/H) after testing was complete and classified as: 0-0.10 (conservative), 0.11-0.2 (moderate) and >0.20 (higher risk). A subset (n=35) of participants completed a PL assessment, and we organized into high-PL and low-PL groups. Analyses included: mean AT/H by cue group, counts of individuals within AT/H categories, PL-based differences in zone classification.

Results

Mean AT/H values were similar across cue groups (Left: .238; None: .218; Right: .233), indicating limited cue effects on affordance. However, distributional patterns revealed notable differences. The higher risk zone (>0.20) contained 7 participants in the no-cue group, versus 4 in Left and 3 in Right. The conservative zone (0–0.10) contained 4 Right-cue participants and 0 from Left or None. Moderate-zone counts were more evenly distributed (Left: 5; None: 8; Right: 4). Physical literacy strongly moderated outcomes: all conservative-zone participants were high-PL (n=4), while low-PL individuals were heavily concentrated in the high-risk zone, especially under no-cue condition (6 low-PL vs. 1 high-PL).

Discussion

Although cue condition did not influence mean AT, the distributions indicate that perceptual cues meaningfully shape affordance selection. The no-cue condition produced the most participants selecting excessive reach distances, suggesting that reduced perceptual input increases judgment variability.

PL further moderated outcomes, with low-PL individuals concentrated in the high-risk zone. These findings show that affordance selection varies under uncertainty and supports physical literacy training as a potential WR-MSD risk-control measure.

Sex differences in three-dimensional accelerometer orientation during seated whole-body vibration exposure

Ms. Eliza Cazzola B.Eng, MASc[1,2], Mr. Ian Scagnetti MSc, PhD Candidate[1], Dr. Megan Govers[1], Dr. Michele Oliver P.Eng[1]

[1]University of Guelph, Guelph, Ontario, Canada. [2]HumanSystems Inc., Guelph, Ontario, Canada

Introduction

Individuals who operate heavy mobile machinery are exposed to whole-body vibration (WBV) which is associated with back injury. Although females experience a greater incidence of back injuries compared to males, sex is generally not considered in WBV exposure analysis. ISO 2631-1 is frequently used to evaluate WBV exposure and associated health risk, where risk is assessed based on acceleration assumed to be in a basicentric coordinate system (BCS) that originates on the seat. ISO 2631-1 indicates that accelerometer orientation should not deviate more than 15° from the BCS. However, when mounted on the human body, an accelerometer's internal coordinate system becomes misaligned from the BCS which may impact accuracy of BCS acceleration measurements. The objective of this work was to investigate sex differences in triaxial accelerometer orientation relative to the BCS during seated WBV exposure.

Methods

27 females (25.4±6.0 years) and 23 males (27.4±5.8 years) were exposed to 16 vertical sinusoidal vibrations (1,3,5,7,9,11,13 and 15Hz at 0.25 and 0.50m/s^2) while sitting upright on a rigid seat with no backrest. Four orthogonal motion capture markers were attached to accelerometers at each of the sacrum (S1), lumbar spine (L3), thoracic spine (T6), and head via a bite-bar. Accelerometer orientation (roll, pitch and yaw angles) was calculated from motion capture data. Descriptive analyses were performed to determine if accelerometers deviated more than 15° from the BCS, and a mixed factorial ANOVA (p<0.05) was used to investigate sex differences in orientation.

Results

78% of participants exceeded 15° of pitch rotation in at least one spine location, and accelerometers at S1 and T6 most frequently exceeded 15°. Males and females had significantly different accelerometer orientation at S1 and T6, where females had

significantly greater anterior pitch rotation at S1 and males had significantly greater anterior pitch rotation at T6.

Discussion

The results suggest that accelerometers often deviate from the BCS despite participants adopting and maintaining an upright posture. The identified sex differences in accelerometer orientation at S1 and T6 may lead to sex differences in measurement accuracy in the BCS. The implications of accelerometer misalignment from the BCS on acceleration measurement needs to be further explored.

Effects of a Passive Back Support Exoskeleton on Gross Lumbar Proprioception and the Flexion Relaxation Phenomenon

Ms. Emma Ratke BKin (Honours), Ms. Aurora Battis MSc, Dr. Shawn Beaudette PhD

Brock University, St. Catherines, Ontario, Canada

Ms. Emma Ratke

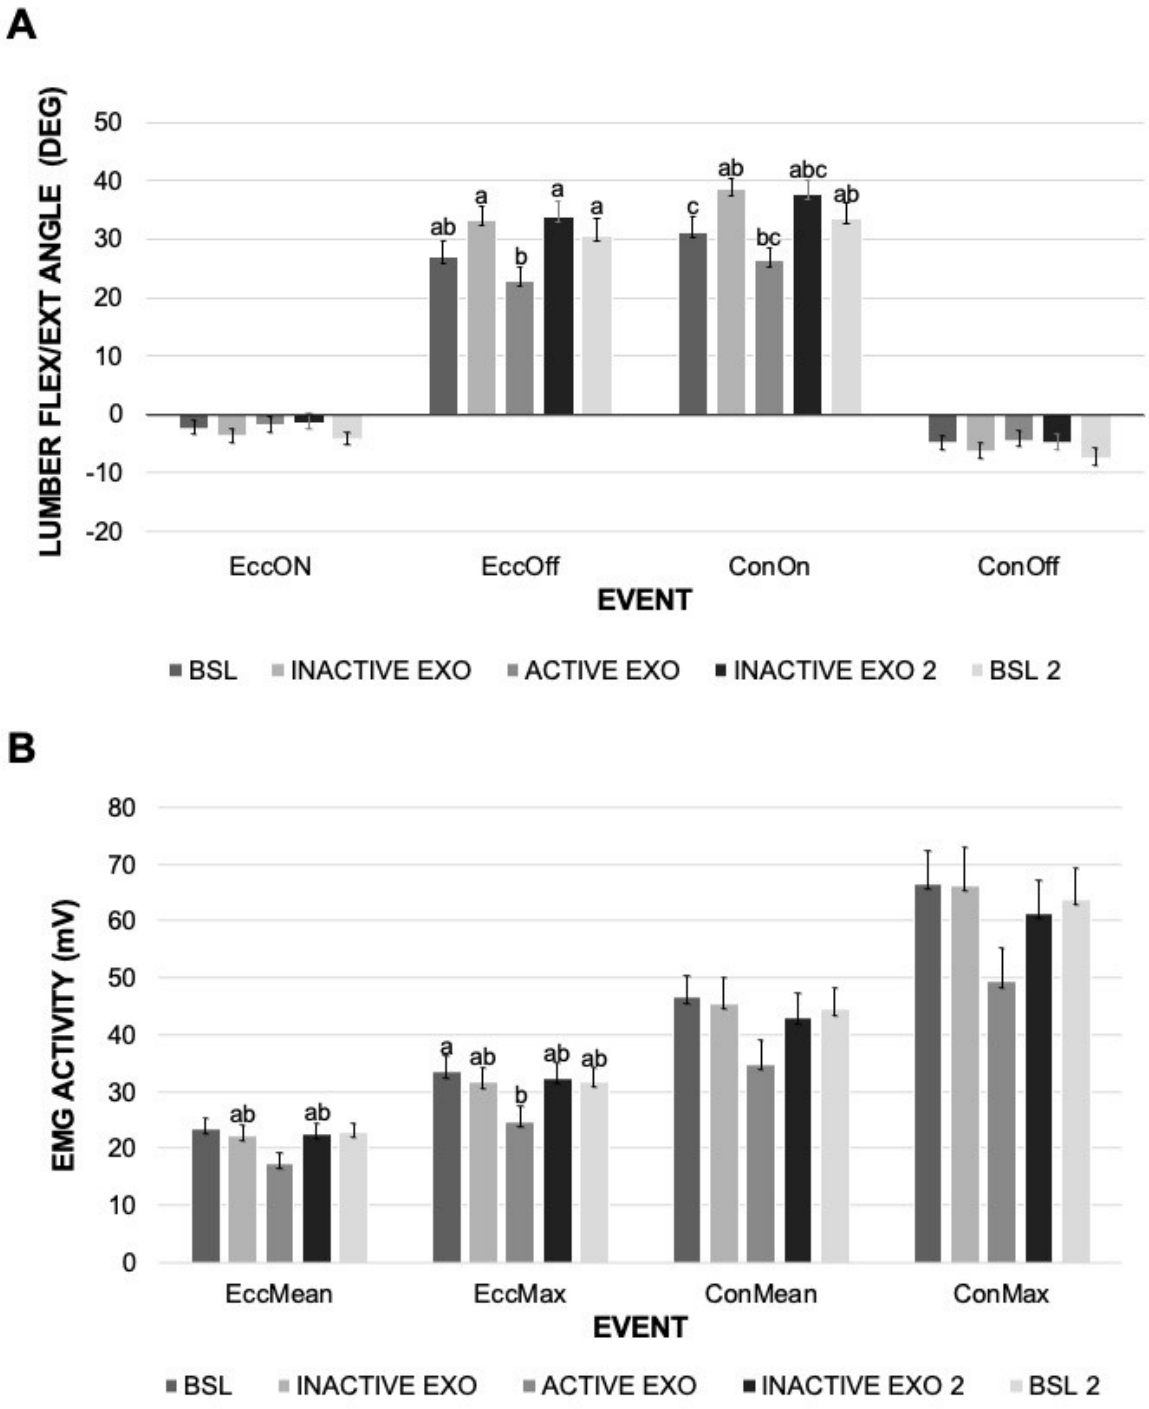
Introduction

The effects of a back support exoskeleton (BSE) on proprioception and the flexion relaxation phenomenon (FRP) should be assessed to understand implications of widespread BSE use in occupational settings. The purpose of this study was to: 1) assess acute BSE effects on lumbar proprioception, and 2) assess acute BSE effects on the FRP. It was hypothesized that lumbar proprioception would be reduced with BSE use. Additionally, it was hypothesized that FRP onset would occur earlier in trunk flexion with BSE use.

Methods

20 participants (10 F) were recruited. Participants' lumbar erector spinae (LES) were instrumented bilaterally with bipolar surface electrodes and IMU's bilaterally on the shoulders, upper arms and forearms, with single sensors placed on the head, sternum, and pelvis and calibrated as per manufacturer guidelines. Participants were fitted with a passive BSE (HeroWear Apex2). To assess the FRP, participants completed 5 repetitions of maximum flexion paced by a metronome. To assess proprioception, participants completed 5 midrange rematching trials. They were asked to flex forwards, told to stop at a randomized mid-range posture, return upright, and rematch the midrange posture. A one-way repeated measures ANOVA was used to compare differences in ratings of perceived exertion (RPE) across conditions and absolute lumbar angle error in the rematching trials. A two-way repeated measures ANOVA was used to compare differences between right and left LES activation and dependant variables across conditions. Pairwise post-hoc tests were used to examine any significant main effects ($a = 0.05$).

Results



No significant differences existed in RPE ($p=0.1309$) and error in the rematching task ($p=0.6548$). Maximum flexion was significantly higher in both InactiveExo1 ($p=0.0085$) and

InactiveExo2 (p=0.0038) compared to the ActiveExo condition. Results for lumbar flexion/extension angle (Panel A) and EMG activation (Panel B) during FRP events are presented in Figure 1.

Discussion

The results suggest acute BSE use does not impact lumbar proprioception however does impact the FRP. The BSE results in a reduced capacity for trunk flexion, decreased muscle activation, and increased myoelectric silence of the paraspinals. This is likely due to the BSE offsetting gravitational torque, allowing the passive structures to support the mass of the trunk.

Exploring Maximal Shoes as a Viable Intervention for Mitigating Low Back Pain During Prolonged Standing in Healthcare Professionals

Ms. Isabel Evans BKin[1], Dr. Jackie Zehr PhD[2], Dr. Jack Callaghan PhD[3], Dr. Kayla Fewster PhD[1]

[1]Western University, London, ON, Canada. [2]University of Toronto, Toronto, ON, Canada. [3]University of Waterloo, Waterloo, ON, Canada

Introduction

It is well established that approximately 50% of individuals are susceptible to acute low back pain (LBP) during prolonged standing [1], including healthcare workers [2]. Existing standing aids aimed at reducing standing-induced LBP, are typically immobile and thus impractical for this mobile population. Soft cushion maximal shoes were evaluated as a mobile standing intervention.

Methods

Twenty-one female healthcare workers completed a control shoe day and maximal shoe day. Non-destructive mechanical testing was completed to quantify sole mechanical properties [3]. On each day, five walking gait trials pre- and post-standing and a 75-minute prolonged standing trial were completed. EMG of bilateral trunk stabilizers, lumbar spine angle, and pain were monitored. An independent samples t-test evaluated any significant differences in shoe characteristics. A two-way repeated measures ANOVA was conducted across shoe type and time point (pre- and post-standing) to evaluate differences in gait. A hierarchical logistic regression model evaluated if any of the standing outcome variables significantly predicted the development of LBP.

Results

The maximal shoe (71.25 ± 0.33 N/mm) was significantly more compliant than the control shoe (100.72 ± 0.83 N/mm), $p<.001$. No significant differences were observed across gait trials for knee adduction moment (Maximal = 0.45 ± 0.13 Nm/kg; Control = 0.44 ± 0.13 Nm/kg; p =.49) or knee flexion angle (Maximal = 0.72 ± 6.61˚; Control = 0.10 ± 5.49˚; p=.54). In the hierarchical logistic regression, shoe type was the only significant predictor of LBP across standing variables (B = −2.38, SE = 1.14, p =.036). Maximal shoes reduced the risk developing LBP by 91%.

Discussion

In line with previous research, the more compliant material decreased LBP [4]. The mechanism for LBP reduction remains unknown as no other variables were significant pain predictors, prompting a secondary analysis into movement quality [5]. Given that LBP decreased and gait was not altered, maximal shoes could be considered an effective prolonged standing intervention for healthcare workers.

Accumulation and Recovery of Prolonged Low-Frequency Force Depression and Force Stability at Different Intensities of Repetitive Isometric Contractions

Mr. Jared-Isaac Friedel MSc, BSc, Dr. Steven Fischer PhD, MSc, BSc

University of Waterloo, Waterloo, Ontario, Canada

Mr. Jared-Isaac Friedel

Introduction

Workers are still getting injured in the workplace despite peak loading being reduced, suggesting that MSDs may be impacted by lower intensity, yet frequent loading across days. Prolonged Low Frequency Force Depression (PLFFD), which is an alteration in submaximal muscle fibre firing, may be a possible explanation for this cross-day accumulation effect and may contribute to MSD risk. This research investigated whether PLFFD progressed differently between workload-matched protocols and whether PLFFD impacted task performance.

Methods

20 participants (9 males, 11 females) performed two repetitive isometric biceps flexion protocols one week apart. The protocols were four hours long and impulse-matched to expose the participants to the same total work ($N \cdot s$) at different force magnitudes and duty cycles. Participants performed the protocol in one-hour segments with a 15-minute break between each segment, followed by three hours of monitored rest. PLFFD (through transcutaneous muscle stimulation [1]), task performance metrics (through a force matching task [2]), and Maximum Voluntary Force (MVF) were measured intermittently throughout the protocol, rest hours, and on a follow-up visit and compared using ANOVAs.

Results

The protocols invoked a PLFFD effect that lasted to the next day (Table 1). The protocols invoked significant reductions in MVF that lasted for the 3 hours of rest, but not to the next day (Table 1). No significant differences between protocols were observed in PLFFD or MVF. PLFFD and MVF were both observed to be significantly correlated with reductions in task performance ($R^2 = 0.035$, $p < 0.001$ and $R^2 = 0.116$, $p < 0.001$ respectively).

Discussion

No protocol-specific effects were observed, suggesting that the progression of PLFFD within a muscle is independent of fibre type. Reductions in MVF over time more closely correlated with reductions in task performance when compared to PLFFD. Therefore, PLFFD may not have a substantial impact in the quality of occupational tasks, however muscle fatigue might. Future research investigating how muscle fatigue invoked from workload-balanced protocols impacts task performance may generate guidelines on how to facilitate optimal performance based on task requirements.

Low and High Affordants Have Increased Risk for Musculoskeletal Disorders in a Simulated Baggage Handling Task

Dr. Jon Doan Ph.D., P.Eng., Mr. Dean Stewart, Dr. Hardeep Ryait Ph.D., P.Eng.

University of Lethbridge, Lethbridge, Alberta, Canada

Introduction

Airline baggage handling is an occupation associated with both musculoskeletal injury and affordance-rich task parameters like variable loads, alternative load couplings, some confined working spaces, and dynamic postures. The purpose of this research was to examine affordances and mechanics of handling in a simulated baggage handling task.

Methods

60 healthy adult participants (23.9 +/- 8.3 years, 36 F) were outfitted with static contrast markers on anatomical segment endpoints on their right side. Participants' feet were positioned in a defined floorspace 40 cm x 40 cm and 25 cm posterior from the centre of the suitcase target. Lateral distance to the centre of the suitcase target was set to 25% stature for each participant. Prior to mounting the suitcase, participants hoisted the load by the handle with their dominant hand to obtain a perception of mass (8 kg) and mass distribution (perimeter weighting, 57 L volume).

Participants were read the fixed script of a handling task that defined job plus task parameters. After the script, participants were instructed to chose the affordant vertical height that would "allow them to handle the bags as safely as possible without causing pain or discomfort". Each participant then completed 5 isometric handling trials at their affordant vertical height, and pulling force was recorded through the dynamometer (Lido WorkSet, Loredan Biomedical) while behaviour in the frontal plane was recorded. Video data were clipped and analyzed (DartFish TeamPro). Participants also completed a validated personality inventory.

Participants were post hoc sub-grouped by normalized affordant height into equal sized LOW, MODERATE, and HIGH affordant sub-groups. Group differences were tested with ANOVA, and significant group effects were further isolated using independent t-test.

Results

LOW, MODERATE, and HIGH sub-groups differed significantly on normalized vertical affordance for handling. These differences were manifest in significantly increased handling forces and lateral deflections amongst the LOW and HIGH groups. Simple personality typing did not explain sub-group differences.

Discussion

Perceived task performance is associated with occupational behaviours. Interventions that can modify perceptions, like physical literacy training and visual cues, may be more successful approaches to change occupational behaviours and control musculoskeletal demands.

Development and EMG Evaluation of a Spring–Actuator Module to Induce Cocontraction and Enhance Joint Stiffness in Laparoscopic Posture

Mr. Junyeol Choi MS Candidate, Prof. Ho Seon Choi Assistant Professor

Sejong University, Seoul, Seoul, Korea, Republic of

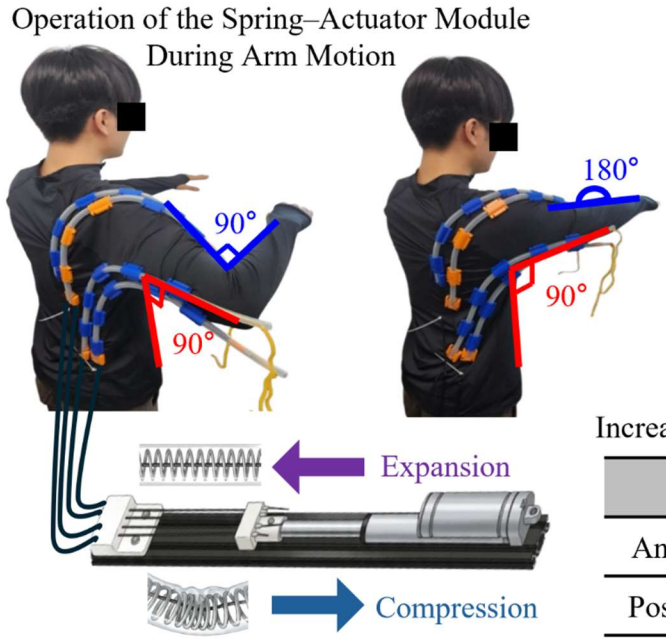
Mr. Junyeol Choi

Introduction

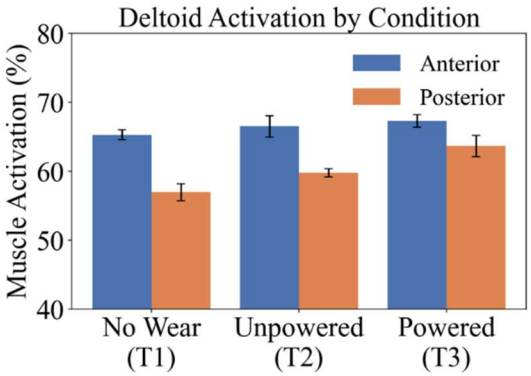
Laparoscopic surgeons must maintain the same posture for extended periods, and accumulated shoulder fatigue can reduce cocontraction and joint stiffness, ultimately decreasing task precision. To address this issue, we developed a spring–actuator wearable module designed to enhance shoulder joint stability even under fatigue-inducing conditions.

Methods

A spring–tube module was designed by inserting a spring inside a rubber tube to prevent lateral dispersion of elastic force during compression, and an additional elastic band was attached at the distal end to assist restoring force. This module was connected to a linear actuator that controlled spring compression and extension. Four modules were used in total—two placed over the anterior deltoid and two over the posterior deltoid. Surface EMG sensors were attached to both muscles to measure activation. The experimental task required maintaining 90° of shoulder abduction while flexing the elbow from 90° to 180° and repeatedly performing this movement for 30 seconds, a motion selected to include non-ideal ranges that may occur in laparoscopic procedures. MVC of both deltoid regions was measured individually based on the Manual Muscle Test (MMT), and muscle activation was compared across three conditions: without the device (T1), wearing the device without spring compression (T2), and wearing the device with spring compression (T3).



Results



Compared with T1, muscle activation increased by 1.22% (anterior) and 2.80% (posterior) in T2, and by 1.99% (anterior) and 6.67% (posterior) in T3. These results indicate that spring compression increases mechanical resistance during movement, requiring greater muscle activation to perform the same task.

Discussion

Based on these findings, the additional mechanical resistance generated by spring compression is expected to physically reduce anterior–posterior shoulder sway. This suggests that even when fatigue reduces joint stiffness, activating the compression mechanism may artificially provide stability similar to increased cocontraction, thereby supporting posture maintenance during surgical tasks. Future work will involve determining optimal spring compression ranges through simulation-based motion analysis, integrating control algorithms into the actuator system, and conducting experiments with a larger participant group.

Spine Posture and Movement in E-Sports Gamers during Computer Gaming

Ms. Kate Krivenko BSc, Ms. Jessa Davidson MSc, Dr. Jack Callaghan PhD

University of Waterloo, Waterloo, Ontario, Canada

Ms. Kate Krivenko

Ms. Jessa Davidson

Introduction

Computer gaming involves highly repetitive, fast, and precise upper-limb movements [1]. Nevertheless, the sport involves hours spent sitting which leads to neck and low back discomfort that is similar to that associated with computer work [1]. Gaming involves seemingly active behaviours in sedentary state, thus the objective of this study was to evaluate movement behaviours and metabolic demands in gamers playing computer games.

Methods

Sixteen e-sports gamers who were ranked in Valorant completed 20-minutes of osu! and Aimlabs, and one competitive game of Valorant in two gaming chairs (Embody and Titan Evo). Four tri-axial accelerometers were affixed onto spine and head to determine spine motion relative to individual standing posture (º) and range of motion (%). Lumbar spine postures (amplitude probability distribution function (APDF)) and micromovements (shifts and fidgets [2]) were evaluated. A portable metabolic system (MetaMax) was used to sample breath-by-breath gas exchange and ventilation at the mouth over steady state gaming.

Results

The spine postures showed limited variability across the APDFs, with the mean static (10%) and peak (90%) postures remaining within a 10° or 15% range. Participants performed 4 ± 4 shifts and 11 ± 3 fidgets over 20 minutes of gaming, with more fidgets in Aimlabs than osu! ($p = 0.018$). During Valorant, minute ventilation, was higher in Embody (11.3 L) than Titan (10.4 L, $p = 0.006$), likely from increases in tidal volume rather than breathing frequency.

Likewise, VO_2 and VCO_2 were also higher in Embody than Titan during Valorant ($p \leq 0.008$). The mean energy expenditure across chairs and games was 1.49 METs, indicating that computer gaming was sedentary.

Discussion

Lumbar micromovements and metabolic measures were consistent with sedentary computer work [2,3]. Increased upper limb motion in gaming did not translate to increased spine motion or metabolic demands. The current results demonstrate that e-sports gamers face similar health risks to sedentary office workers. Recommendations specific to the gaming environment such as active trunk support may mitigate those risks, while maintaining or even improving performance.

Ground Reaction Forces During Locomotive Descent

Dr. Luis Nolasco PhD, Mr. Abdul Dannaoui, Dr. Natasha Vernooij PhD, Mr. Brian Weaver MS, PE

Explico Inc.,, Novi, Michigan, United States

Dr. Luis Nolasco

Mr. Abdul Dannaoui

Dr. Natasha Vernooij

Introduction

The forces associated with dismounting rail equipment are commonly claimed to cause workplace injuries in the freight rail industry. Previous research evaluated ground reaction forces (GRF) descending fire-fighting vehicles and heavy trucks [1,2], finding that facing the equipment reduced GRFs. The required height of 19” from the top of the rail for the last step of a switching locomotive results in a larger step to the ground compared to other vehicles. However, no previous research has quantified the impact forces experienced while descending locomotive steps. Therefore, the purpose of this study was to quantify these forces.

Methods

Twenty-one individuals (5F/16M; Avg. 28 years; 83.18 kg; 1.78 m) performed a ‘normal’ and ‘drop-down’ descent on replica locomotive steps with handrails (EMD SD40-2). Vertical and anterior/posterior forces were measured (1000Hz) for three trials per condition. Participants descended facing the steps, placing one foot on each step. The bottom step was 22.75” above the force plate. For the ‘normal’ descent,forces were measured on the last step and the floor. Drop-down descent: participants skipped the last step with their body-weight to carrying them from the last step to the floor.

Results

Normal descent: average GRF on the last step of the locomotive and the floor was 1 and 1.3 times body-weight, respectively (Figure 1). Drop-down descent: average GRF was 2.1 times body-weight.

Discussion

Normal locomotive descent had lower GRFs than standard stair descent [3], likely due to the support from the handrails. GRFs were lower than those from fire fighting vehicles and similar to heavy trucks, likely due to fire fighters added gear. However, the locomotive steps had a higher step compared to these other vehicles. GRFs were greatest when participants dropped to the floor by skipping the last step. However, these GRFs were similar to those of fast walking and running [4]. Thus, the impact forces while dismounting a locomotive are comparable to descending other vehicles and general, non-injurious activities.

Joint Loading in Patient Handling: Comparison With and Without Assistive Technology

Ms. Madison Holmes[1,2], Ms Michelle Léger[1,3], Ms Cynthia Dion[1,3], Dr Michelle Cardoso[3], Dr Wayne Albert[1]

[1]University of New Brunswick, Fredericton, New Brunswick, Canada. [2]Université de Moncton, Moncton, New Brusnwick, Canada. [3]Université de Moncton, Moncton, New Brunswick, Canada

Introduction

Manual patient handling [PH] is the leading risk factor for musculoskeletal injuries among healthcare workers, contributing to increased disability, lost work time, and risks to patient safety [1,2]. The Vendlet is an automated repositioning system that offers a potential solution.

The purpose of this study was to compare joint and spinal loading during patient repositioning tasks performed manually and with the Vendlet system.

Methods

Twenty-seven health science students aged 17 to 40 with no previous PH training received an in-depth expert training session on proper PH techniques. Participants performed two tasks: turning a patient onto their side and moving a patient horizontally in bed, both manually and using the Vendlet system.

A Qualisys motion capture system was used to record participants' movements, and Visual3D software was used to calculate joint angles. Following each repetition of the PH task, participants immediately replicated the hand force applied using a VALD DynaMo dynamometer. Hand forces and joint angles were used as inputs to an inverse dynamics biomechanical model to calculate joint and spinal forces. Statistical differences were assessed using Wilcoxon signed-rank tests.

Results

When turning a patient onto their side, the Vendlet system resulted in significantly lower: 1) mean and peak horizontal and vertical joint forces bilaterally at the wrist, elbow, shoulder, and trunk; 2) cumulative load at the left wrist, elbow and shoulder; and 3) mean and peak

shear and compression spinal forces. Manual techniques resulted in significantly lower cumulative loading at the right wrist, elbow, shoulder, and trunk.

When moving a patient horizontally in bed, the Vendlet system resulted in significantly lower: 1) mean and peak horizontal and vertical joint forces and cumulative load bilaterally at the wrist, elbow, shoulder, and trunk; and 2) mean and peak shear and compression spinal forces.

Discussion

Although the manual PH techniques were designed based on biomechanical principles, they still produced high joint forces and cumulative loads, exceeding recommended limits for peak shear and compression spinal forces. Compared to manual PH, the Vendlet repositioning system reduced joint and spinal forces, as well as cumulative loading.

Evaluating the Safety and Comfort of a Pediatric Upper Extremity Exosuit

Ms. Ipsita Sahin[1], Ms. Mehrnoosh Ayazi[2], Ms. Melanie Barahona[1], Dr. Konstantinos Karydis[2], Dr. Elena Kokkoni[1]

[1]Dept. of Bioengineering, University of California, Riverside, Riverside, CA, United States. [2]Dept. of Electrical and Computer Engineeringing, University of California, Riverside, Riverside, CA, United States

Introduction

Design considerations for assistive exosuits should consider safety and user comfort, as neglecting these factors can reduce device adoption [1]. While past studies have been conducted for exosuits developed and tested with adults, limited attention has been given to studying the safety and comfort of exosuits designed for young pediatric populations. This work assesses these parameters for a custom pediatric, upper-extremity pneumatic exosuit by evaluating exerted forces, combined with collecting user feedback.

Methods

Our approach is twofold. First, experiments were conducted on two 3D-printed test rigs to characterize the forces exerted by the soft, fabric-based, and pneumatic-powered actuators of the exosuit on parts of the rig that correspond to the forearm, upper arm, and torso segments. Each test rig incorporated two load cells to measure the normal contact forces exerted on actuator anchoring locations. Appropriateness of the generated forces was based on threshold values estimated from related literature: for an average body weight of a 12-month-old infant (10.80 kg), acceptable limits of force may vary from 43-184 N for each segment (i.e. 0.4-1.7 times the body weight) [2]. The second step includes collecting information from both infants (via assessing their facial expressions during use) and their caregivers (through questionnaires). Modified versions of the Comfort Rating Scale, System Usability Scale, and Technology Acceptance Model questionnaires were selected to measure the latter's perceptions of the fit and broader acceptance of the exosuit.

Results

Testing with the test rigs confirmed the safe operation of the exosuit's actuators, thereby supporting their functionality for pediatric exosuit design. All actuator variants generated peak forces between 4 and 32 N, which is below the estimated force comfort limits

established for the target pediatric population. This result supports safe deployment during experiments with pediatric users within this ongoing study.

Discussion

This work contributes to identifying force limits for the infant population, offers guidance on suitable actuator selection, and outlines a design framework for pediatric wearable robotic exosuits.

Identifying Overhead Work Zones: A K-Means Cluster Analysis of Maximum Acceptable Duty Cycles

Mr. Michael Watterworth PhD. Candidate, Dr. Nicholas La Delfa PhD.

Ontario Tech University, Oshawa, Ontario, Canada

Mr. Michael Watterworth

Introduction

Work-related musculoskeletal disorders are among the leading causes of global pain and disability, with the shoulder being one of the most frequently affected regions. Shoulder injury risk increases two- to threefold in jobs involving overhead work, prompting companies to restrict above-shoulder time (e.g., 33% at GM; 50% at Ford). Yet, despite widespread reliance on duty-cycle limits, existing ergonomics tools cannot directly estimate the Maximum Acceptable Duty Cycle (MADC) for a given overhead task.

Methods

The Above-Shoulder Tool was recently extended to estimate MADCs for specific force demands, directions, and hand locations. Using this new equation, an algorithmic case study examined how hand location and upward force affect MADC values in the sagittal plane. Posturing of a 50th-percentile female model throughout their viable reach envelope was performed with three constraints: neutral wrist–forearm alignment, movement restricted to the vertical plane, and an upright trunk. Z-score–normalized MADCs were clustered using K-Means (k = 7) to identify common overhead-work zones. Force demands were incrementally increased from arm weight alone until only one overhead zone remained at a 33% duty-cycle threshold.

Results

The K-Means clusters aligned with established ergonomic risk patterns, identifying zones where overhead posture and increased joint moments elevate fatigue and injury risk. Mean MADC was substantially lower at or above shoulder height (17%) compared to below the shoulder (60%). Two clusters showed particularly low MADCs (Figure 1): (1) outstretched exertions at or above shoulder height, which had the second-lowest MADC (10%) due to large moment arms (Dark Green), and (2) high overhead reaches, which had a median

MADC of 0%, indicating no acceptable duty cycle for a 5 N upward exertion (Light Blue). Conversely, an optimal overhead zone was identified where limiting work to 33% of the cycle would be acceptable (Dark Blue).

Discussion

These findings highlight the potential of posture-specific MADC estimates to improve job design, duty-cycle limits, and placement of overhead work. However, results are constrained by the model's simplified assumptions (fixed postures, standardized anthropometry and strength), limiting generalizability to all workers. Future research should perform an experimental validation of the model to refine this approach for applied ergonomics.

Effects Of New Technology on Healthcare Workers' Posture During Patient Handling

Ms Michelle Léger[1], Ms Madison Holmes[1], Ms Cynthia Dion[1], Dr. Wayne J. Albert Dr.[1], Dr. Michelle R. Cardoso Dr.[2]

[1]University of New Brunswick, Fredericton, NB, Canada. [2]Université de Moncton, Moncton, NB, Canada

Introduction

Patient handling (PH) is one of the leading causes of workplace injuries among healthcare workers (HCWs) and represents a substantial proportion of their patient care activities[1]. Consistent safe PH practices are often hindered by barriers such as bariatric patients, staffing shortages, insufficient training, and work-related stress[2].

The objective of this study was to compare health care worker postures during PH techniques performed manually and with the Vendlet technology.

Methods

Sixteen HCWs aged 22-59 years were recruited for this laboratory-based study. Participants visited the laboratory both before and after their 8-hour work shift. Prior to data collection, they received training on two PH techniques: turning a patient (Technique-Turn) and moving a patient towards the bed's edge (Technique-Side),

manually and with the Vendlet technology.

Kinematic data were collected using a Qualisys motion capture system, coupled with the Theia software, to quantify the joint angles of the head, shoulders, elbows, wrists, hips, pelvis, knees, and trunk-pelvis (flexion/extension, lateral bend, and rotation). Joint angle data were normalized to 101 points. A Wilcoxon signed-rank test with a within-subject comparison was conducted on five participants to compare peak joint angles for both PH techniques, using the Vendlet versus manual techniques under pre- and post-work shift conditions. All sixteen participants will be processed and analyzed for WCB.

Results

For Turn, when using the Vendlet pre- and post-shift, participants had significantly lower peak values for the following joint angles: head, left hip, left shoulder, pelvis, right hip, right knee, and right shoulder.

For Side, when using the Vendlet pre- and post-shift, the participants had significantly lower peaks for the following joint angles: head, left shoulder, pelvis, right hip, right wrist, and trunk-pelvis.

No significant patterns were observed for lateral bend and rotation for both techniques.

Discussion

The Vendlet technology resulted in lower overall joint peak angle values, indicating that it led to more neutral postures compared to manual techniques. The Vendlet is a technology that has the potential to reduce work-related injuries and promote a safer work environment.

Single-Image Ergonomic Assessment: User-Selected vs. App-Derived Workstation Configurations

Mr. Ryan Chhiba[1], Ms. Diana Gillstrom[2], Dr. Peter J. Keir[1]

[1]McMaster University, Hamilton, ON, Canada. [2]Ellustros, The Blue Mountains, ON, Canada

Introduction

The use of ergonomic office devices and furniture is ubiquitous, yet workstation setup often falls short of recommended guidelines. Recommended setup helps prevent user discomfort and decreases the risk of developing injuries and disorders [1]. Office guidelines are important yet misunderstood by a large proportion of workers. An individual's preferred workstation setup may be deemed comfortable but may not be ergonomically appropriate. The objective of this study was to quantify differences between user-selected workstation configurations and those recommended using an AI-based ergonomic application.

Methods

Participants were asked to set up an office workstation consisting of a chair, desk and monitor. They adjusted settings such as seat and arm rest height, as well as desk and monitor heights. Using the tros.ai application (Ellustros, The Blue Mountains, Canada), an ergonomically defined setup was calculated using participant height and anatomical landmarks taken from a photo of the individual [2]. Differences between the self-selected and ergonomically appropriate workstation heights were determined.

Results

Preliminary results from 20 participants show the mean self-selected seat height (40 cm) was lower than the ergonomically defined height (43 cm). Self- selected arm rest height and desk height (68 cm, 73 cm) were higher than those determined from the app (60 cm, 61 cm). Self-selected monitor height (120 cm) was higher than the calculated height (118 cm). Figure 1 shows the mean difference between the self-selected and ergonomically (app) defined setups. Further analyses will include more participants to capture a diverse range of anthropometrics and working populations.

Discussion

Identifying discrepancies between self-selected and ergonomically determined workstation setups can identify which workstation parameters heights may be driving user discomfort. This work will inform ergonomic interventions in the office workspace and help

educate workers to decrease risk of work-related injury. Additionally, this app provides an accessible method for generating individualized ergonomic recommendations from a single image, offering a scalable tool for improving workstation setup. The results from this study suggest that individual workstation interventions may be effectively and efficiently incorporated by using a smartphone.

Images (Optional)

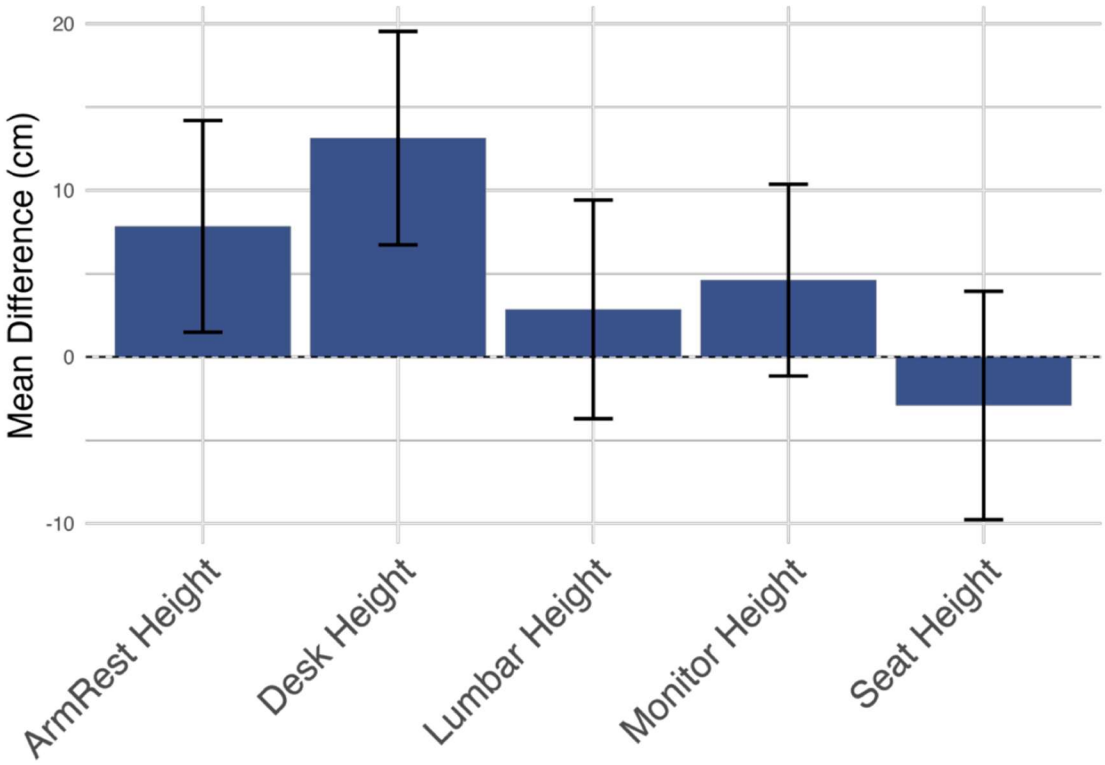

Figure 1. Mean difference (cm) between the self-selected and ergonomically defined setup. Positive mean difference indicates a higher self-selected height compared to ergonomically derived heights. Negative mean difference indicates a lower self-selected height compared to ergonomically derived heights. Error bars represent the standard deviation of mean difference (cm).

Influence of Work Demands and Organization on Upper Limb Motor Variability During Repetitive Pushing

Mr. Ryan Chhiba, Ms. Joanna M. Misquitta, Dr. Peter J. Keir

McMaster University, Hamilton, ON, Canada

Introduction

Prolonged repetitive upper limb tasks are leading causes of workplace musculoskeletal disorders [1]. While true repetition repeatedly stresses the same tissues, the neuromuscular system can generate multiple movement solutions for the same task through motor redundancy, or abundance [2], which may be a protective strategy to prevent overuse injuries [3]. Little is known about the modulation of motor variability in response to task demands such as frequency and force. While most studies use a fixed cadence, many jobs are quota-driven, requiring a prescribed amount of work in a specified time. This study aims to evaluate how task demands (force, frequency, work organization) influence motor variability.

Methods

Participants completed eight randomized 5 minute upper limb pushing trials at the same workload under varied conditions. EMG, motion data, potentiometers, and rated perceived exertion captured motor variability, task accuracy and effort. Data was segmented to capture cycle-to-cycle variability. A model tested main effects of Force (2 kg/4 kg), Frequency (low/ high), Work Organization (set pace/ quota), and interactions.

Results

Preliminary analysis of ten participants are presented. The average cycle-to-cycle median absolute deviation of upper limb muscle activity during the low force, low frequency and the high force, high frequency tasks are presented in Figure 1. Higher force and frequency work conducted at a set pace had higher variability, whereas quota driven work at lower force and lower frequency demands had increased variability. Further analyses will include kinematics, performance and perceived effort to better elucidate how motor variability is modulated by word demands.

Discussion

Motor variability in relation to work demands may not depend solely on task intensity but also work structure. Larger variability in muscle activation during the high force high frequency set pace conditions suggest motor redundancy may prevent muscular fatigue

and preserve performance. Participants completed the low force low frequency condition faster than set pace, indicating self-paced movements likely elevate motor variability. By integrating neuromuscular control theories, with occupational injury mechanisms this study aims to improve our understanding of upper extremity function to provide insights into the potential risk of dysfunction.

Images (Optional)

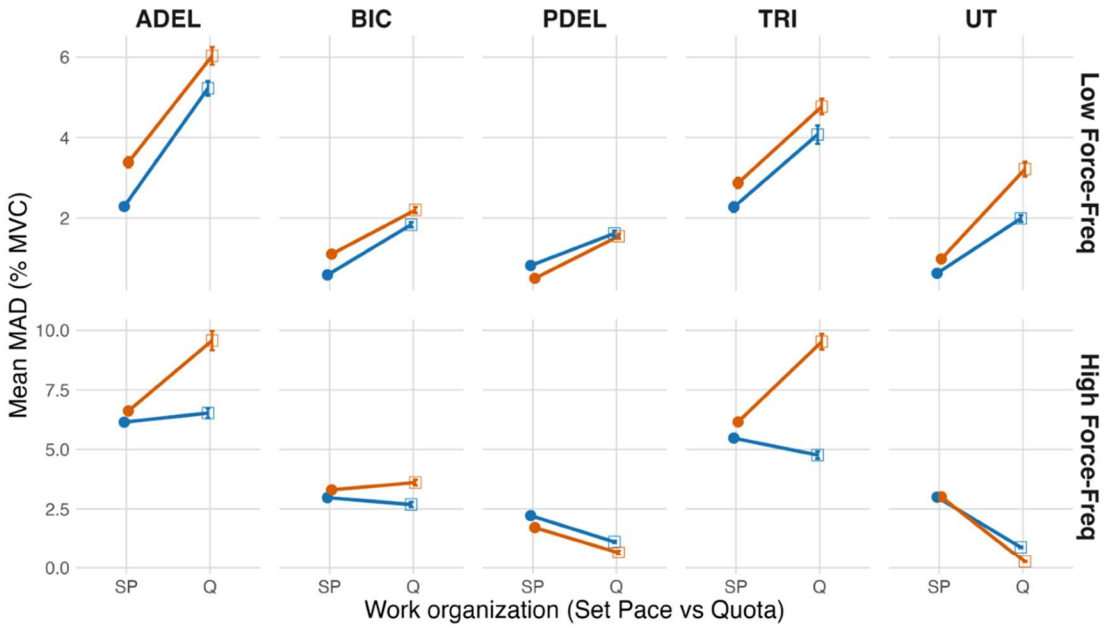

Figure 1. Mean cycle-to-cycle median absolute deviation (MAD) of muscle activity (% MVC) during Set Pace (SP - circle) and Quota (Q – square) work organizations. Muscles include, left (blue) and right (orange) anterior deltoid (ADEL), biceps (BIC), posterior deltoid (PDEL), triceps (TRI) and upper trapezius (UT). Top row = low frequency, low force condition, bottom row = high force, high frequency condition.

Can Acute Abdominal Bracing and Hip Motion Coaching Reduce Lumbar Spine Flexion Angles and Extensor Moments During Lifting?

Ms. Sadie Finch CAT(C), Dr. Jordan Cannon PhD

University of Waterloo, Waterloo, Ontario, Canada

Ms. Sadie Finch

Introduction

High magnitudes of lumbar spine flexion while lifting reduces the failure tolerance of the lumbar spine, alters load distribution across tissues, and compromises extensor muscles' capabilities to resist anterior shear forces; and is linked to greater low back injury risk [1]. During lifting tasks, increasing lumbar spine stiffness (via abdominal bracing) and redistributing motion and load demands to the hips may reduce low back demands. This study sought to determine if an acute abdominal bracing and hip motion coaching intervention prior to lifting could redistribute flexion motion and extensor moments from the lumbar spine to the hips.

Methods

Full-body kinematics and ground reaction forces were collected on 14 female university athletes. Bottom-up inverse dynamics calculated lumbar spine and hip moments. Floor-to-waist lifting and lowering tasks were performed pre- and post-coaching intervention with two load conditions: light (1kg) and heavy (15kg). An acute coaching intervention was implemented while participants performed quadruped rock backs, focussing on isolating the lumbar-pelvis-hip linkage to minimize lumbar spine motion and maximize hip flexion, via abdominal bracing and hip-driven cueing. Two-way repeated measures ANOVAs examined the effects of time, load, and their interaction, on peak flexion angles and extensor moments of the lumbar spine and hip.

Results

Peak lumbar spine flexion was significantly reduced post-intervention in both light and heavy conditions. Peak lumbar spine extensor moment was significantly reduced in the light but not heavy condition. Contrary to our hypothesis, peak hip flexion angles were

unchanged following the intervention while peak hip extensor moment decreased in the light but not heavy condition.

Discussion

An acute coaching intervention in a simplified, constrained task was able to reduce lumbar spine flexion motion during floor-to-waist lifting. However, lumbar spine changes were not facilitated by changes in hip motion. This suggests motion demands were distributed across other joints spanning the lower and upper extremities. Lower lumbar extensor moments only in the light condition suggest a moment distribution strategy lacking capacity for heavier demands. Small effect sizes limit practical significance but indicates potential utility in extending the coaching to a short-term intervention program to facilitate implementation of new movement solutions.

Images (Optional)

Table: Peak angle and moment differences [and percent change] from pre-to-post intervention for the lumbar spine and hips. A positive (negative) value represents an increase (decrease) in post- compared to pre-intervention.

	Light Load		Heavy Load	
	Angle (°)	**Moment (Nm)**	**Angle (°)**	**Moment (Nm)**
Lumbar Spine	-5 [-12%]	-16 [16%]	-4 [-10%]	-5 [3%]
Hip	4 [4%]	-6 [8%]	1 [1%]	-6 [5%]

Effects of Lifting Task and Infant Weight on Lumbopelvic Muscle Activity, Kinematics, and Kinetics in Nulliparous Women

Dr. Safeer Siddicky Ph.D.[1], Dr. Kathryn Havens Ph.D.[2]

[1]The University of Texas at Austin, Austin, TX, United States. [2]University of Southern California, Los Angeles, CA, United States

Dr. Safeer Siddicky

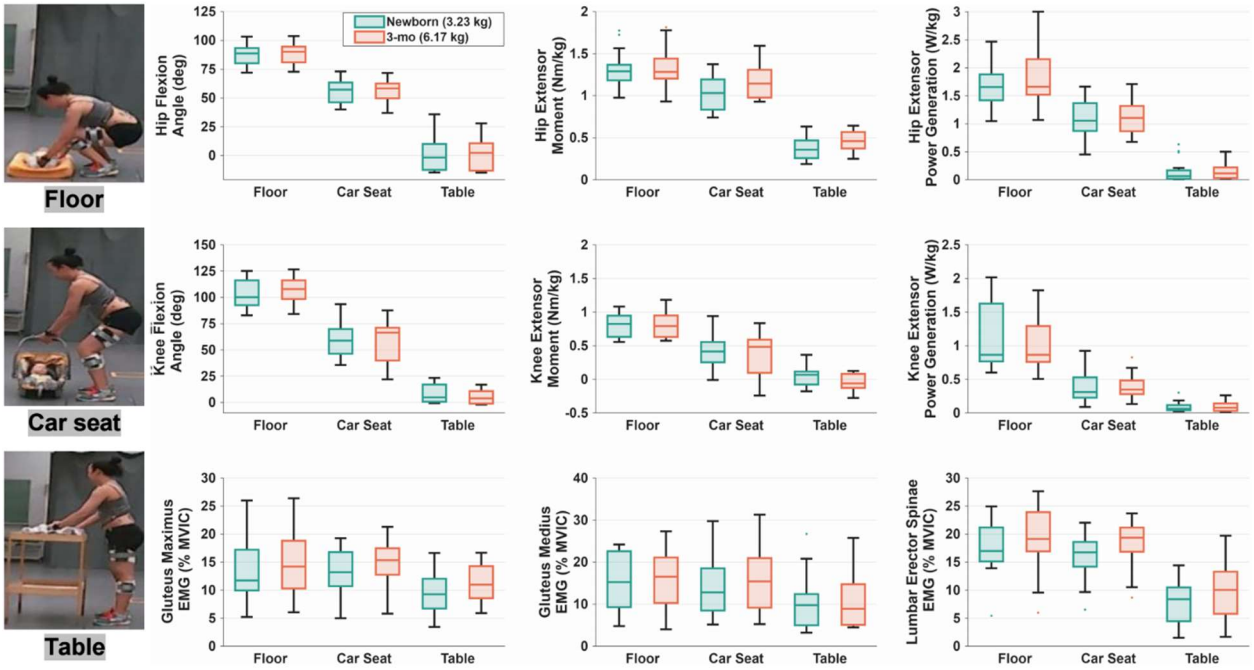
Introduction

Infant caregiving involves frequent lifting, yet the biomechanics of these tasks remain understudied. Prior work in postpartum individuals shows that lift type and context influence movement patterns and loading [1,2], but baseline mechanics of nulliparous adults remain unknown. Establishing these patterns across common caregiving tasks and varying infant weights is important for identifying potential musculoskeletal risks. We therefore examined how lift type and infant weight affect trunk and lower-limb muscle activity, kinematics, and kinetics in nulliparous individuals.

Methods

Seven healthy nulliparous women (29.8 ± 3.1 years; 1.7 ± 0.1 m; 68.9 ± 12.0 kg) completed three semi-continuous lifting tasks (floor lift, car-seat lift from floor, and changing-table lift; Fig.1) using a newborn manikin (3.23 kg) and a weighted 3-month-old manikin (6.17 kg). 3D kinematics (150 Hz; Qualisys), ground reaction forces (1500 Hz; Bertec), and EMG (1500 Hz; Noraxon) were collected and processed in Visual3D and MATLAB. Descriptive statistics are reported.

Results



Lumbopelvic EMG and sagittal hip and knee mechanics were altered with task demand and infant weight. The floor lift required the greatest hip and knee flexion, extensor moments, and extensor power generation, along with the highest gluteus medius and lumbar erector spinae activation (Fig.1). Lifting from the changing table involved minimal hip and knee involvement and the lowest activation for all muscles. Lifting infants in a car seat introduced unique constraints due to the additional weight. The elevated handle height reduced lower-extremity flexion compared to the floor task, while producing the highest

gluteus maximus activation. Increasing infant weight increased activation across all muscles and variably affected joint moments. Hip extensor moments notably increased, while knee extensor moments remained largely unchanged [3].

Discussion

These findings highlight the demands of caregiving lifting tasks, and suggest biomechanical adaptations required as infants grow. As caregiver lifting demands continue into children's school-age years, the biomechanical differences observed with a modest ~3 kg increase are likely to become even more pronounced when lifting progressively larger loads. Future work will explore task-specific asymmetries and compare lifting mechanics with postpartum mothers.

The Effects of Driving and Whole-body Vibration on Upper Body Posture

Ms Sara Sagen BSc, Dr. Angelica Lang PhD

University of Saskatchewan, Saskatoon, Sk, Canada

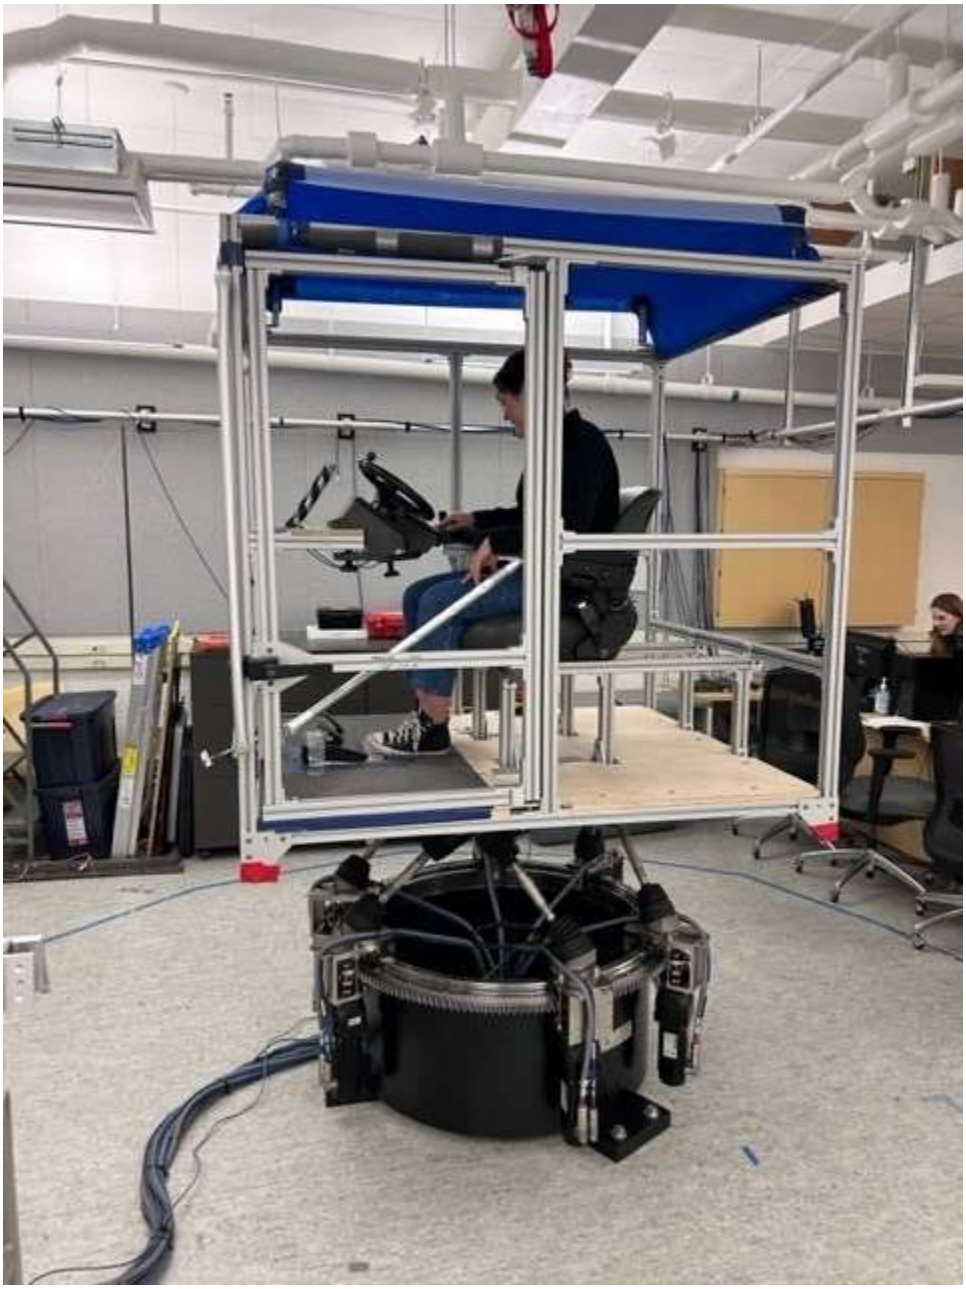
Introduction

Farm machinery operators are frequently exposed to whole-body vibration (WBV), contributing to musculoskeletal discomfort and altered postures during prolonged work. Although WBV is commonly associated with low-back pain, it is also an important risk factor for neck and shoulder pain, possibly due to amplified vibration at the head [1]. This increased transmission highlights the need to understand upper-extremity responses to WBV, which could further contribute to neck or shoulder injury. The objective of this study was to assess if simulated WBV exposure influenced driving postures over a 60-minute exposure.

Methods

Thirty participants (9 neck/shoulder pain; 6 asymptomatic) completed two 60-minute driving simulator sessions: stationary (non-WBV) and vibration (WBV). Upper-body joint angles were recorded using inertial measurement units; the mean joint angles were analyzed in 10-minute blocks, adhering to the International Society of Biomechanics standards. A mixed repeated-measures ANOVA was conducted with condition, joint and pain group as factors.

Results



WBV significantly altered joint angles only during the first 10 minutes. Compared with non-WBV, WBV increased neck rotation (+36.2°, $p < .001$), left humeral flexion (+28.3°, $p < .001$), and right elbow pronation (+24.8°, $p = .010$), while decreasing right humeral flexion (–34.3°, $p < .001$) and right humeral rotation (–33.8°, $p < .001$). At minute 20, only the right elbow pronation increased and persisted under WBV (mean +31.7°, $p=.008$). No WBV-related differences were observed beyond 20 minutes. The pain group did not influence postural responses.

Discussion

These preliminary findings indicate that WBV produces early deviations in upper-limb posture that diminish after the first 10 minutes, likely reflecting a habituation response in which the nervous system reduces upper-body stabilizing corrections as vibration becomes predictable. This pronated elbow posture may reflect participants using a rigid

forearm position to brace the upper body and stabilize the steering wheel. Together, these results suggest that early WBV exposure elicits postural adjustments that consolidate into localized distal stabilization strategies over time. Full-sample analysis will examine in-depth how WBV and postural changes influence the development of discomfort over the driving period.

Validation of Accuracy of an IMU-Based Machined Learning Classification Model for Detecting Injurious Patient Transfers in Healthcare Providers

Dr. Seyoung Lee PhD[1], Dr. Kitaek Lim PhD[1], Dr. Ohyun Kwon PhD[1], Dr. Chunghwi Yi PhD[1], Dr. Gwi-Ryung Son Hong PhD[2], Dr. Woochol Joseph Choi PhD[1]

[1]Yonsei University, Wonju, Kangwon, Korea, Republic of. [2]Hanyang University, Seoul, Seoul, Korea, Republic of

Introduction

Lower back injuries are common in healthcare providers, with frequent patient transfers recognized as a contributing factor [1,2]. Inertial measurement units (IMUs) are increasingly used as practical tools for analyzing movements related to injury risk [3,4], and IMU-based, injurious patient transfer detection system has recently been developed with young adults [5,6]. The objective of this study was to validate the accuracy of this system with healthcare providers.

Methods

Ten healthcare providers performed bed to wheelchair transfers while wearing five IMU sensors placed on both forearms, both upper arms, and the waist (Figure 1). Trials were acquired with different knee assist techniques, patient body masses, and manual versus mechanical lift. Transfers were classified as injurious when a compressive force at L5/S1 exceeded 3,400 N. A total of 95 trials (75 injurious and 20 non-injurious transfers) were used to test accuracy of the developed model. To address class imbalance, the training set was up-sampled. A nonlinear SVM with an RBF kernel (LIBSVM) [7] was optimized via grid search and five-fold cross-validation. Eighteen features (mean and variance of tri-axial acceleration, linear and angular velocities) were extracted from IMU signals. Model performance was evaluated across five sensor configurations and 25 combinations of lead time and window size.

Results

Depending on the sensor configuration, the accuracy for distinguishing injurious from non-injurious patient transfers ranged from 85.0% to 86.4%, while specificity ranged from 54% to 58%. Sensitivity remained consistently high at 100% across all configurations (Table 1).

Discussion

Our findings suggest that the IMU-based, injurious patient transfer detection system demonstrates potentials for practical use among healthcare providers in real-world settings. Specificity remained consistently low (54-58%) across all sensor and temporal parameter combinations, indicating that mean- and variance- based IMU features effectively detect injurious patterns but have limited ability to characterize non-injurious transfers.

Evaluation of Musculoskeletal Human Models for Overhead Tasks With Shoulder Exoskeleton–a Preliminary Study.

Ms Shantha Sindhu Pudhota, Dr David Scherb, Prof Robert Weidner

Technische Universität Bergakademie Freiberg, Freiberg, Sachsen, Germany

Introduction

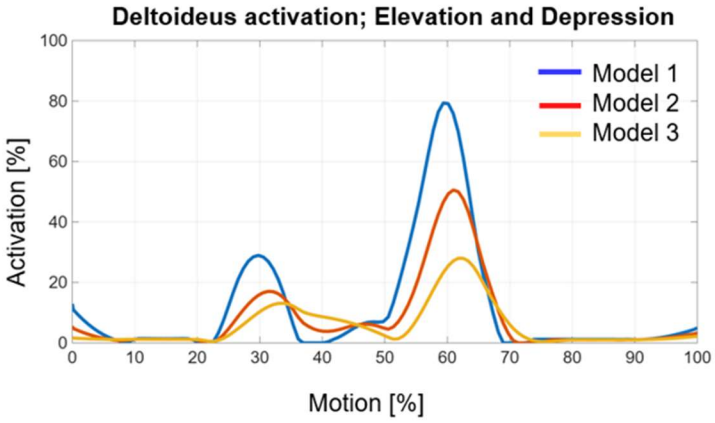
Overhead manual tasks elevate glenohumeral loading and rotator cuff fatigue, increasing the risk of work-related musculoskeletal disorders. Occupational exoskeletons mitigate these demands by applying external supportive torque to reduce shoulder loading. Due to the biomechanical influence of exoskeleton support, musculoskeletal human models are often used to simulate these effects, which enables the derivation of design implications and support adjustments. However, current models are not specifically designed for exoskeleton interaction, leading to high variability in simulation. Therefore, the aim is to develop a musculoskeletal human model in OpenSim specifically designed for simulations with shoulder exoskeletons; this preliminary study involves the initial evaluation of different created models using defined use cases.

Methods

Three healthy participants execute two standardized tasks (overhead drilling and bilateral overhead lifting) under unsupported and exoskeleton-supported (exoIQ S700) conditions. Data acquisition included whole-body kinematics and surface electromyography(sEMG) of the upper body musculature. Three created OpenSim musculoskeletal human models are used to simulate the biomechanical effects of the exoskeleton support for each participant. Model suitability is assessed by comparing the simulations results with captured data (e.g. muscle activation) and literature findings (e.g. joint reaction forces).

Results

The results demonstrate consistent directional effects across models: reductions in predicted deltoid and rotator cuff activity and lower glenohumeral joint reaction forces in the exoskeleton condition. Nonetheless, considerable variability is observed between models, primarily in the timing and magnitude of muscle activation and differences in the size of the simulated exoskeleton stress-reduction effect (Figure 1). One model proved most accurate and stable, consistently producing smoother muscle activity results, confirming its greater suitability for simulating human-exoskeleton interaction.



Discussion

The study indicates that while all evaluated models capture the expected unloading effect of the exoskeleton, their simulation fidelity varies substantially. This preliminary work has provided valuable insights by identifying models capable of better replicating the biomechanical behavior of human-exoskeleton support systems. This identification is essential for designing the forthcoming large-scale study, which will encompass an expanded user group, additional task types, and multiple exoskeleton configurations. The present findings provide the methodological foundation and initial selection criteria for future validation of the most suitable model for systematic exoskeleton simulation.

Worker Perception and Lifting Behaviours in Hospital Laundry Handling

Ms. Teresa Lau[1,2], Dr. Carolyn Sparrey[1,2]

[1]Simon Fraser University, Surrey, British Columbia, Canada. [2]International Collaboration on Repair Discoveries (ICORD), Vancouver, British Columbia, Canada

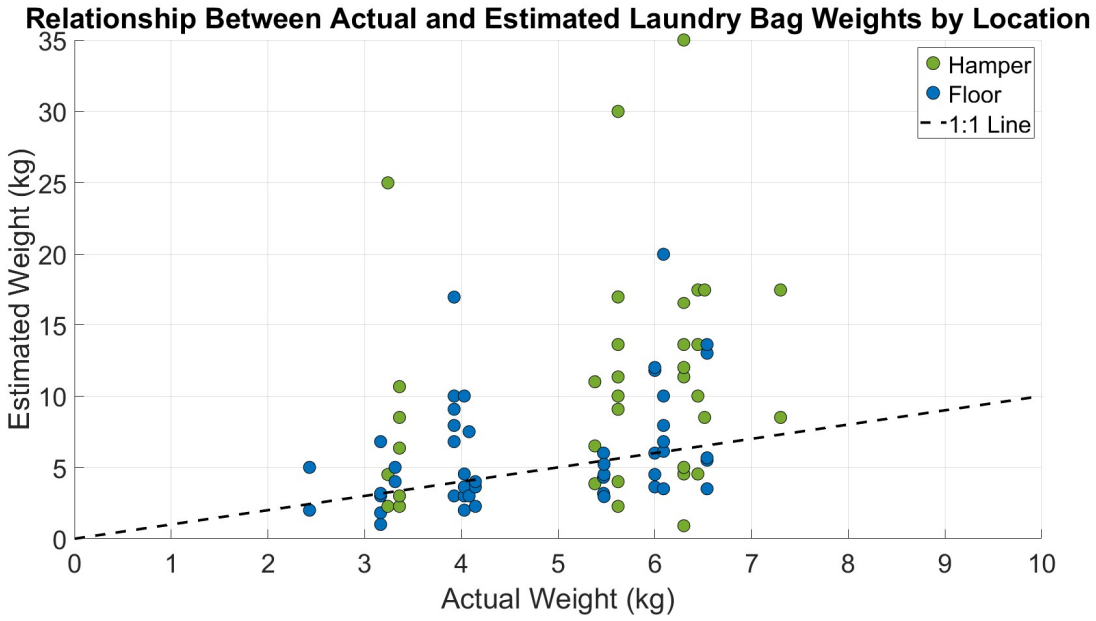
Ms. Teresa Lau

Introduction

Overexertion is the leading cause of musculoskeletal injuries among hospital workers, accounting for nearly half of all injury claims in British Columbia and costing over $172 million in the last ten years [1]. While laundry handling is not traditionally classified as high-risk, hospital support staff routinely perform lifts involving awkward postures and unpredictable loads. Current ergonomic guidelines recommend a safe lifting limit of 5-6 kg for two-handed lifts [2]. However, real-world hospital demands may not always reflect these assumptions. This study characterized the biomechanical demands and perceptual biases of laundry bag handling among non-laundry healthcare staff to identify system-level contributors to overexertion risk.

Methods

27 hospital support aide workers participated in an observational task analysis and a structured load perception activity. Common lifting behaviors were noted during naturalistic observation sessions, and the weight of handled laundry bags were recorded. In the perception activity, participants estimated pre-weighed laundry bags presented in two conditions: tied bags on the floor and untied bags in standard hospital hampers. Descriptive statistics summarized weight perception trends and general lifting behaviours.



Results

Across all participants, laundry bags placed inside hampers were systematically overestimated. Bags in hampers showed an average error of approximately +100%, while bags on the floor showed smaller but consistent overestimation. Most bags handled during observation sessions weighed under 3 kg, below the safe lifting limit. Of those lifts, approximately 73% involved semi-stooping, asymmetrical, or one-handed postures, and these patterns were consistently observed across multiple sessions.

Discussion

The results show a clear mismatch between actual and perceived laundry bag weight, particularly for bags stored in hampers without clear load indicators. Participants also commented that bags “looked heavier than they actually feel,” aligning with the overestimation trends observed. These perceptual mismatches may influence how workers approach lifting tasks and help explain the frequent use of non-neutral postures, despite handling lighter loads. This behaviour contrasts assumptions in standard ergonomic guidelines for two-handed lifts, highlighting a gap between standard guidance and real-world practice. Addressing system-level factors, like improving hamper design and load transparency, could help reduce overexertion risk.

Load-Displacement Behavior of Running Specific Prostheses: In-Vivo vs Machine Testing

Mr. Abed Khosrojerdi M.Sc., Dr. Isaac Kumi Ph.D., Ms. Paige Agnew M.Sc., Dr. Amit Kulkarni Ph.D., Dr. Hunter Bennett Ph.D., Dr. Stacie Ringleb Ph.D.

Old Dominion University, Norfolk, Virginia, United States

Mr. Abed Khosrojerdi

Dr. Isaac Kumi

Ms. Paige Agnew

Dr. Hunter Bennett

Introduction

The design and mechanical properties of running specific prostheses (RSPs) influence athletic performance. The only guidance given on how to select the best RSP is simply based on the user's mass. Researchers have investigated mechanical properties using laboratory testing. However, standard machine testing does not load RSPs the same way they are loaded in-vivo. The objective of this study was to compare load–displacement behavior of RSPs measured in-vivo during running with values obtained from a material testing machine.

Methods

Three individuals with lower limb amputations (two transtibial, one transfemoral) wearing RSPs rated for their mass (small, medium, and extra-large) participated in the study. Participants ran at self-selected pace over an 18m walkway. Data were acquired using a 12-camera Vicon system with three synchronized force plates. Prosthesis deformation during stance was quantified during loading and unloading phases. Peak ground reaction

force (GRF) and load-displacement curves were derived from force plate data using custom MATLAB code (R2023a, MathWorks, Inc.).

An MTS machine applied a load equivalent to twice the minimum and maximum manufacturer-specified weight the RSPs at a rate of 6 mm/s. Load-displacement curves were generated using custom MATLAB code.

Results

Hysteresis curves from in-vivo and MTS testing demonstrated similarities in loading for the transtibial amputees (Figure a and c). The in-vivo and laboratory testing were dissimilar in unloading. Specifically, unloading showed more hysteresis for all participants, possibly because the MTS machine loaded and unloaded vertically, while in-vivo data included loading through the motions of the stance phase.

Discussion

All prostheses displayed hysteresis loops indicating energy dissipation. In the transfemoral amputee, the behavior was not similar to the MTS in loading or unloading. This difference may be due to the additional influence on dynamics from the computerized knee. Thus, the energy return of RSPs is difficult to predict with the MTS machine for transtibial amputees, and material testing may not provide insight into the behavior of RSPs for transfemoral amputees. Future studies should include a larger, more diverse participant cohort with various amputation types and adjust MTS loading rates to better simulate in-vivo deformation rates during running.

Enhancing Upper Extremity Rehabilitation's Engagement & Quality in Children with Cerebral Palsy by Integrating BCI-HABIT-VR: A Feasibility Study

Ms. Mobina Masaei, Dr. Ahad Behboodi

University of Nebraska at Omaha, Omaha, Nebraska, United States

Introduction

Cerebral palsy (CP) is the most prevalent neurological disorder, permanently altering motor function, and frequently produces upper-limb deficits that constrain function. Hand and Arm Bimanual Intensive Therapy (HABIT) has demonstrated efficacy in improving manual ability in this population, but is often limited by task repetitiveness and reduced participant engagement. Brain-Computer Interface Neurofeedback Training (BCI-NFT) is another strategy coupling cortical motor signals with contingent sensory feedback (e.g., neuromuscular electrical stimulation (NMES)) to augment cortical activation and drive neuroplasticity. This study introduces BCI-HABIT-VR, a novel, gamified upper limb rehabilitation approach that integrates BCI-NFT with the HABIT-VR framework to enhance engagement and therapeutic outcomes in children with CP, using participant feedback as the primary outcome. This is the first BCI-NFT camp for children with CP.

Methods

Four children with hemiplegic or diplegic CP (ages 10-14) participated in a two-week intensive VR camp comprising 40 total training hours. During each session, participants wore a VR headset and an EEG cap while engaging in the BCI-HABIT-VR game. The primary task involved extending the more affected arm to target aliens and propel a virtual rocket, during which NMES was applied to the extensor digitorum communis to assist movement. Continuous EEG was processed to detect motor intention; detection events triggered closed-loop NMES applied to the extensor digitorum communis to assist volitional movement. Each participant completed at least 50 task repetitions per day with BCI-mediated NMES activation (BCI-NFT). Feasibility and user experience were assessed after each session using a 7-point questionnaire developed by the clinical team.

Results

Questionnaire responses indicated 'Game Fun' received the highest score (M=6.34), while 'EEG Comfort' was the lowest (M=3.61), below the midpoint of 4 (Figure 1). Other metrics scored in the moderate-to-high range.

Discussion

In this small cohort, BCI-HABIT-VR proved deliverable within an intensive camp and was well received, notably enhancing game-based engagement- an important mediator of adherence in repetitive upper-limb therapies. Suboptimal EEG comfort underscores the necessity for improved cap ergonomics and tolerability prior to broader implementation. These preliminary findings support feasibility and warrant further investigation in larger, controlled trials emphasizing both efficacy and hardware optimization.

Images (Optional)

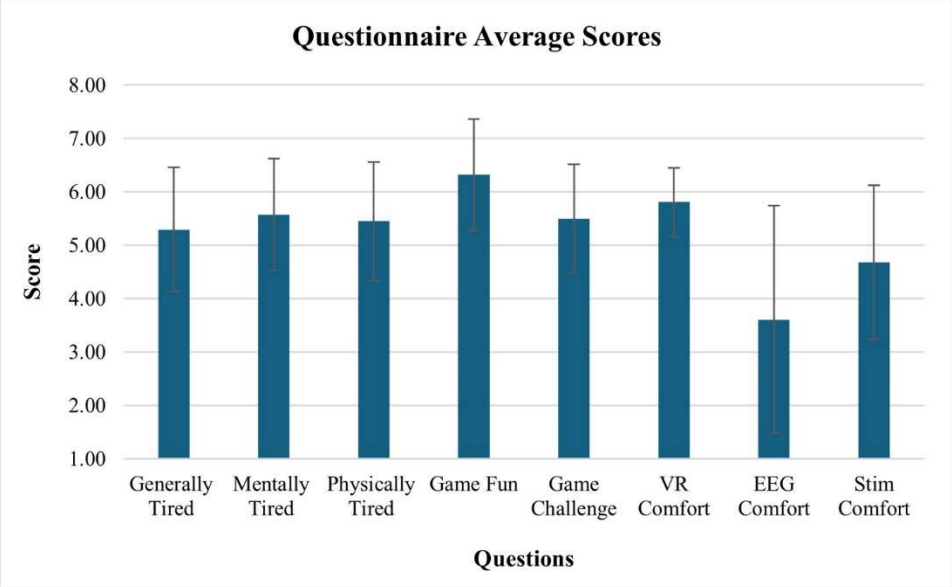

Figure 1. Items on the questionnaire assessed general, mental, and physical fatigue, as well as their enjoyment of the game, its difficulty, and their comfort with the VR headset, EEG cap, and stimulus. Mean scores and standard deviations for each item on the questionnaire across all subjects. Participants rated their experience after each day on a 7-point scale across categories related to tiredness, game experience, and comfort with the equipment. The results indicate a positive reception for game-related items and a lower comfort level with the EEG cap.

Biomechanical Evaluation of a novel Dental Implant Design

Dr. Ahmed Fouda, Dr. Ludger Keilig, Dr. Christoph Bourauel

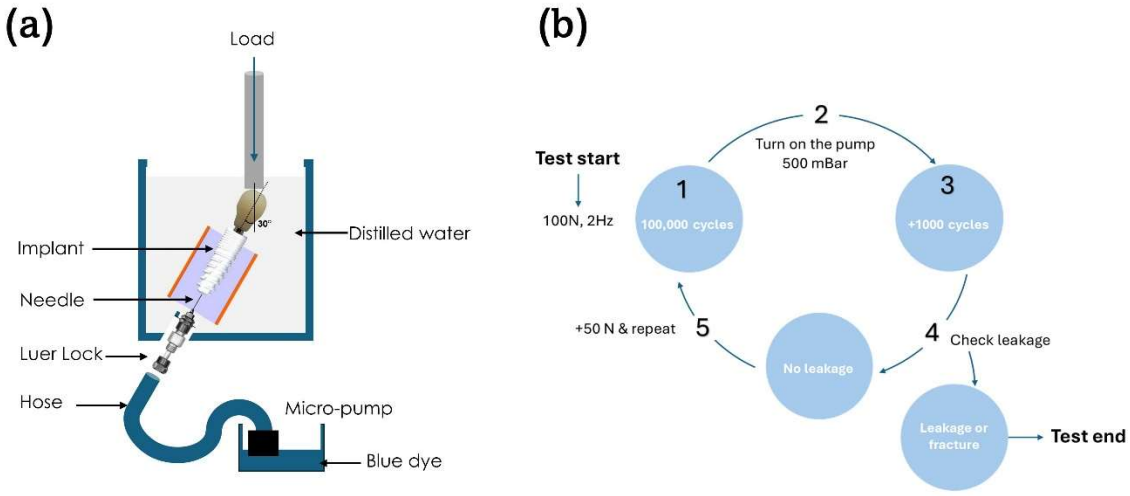
University Hospital Bonn, Bonn, NRW, Germany

Introduction

Recent advancements in implant technology have led to a wide range of dental implants available on the market. A crucial factor that influences the success of dental implants is the stability of the implant-abutment interface. An unstable connection can create micro-gaps at the interface, leading to microbial leakage and potential biological complications. To overcome the biological complications caused by an unstable implant-abutment interface, a new implant design featuring an external conical connection was developed. This design aims to establish a stable, gap-free junction between the implant and either titanium abutments or abutment-free restorations. The objective of this study is to evaluate the microleakage and micromovements at the Implant/Suprastrucure Junction under load.

Methods

An experimental conical connection design between the implant and suprastructure was proposed and prototypes were produced from titanium alloy. Two suprastructures were tested: Titanium Abutment (TiAbt) and Zirconia Abutment-free crown (ZrAbt-free). For the micromovement test, 20 implants were produced (n=10), patterned, and mounted to a universal testing machine (Zwick) then loaded from 0-200N with step size of 25N. A 3D Aramis scanner system was used to record micromotion under load. The angle between the implant and suprastructure was calculated using Direct Image Correlation on GOM software (Zeiss, Switzerland). A total of 12 specimens were used for the microleakage test (n=6) . The implants were drilled up to the screw level and connected to a peristaltic pump and blue dye reservoir. The test setup and procedures are explained in Figure 1.



Results

The mean deviation angle between implant and ZrAbt-free crown was 0.14 ±0.06 degree at 25N and 1.97 ±0.36 degree at 200N, while for the TiAbt group, it was 0.02 ±0.01 degree at 25N and 0.58 ±0.1 degree at 200N. The microleakage results revealed that all the specimens showed no leakage under loading. The mean failure force of TiAbt group was 300N, while ZrAbt-free group had mean fracture force of 200N.

Discussion

The experimental implant design showed a stable junction between implant and suprastructure in both tested groups. The connection to Ti abutment was more stable than Abutment-free Zirconia. In the future, the design will be tested with different material combinations.

Mechanical Evaluation of a Novel Dynamic Shoulder Orthotic for Post-Stroke Subluxation

Miss Aliki Statiri, Dr. Angela Kedgley

Imperial College London, London, UK, United Kingdom

Introduction

Shoulder subluxation is a prevalent secondary complication for stroke survivors, affecting 17-81% of that population [1]. Treatment may include physiotherapy, FES, and external supports. Dynamic shoulder orthotics utilise elastic components to realign and support the glenohumeral joint (GHJ). This study aimed to assess the performance of a novel device featuring springs of different stiffness in 1) offloading the GHJ and 2) achieving unrestrained movement during the range of motion (RoM) typical of activities of daily living.

Methods

A custom-made orthotic was fit to a model shoulder that allowed 2 cm inferior subluxation (Figure 1a). The RoM was defined as 0-70° in both flexion and abduction [2]. A linear actuator created arm elevation. A loadcell was used to assess if the device impeded movement by measuring the force required to rotate the arm through the RoM. A second loadcell measured the vertical force on the arm across the RoM to determine the support provided by the device. Ten repetitions of four conditions were tested: three springs (k=0.416, 0.51, 1.019 N/mm) and no device (control).

Results

The device was fully weight-bearing from 0-30° flexion (Figure 1b) and 0-55° abduction (Figure 1c) for all springs. For the remaining RoM, partial weight bearing was found, except for the stiffest spring for 50-70° flexion (Figure 1b). The device did not impede the motion in any testing condition, as the horizontal elevation force matched the control throughout the RoM.

Discussion

The most compliant springs provided the best overall support. The reason was that arm rotation led to a decrease in spring deformation. This explains why softer springs can provide partial support for the whole range, whereas stiffer springs, which required smaller deformation to carry the weight of the arm, lose functionality for higher arm elevation angles. These results highlighted the effect that spring constant has on this novel device and importance of pre-clinical testing of orthoses across the full functional range.

EMG and Force Biofeedback Alter Rotator Cuff Muscle Activation During Constant-Force Isometric Shoulder Abduction

Graduate Student Alireza Chalik MASc[1], Professor Arash Arami Associate Professor[1,2], Professor Clark Dickerson Professor[3]

[1]Department of Mechanical and Mechatronics Engineering, University of Waterloo, Waterloo, Ontario, Canada. [3]Department of Kinesiology and Health Sciences Faculty of Health University of Waterloo, Waterloo, Ontario, Canada

Graduate Student Alireza Chalik

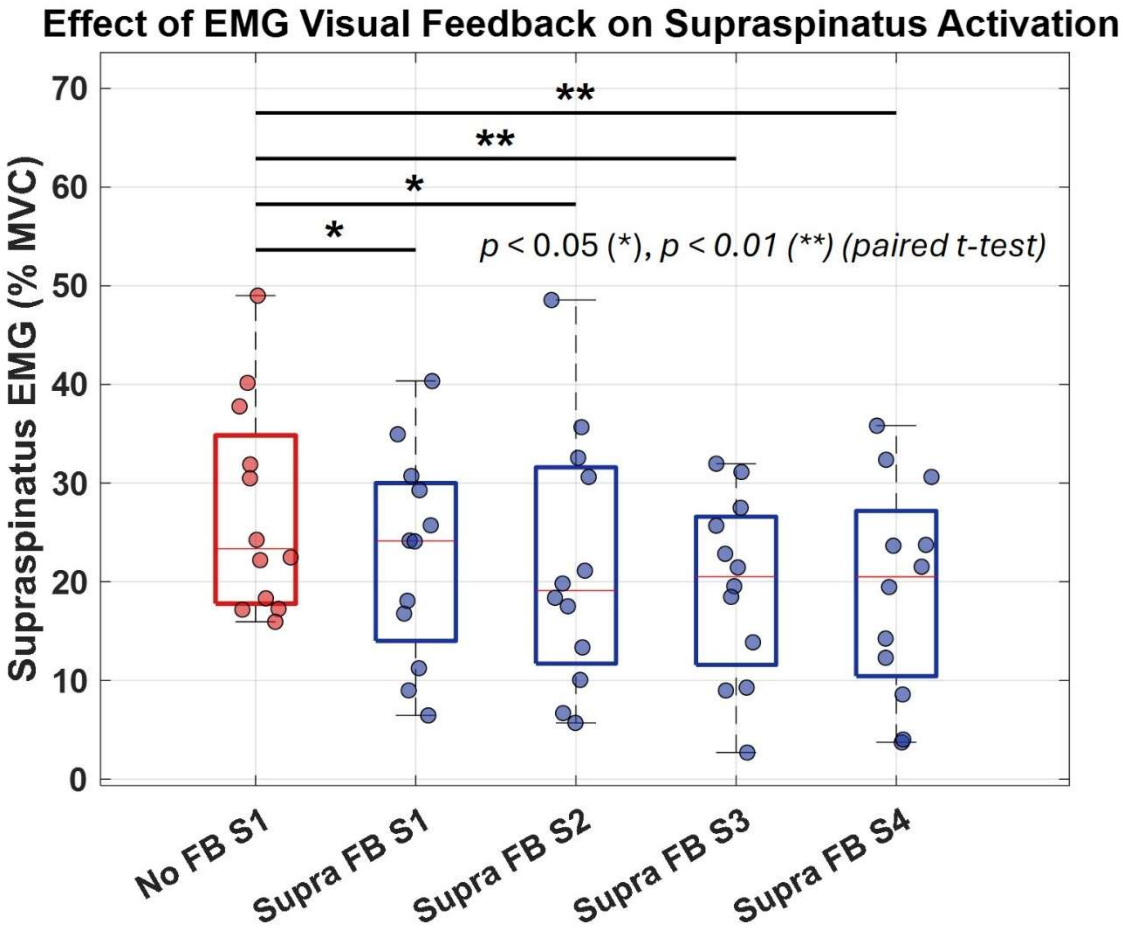
Professor Arash Arami

Introduction

Rotator cuff tears, especially of the supraspinatus, are common and prone to re-tear[1]. Early rehabilitation exercises may overload the healing tendon. We investigated whether an EMG- and force-guided isometric abduction task could promote alternative coordination patterns that selectively reduce supraspinatus activation while maintaining a constant abduction force [2].

Methods

Twelve healthy adults completed four sessions. Participants performed isometric shoulder abduction while gripping a 6-axis force sensor. On Day 1, each participant generated an abduction effort equal to 30% of their middle-deltoid MVC, and the resulting force was used as their personal target force for all remaining blocks and sessions. Real-time visual feedback was provided using a 2D cursor: the vertical axis represented force relative to this target, and the horizontal axis represented supraspinatus EMG (%MVC). Each daily session included 1 baseline block (no EMG feedback)(12 trials) and 4 EMG–force training blocks (12 trials each). Participants were instructed to move the cursor by applying the target force while minimizing supraspinatus activation. The RMS of filtered EMG(normalized to MVC values obtained at each session) during the force-holding period was used.



Results

Force direction and magnitude remained stable across days. Supraspinatus activation showed significant decreases with training in all sessions. The largest reduction occurred on Day 4, Block 5, where supraspinatus RMS decreased from 27.25% MVC (baseline) to 19.18% MVC ($p = 0.007$). Block-level reductions were also evident within days: on average, supraspinatus decreased by around 3.8%MVC per day, corresponding to 14% relative reductions from the first to the last block of a session. Across all participants and sessions, supraspinatus EMG variability decreased by around 20%, indicating more consistent suppression. Other muscles showed minimal change: mid-deltoid decreased by about 3%MVC across days, and anterior/posterior deltoid, infraspinatus, and upper trapezius changed by ≤2%MVC, demonstrating selective modulation rather than global reductions.

Discussion

Participants learned to reduce supraspinatus activation while maintaining a constant abduction force. These findings demonstrate that EMG-based biofeedback can reshape shoulder muscle coordination and may support tendon-protective strategies during rehabilitation.

Dr. Angie Meloy

Dr. Joy Cochran

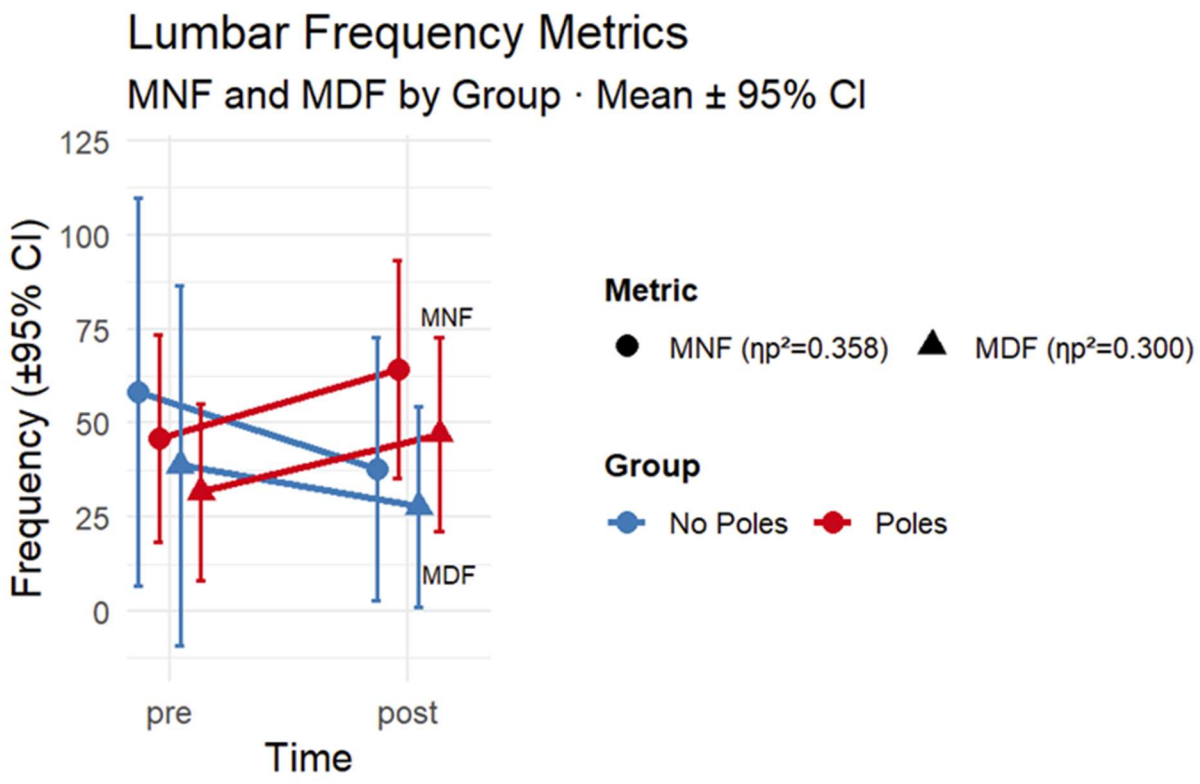
Mr. Patrick Roscher

Introduction

Postural dysfunction is a common debilitating feature of Parkinson Disease (PD) and associated with poor neurophysiological function across supporting postural muscles. Pole walking has emerged as an innovative approach that may enhance upright posture and address these dysfunctions. This pilot study aimed to evaluate the feasibility and effectiveness of an 8-week independent pole walking program on gait characteristics.

Methods

This was a randomized controlled single blinded pilot analysis on males and females with PD. Subjects were evaluated before and after an 8-week independent walking program with or without walking poles. Surface EMG sensors were placed on lumbar and cervical extensors. Postural gait characteristics were derived from IMUs on the thoracic spine and arms. Pre- and post-intervention data were analyzed using two-way repeated measures ANOVA with “group” and “time” as independent factors. Alpha was set to 0.05 and ηp2 was calculated for effect size (small = .01, medium = .06, large = .14).



Results

11 subjects participated in the study (6 intervention, 5 controls). There were no significant differences in electromyographic or postural characteristics. Inferential analysis revealed moderate effect sizes for “time” in cervical extensor mean frequency (ηp2 = 0.092; MNF) and peak power (ηp2 = 0.105). There were large effect sizes for interactions between groups pre and post intervention in lumbar extensor MNF (ηp2 = 0.358) and median frequency (ηp2 = 0.30; MDF). Subjects in the intervention group increased across all lumbar power spectrum metrics post intervention while control subjects decreased (Figure 1). There were moderate effect sizes for “time” in thoracic forward tilt (ηp2 = 0.118) and shoulder flexion (ηp2 = 0.095) and interactions between groups pre and post intervention in thoracic rotation (ηp2 = 0.078).

Discussion

This pilot trial demonstrated that standard walking and pole walking were associated with improvements in postural alignment and muscle activity in individuals with PD, supporting the safety, feasibility and effectiveness of independent walking programs. Effect size patterns suggest that pole walking specifically may provide additional postural and neurophysiological benefits. These findings warrant further investigation in larger, fully powered studies to confirm and expand upon the potential advantages of pole walking as a rehabilitative strategy.

Effect of Simulator Rolling Resistance Compensation on Manual Wheelchair Propulsion Biomechanics

Ms. Ateayeh Bayat[1,2], Prof. Félix Chénier[3,2]

[1]Department of Systems Engineering, École de technologie supérieure, Montreal, QC, Canada. [2]Centre for Interdisciplinary Research in Rehabilitation of Greater Montreal (CRIR), Montreal, QC, Canada. [3]Department of physical activity science, Université du Québec à Montréal (UQAM), Montreal, QC, Canada

Introduction

Manual wheelchair simulators use dynamic models to control velocity based on user-applied force and system parameters, including rolling resistance. However, a portion of this resistance originates from the simulator's own mechanics (e.g., roller–wheel interface friction). This study investigates how two levels of simulator rolling resistance compensation—intended to neutralize this inherent friction—influence propulsion biomechanics during standardized wheelchair tasks.

Methods

Desired rolling resistance coefficients ($\mu_{desired}$) were defined for straight-line (0.01325) and ramp (0.024) surfaces. To replicate these accurately, the simulator's inherent resistance (μ_{sim}) must be deducted from the model. Coast-down tests established two compensation levels. The "one-step" configuration deducted the initially measured μ_{sim} of 0.00474. To achieve a target of zero difference between defined and simulated resistance, a second calibration yielded a total μ_{sim} of 0.0098, defining the "two-step" configuration.

Seven able-bodied participants performed straight-line and ramp propulsion tasks under both compensation settings (One-step vs. Two-step). Participants attempted to match their overground average velocity using real-time feedback. Biomechanical metrics were extracted from acceleration (ACC), constant-speed (CST), and ascending (ASC, 5.2° ramp) segments using the 10 most repeatable pushes.

Results

Despite a near two-fold difference in compensation, applied forces and moments remained similar across conditions. However, actual velocities deviated from targets. Key findings (Table 1) indicate large effect sizes in ACC and CST velocities and ACC push time. Moderate effects were noted for CST cadence and recovery time, ACC M_z, and ASC

push/recovery time. Notably, the number of collisions was lower in the one-step calibration (0.57±0.53) compared to the two-step (1.57±1.27), suggesting improved control under the higher net resistance of the one-step condition.

Discussion

Results suggest that user effort is not linearly driven by rolling resistance in virtual environments, in contrast to overground conditions. This deviation may stem from reduced physical feedback or altered effort perception not present in real-world settings. While force profiles remained stable, participants reported improved control and self-perception under the higher resistance (one-step). This underscores the role of perceptual and proprioceptive feedback (e.g., vibration, trunk involvement) in simulator realism, which should be integrated alongside mechanical optimization.

Images (Optional)

TABLE I. Mean, standard deviation (SD), and effect size comparing one-step vs. two-step rolling resistance calibration for key propulsion metrics. Effect sizes are interpreted per Cohen's convention: orange indicates moderate effects, and red indicates large effects.

Evaluation of the Advanced System for Implant Stability Testing (ASIST) for Measuring Bone Anchored Hearing System (BAHS) Implant Stability Using Polyurethane Foam

Mr. Boyu Pan[1], Dr. Mostafa Mohamed[1], Dr. Martin Johansson[2,3], Dr. Anders Palmquist[2], Mr. Thomas Eriksson[3], Dr. Dan Romanyk[1], Dr. Mustafa Gül[1], Dr. Lindsey Westover[1]

[1]University of Alberta, Edmonton, Alberta, Canada. [2]University of Gothenburg, Gothenburg, Västra Götaland County, Sweden. [3]Oticon Medical AB, Gothenburg, Västra Götaland County, Sweden

Introduction

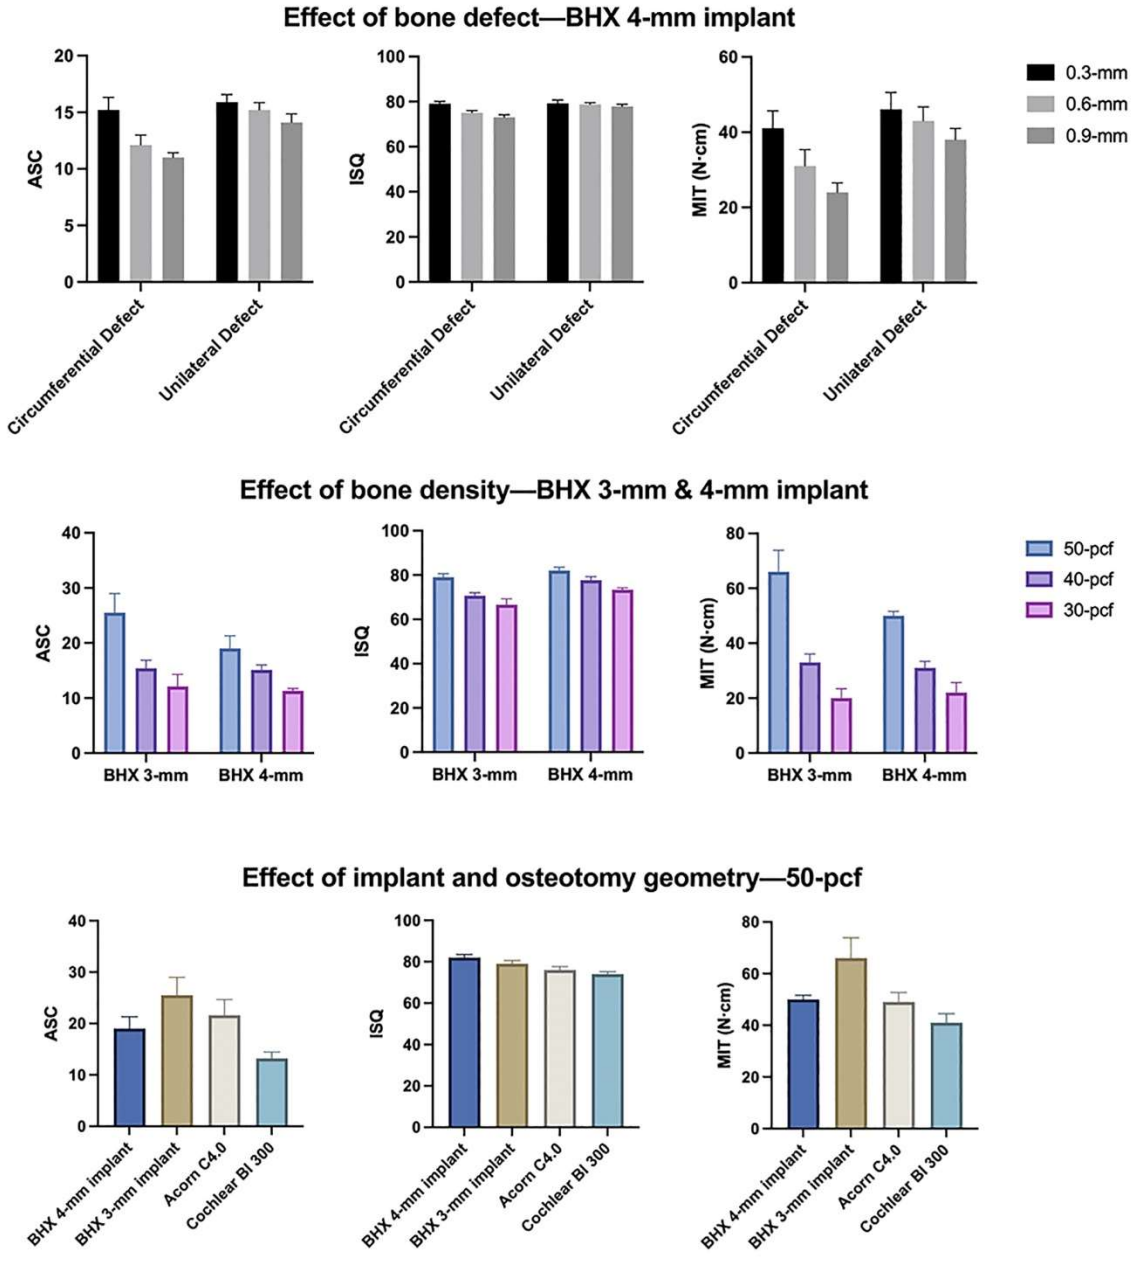
The ASIST is a non-invasive system designed to measure implant stability by analyzing the vibration response of the implant system. Clinically, infections, bone resorption, and bone defects may occur around Bone Anchored Hearing System (BAHS) implants due to poor initial bone quality, postoperative infections, and inflammation. The objectives of this study were to evaluate ASIST in BAHS, to assess its sensitivity to variations in polyurethane foam defects surrounding the implants, and to evaluate the primary stability of several clinically used BAHS implants in polyurethane foam with different densities.

Methods

Four types of BAHS implants—Ponto BHX (3-mm and 4-mm), Acorn C4.0, and COH BI300 (4-mm)—were placed into polyurethane foam blocks with different densities following their respective surgical procedures. Primary stabilities were assessed using the maximum insertion torque (MIT), Implant Stability Quotient (ISQ), ASIST Stability Coefficient (ASC), and maximum pull-out force. Two defect configurations, unilateral and circumferential, were created in the foam blocks at depths of 0.3-, 0.6-, and 0.9-mm. For the unilateral defect, ISQ and ASC were obtained in four mutually perpendicular measurement directions, one of which aligned with the center of the unilateral defect.

Results

Figure 1 presents the ASC, ISQ, and MIT results. Pull-out tests are ongoing, and their findings will be reported at the conference. Regarding unilateral defects, no significant differences were observed in ASC or ISQ across the four directions (p>0.05).



Discussion

Greater bone defect severity reduced implant stability. The BHX 4-mm exhibited the most pronounced stability change between no defect and a 0.3-mm defect, compared with other 0.3-mm defect increments, which can be attributed to compression between the flange-

neck region and the osteotomy cavity. Increased bone density enhanced stability. The BHX 3-mm demonstrated higher stability than the BHX 4-mm owing to its osteotomy diameter being 0.1 mm smaller. Although ACORN is shorter than the BHX 4-mm, the former's more aggressive geometry resulted in comparable stability. The BI300, with the largest osteotomy diameter, exhibited the lowest stability.

ASC is more sensitive to the bone defects, density and implant and osteotomy geometry compared with ISQ. Furthermore, for unilateral defects, the measurement direction has no effect on ASC and ISQ.

Tracking Medial Gastrocnemius-Achilles Musculotendinous Junction Excursion During Walking and Bilateral Heel Rises

Miss Camille Nguyen M.Sc., Dr. Karin Gravare Silbernagel PT, ATC, PhD, Dr. Stephanie G. Cone PhD

University of Delaware, Newark, Delaware, United States

Introduction

The Achilles tendon is connected to the muscles of the triceps surae by three individual subtendons enabling ankle plantarflexion, importantly these subtendons may be differentially affected with injury. Tracking muscle-tendon junction (MTJ) excursions during dynamic motion is needed to improve researcher and clinician understanding of Achilles tendon function in activities of daily living and in rehabilitation. This pilot study aimed to establish ultrasound methods to measure medial gastrocnemius (MG) MTJ excursion during functional rehabilitation tasks in healthy individuals.

Methods

Four participants (4 female, 28±4.4yrs, 163±5.0cm, 67.7±16.9kg) with no history of lower extremity injury in the last 6 months were evaluated. Ultrasound imaging was performed to identify the superior calcaneal notch and MG MTJ of the dominant leg [1], and free tendon length was measured. A ProbeFix holder with a VScan Air transducer was affixed while the participant was standing over the MTJ [4]. Three, 10-second ultrasound videos were captured during treadmill walking at 3 miles per hour. Participants completed 30 repetitions of bilateral heel rises on a 10 degree incline while two, 10-second ultrasound videos of the MTJ were captured. The distance between most distal and proximal MTJ locations were measured in Kinovea and reported as MTJ excursion. A paired t-test was used to compare excursions between tasks.

Results

Significant differences were found between walking and heel rise activities ($p<0.05$, Table 1). Mean excursion values were significantly higher during bilateral heel rise activity (1.45±0.16cm) compared to walking (0.77±0.04cm) across all subjects. Variable excursions emerged between subjects despite similar participant heights (Table 1).

Discussion

This study establishes a wearable ultrasound method to quantify the excursion of the Achilles-medial gastrocnemius MTJ during clinically important movements. A cordless probe afforded participant mobility, although experimental challenges with low (10Hz) sampling frequency were observed which may lead to challenges accurately quantifying higher velocity tasks. Additional challenges were experienced measuring tendon excursions in taller subjects, motivating future studies implementing probes with longer imaging footprints.

P2-300

Comparing Distal-to-Shank Force, Displacement, and Work Profiles Between Prosthetic and Intact Limbs

Miss. Chelsea Haddy B.A.Sc., Dr. Jenna Burnett Ph.D, Dr. Kota Takahashi Ph.D

University of Utah, Salt Lake City, Utah, United States

Introduction

Passive prostheses act as springs to store and return energy, but they are unable to generate energy (i.e., net positive work). This inability has often been considered a limitation for replicating biological limb function during walking. However, the biological structures distal to the shank (i.e., foot and ankle) reveal notable spring-like behaviour, including ground reaction force (GRF) and center-of-pressure (COP) displacement profiles that result in nearly zero net work [1]. Whether the distal-to-shank spring-like behaviour can be replicated in passive prostheses remains unknown. Thus, we compared the distal-to-shank mechanics (COP, GRF, and work) of prosthetic and biological limbs during walking.

Methods

Nine individuals with unilateral transtibial amputation (7M/2F, 42.2±13.4 years, 82.1±13.6 kg) walked on an instrumented treadmill (1.0±0.2 m/s) while wearing a passive prosthesis. COP and GRF data were transformed into the shank's coordinate system. We used a unified-deformable segment analysis [1] to quantify power and work due to all structures distal to the shank. Paired t-tests compared prosthetic and intact distal-to-shank work. Data from healthy controls (10M/11F, 26.6±3.9 years, 69.3±9.3 kg) served as reference.

Results

There were no significant differences between prosthetic versus intact limbs in positive work (0.17±0.07 J/kg, and 0.16±0.09 J/kg; p=0.746) and negative work (-0.18±0.08 J/kg, and -0.14±0.04 J/kg; p=0.217), while healthy controls had similar or decreased magnitudes of positive and negative work (0.19±0.07 J/kg and -0.13±0.03 J/kg), respectively. The COP and GRF relative to the shank exhibited spring-like mechanics in all limbs, as evidenced by longitudinal compression and recoil (Figure 1). Notably, the prosthetic limb had GRF directed longitudinally in early stance compared to intact limbs.

Discussion

Individuals with unilateral amputation had symmetrical distal-to-shank work profiles, likely due to the utilization of spring-like properties of elastic prostheses. The prosthetic limb had

altered GRF direction in early stance, possibly as a strategy to deform the spring. Understanding the altered loading patterns in prosthesis users may inform rehabilitation strategies and improve prosthetic designs.

Images (Optional)

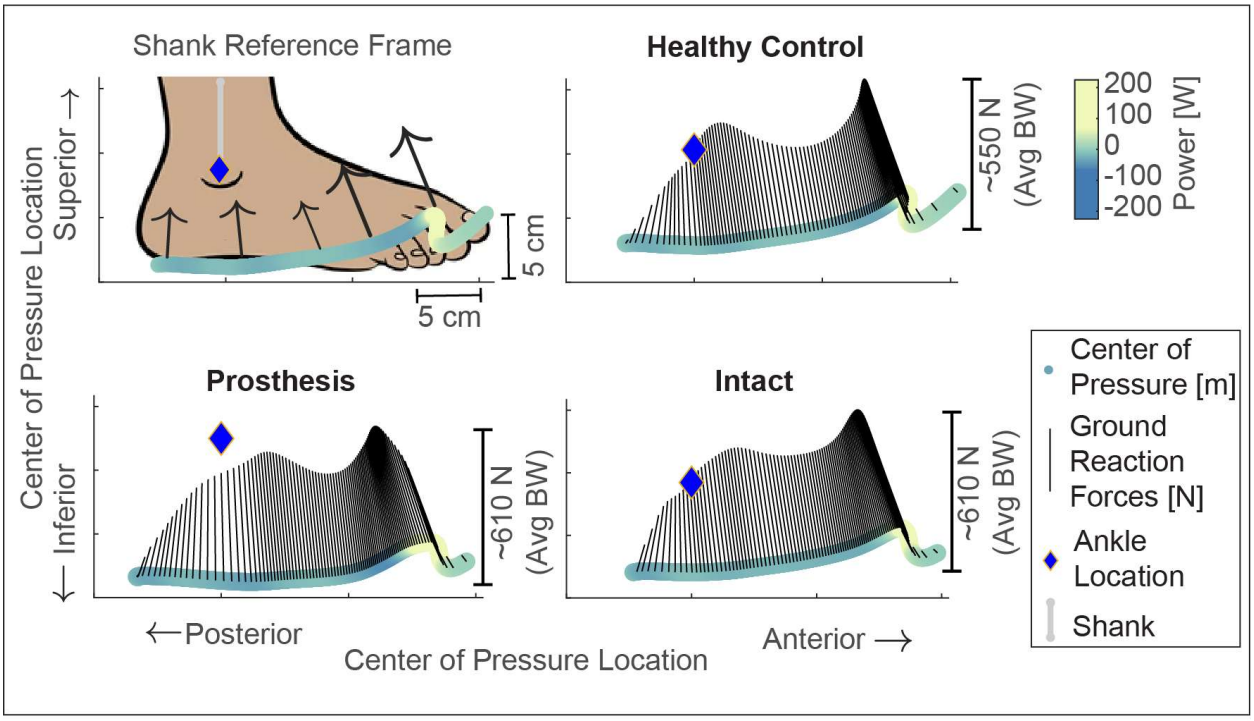

Figure 1: The top left panel shows an example of the shank's reference frame used to express the COP and GRF in all panels. The colour gradient on the COP trajectory indicates the instantaneous power (distal-to-shank).

Fiber Optic Distributed Strain Sensing for Lower-limb Prosthetic Sockets

Ms. Clara Phillips, Dr. Fae Azhari

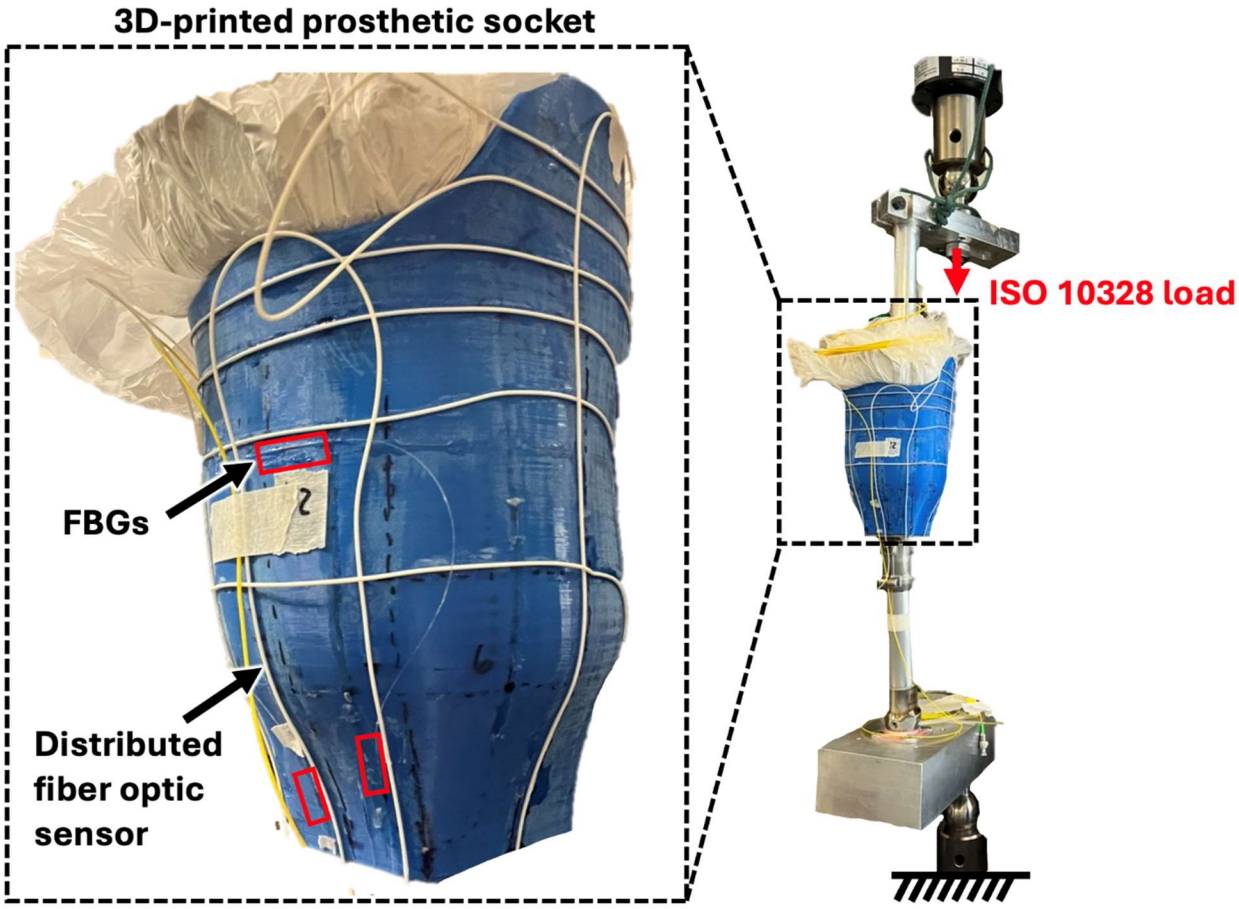
University of Toronto, Toronto, Ontario, Canada

Introduction

Mobility and function with a lower-limb prosthesis depend on the proper fit of a prosthetic socket to the residual limb. Conventional socket fabrication is advancing in several areas, including digital design and manufacturing (specifically, 3D printing), and computational models for predicting fit [1]. However, adoption of these tools is limited due to the lack of standardized bench-top testing methods that can provide evidence of their efficacy. While one standard, ISO 10328, addresses failure testing of sockets, it overlooks strain measurement. Capturing distributed strain data is essential for assessing socket structural integrity, understanding strain transfer to soft limb tissue, and validating computational models. Fiber optic sensing is a promising tool in biomechanics applications due to the fiber's small size, light weight and biocompatibility, yet its application in prosthetic sockets remains largely unexplored [2]. Here, we present a methodology for distributed strain sensing in prosthetic sockets using distributed fiber optic technology.

Methods

An optical fiber was mounted on a 3D-printed socket in longitudinal and circumferential orientations and recorded using a Luna Optical Distributed Sensing Interrogator (ODiSI). Five Fiber Bragg gratings (FBGs) were also mounted for strain comparison at discrete locations (Fig. 1). The socket was loaded according to ISO 10328 loading orientations to 200 N and 300 N, followed by 30 loading cycles from 50 N to 200 N. Strains were measured. A finite element model (FEM) of the socket was developed to simulate the loading conditions.



Results

Trends in strain matched between the ODiSI, the FBGs and the FEM, and the ODiSI accurately detected areas of maximum tensile and compressive strain not captured by the FBGs. Discrepancies in strain magnitudes measured by the distributed vs. discrete sensors were attributed to strain transfer efficiency.

Discussion

By visualizing socket strain distribution under clinically relevant loads, this approach identifies critical regions of deformation that are not captured by existing standards. While more work is required to improve strain magnitude measurement, this method has potential in broad biomedical contexts to inform the design of structurally-sound devices, and validate experimental and computational models of device functionality.

Adaptative Improvement in Dynamic Gait Stability to Repeated Stance-Slips in People with Mild to Moderate Parkinson's Disease

Ms. Diane Brown, Dr. Jiyun Ahn, Ms. Sara MahmoudzadehKhalili, Dr. Feng Yang

Georgia State University, Atlanta, Georgia, United States

Introduction

Falls are highly detrimental in people with Parkinson's disease (PwPD). The use of perturbation-based balance training (PBT), particularly stance-slip perturbations, to reduce falls in PwPD remains limited. As motor learning is the foundation for PBT, this study examined whether PwPD can adapt to and acquire fall-resistant skills through repeated standing-slips. Specifically, we investigated whether PwPD can adaptively improve their dynamic gait stability, as quantified by the Feasible Stability Region (FSR) theory [1], during repeated standing-slips. We hypothesized that PwPD would improve their dynamic stability across slips.

Methods

Ten PwPD (age: 69.9±5.53 years, 1 female, Hoehn & Yahr scale: 1.35±0.63 out of 5), protected by a safety harness, were exposed to five standing-slips (S1-S5) on an ActiveStep treadmill (Simbex, NH). The slip distance was 36 cm with a peak belt speed of 1.2 m/s. Their full-body kinematics were collected by a Vicon motion capture system (UK) from reflective markers attached to bony landmarks. Three time instants: slip onset (ON), recovery step liftoff (LO), and recovery touchdown (TD) were identified through foot kinematics. Center of mass (COM) kinematics were derived from filtered marker paths. COM motion state (i.e., its normalized relative position and velocity to the base of support) was compared to the FSR to compute dynamic gait stability for all three instants [2]. Repeated measures ANOVA analyzed dynamic gait stability. A significant main trial effect was followed by paired *t*-tests between consecutive slips and between S1 and S5 with appropriate corrections. SPSS 29.0 (IBM) and α=0.05 were used.

Results

No adverse events were reported. Participants showed significant improvements in proactive COM control at ON (p=0.017) and in reactive control performance at LO (p=0.009) and TD (p=0.005), with substantial early-to-late trial enhancements (Table 1).

Discussion

PwPD exhibited meaningful adaptive improvements in dynamic stability following repeated stance-slip exposure. The results support our hypothesis and suggest that stance-slip PBT training may be an effective and promising approach for reducing fall risk in this population. Our study could inform the development of effective standing-slip-based PBT fall-prevention interventions for PwPD.

A knee exoskeleton reduces peak knee contact forces during stair navigation

Dr. Emily Miller, Ms. Kai Pruyn, Dr. Lukas Gabert, Dr. Tommaso Lenzi, Dr. Scott Uhlrich

University of Utah, Salt Lake City, Utah, United States

Introduction

Osteoarthritis is a leading cause of disability, and stair navigation is difficult and painful for many individuals due to the large muscle forces and joint loads required. A knee exoskeleton may reduce potentially harmful joint contact forces [1]. This pilot study evaluated whether an exoskeleton providing knee extension torque reduces knee contact forces during stair navigation in a healthy participant, establishing feasibility for future osteoarthritis studies.

Methods

One male participant without osteoarthritis (age 31, height 1.78 m, mass 79.5 kg) wore the 5 kg unilateral Utah knee exoskeleton [1] on the right leg. He completed four trials each of stair ascent and descent at three speeds under two conditions: no exoskeleton (No Exo) and exoskeleton providing assistive torque (Exo). Motion capture, ground reaction forces, and surface electromyography from gastrocnemius medialis, vastus lateralis, and biceps femoris longus were recorded. Inverse dynamics and musculoskeletal modeling with static optimization estimated tibiofemoral contact forces, which were compared across conditions and speeds.

Results

During ascent, peak knee contact force in the Exo condition was 29% lower than No Exo, averaged across speeds and trials. Figure 1 shows representative medium-speed trials. The exoskeleton delivered 50 Nm of extension torque during early stance, reducing the biological knee extension moment by 51%. Vastus lateralis EMG amplitude decreased by 33%, consistent with a 42% reduction in model-estimated activation. During descent, peak contact forces in the Exo condition were 35% lower than No Exo across speeds, peak knee extension moment was 56% lower, and vastus lateralis EMG was 43% lower.

Discussion

This pilot study demonstrates that powered knee assistance can substantially reduce knee contact forces during stair navigation. The observed reductions of 29 to 35 percent far exceed those typically achieved through conventional interventions, which often yield only 10 to 12 percent reductions [2]. Our findings highlight the potential of powered assistance

to meaningfully decrease pain and slow cartilage degeneration in individuals with osteoarthritis [3] and support progression to patient studies where reducing knee loading may provide therapeutic benefit and improve mobility.

Effects of Nonlinear Ankle Joint Stiffness on Metabolic Cost Using Robotic Prosthetic Emulation

Ms. Emma Caringella[1], Ms. Chelsea Haddy[1], Dr. Philippe Malcolm[2], Dr. Kota Takahashi[1]

[1]University of Utah, Salt Lake City, Utah, United States. [2]University of Nebraska at Omaha, Omaha, Nebraska, United States

Introduction

During walking, the human ankle behaves as if it were a rotational spring [1] that can store and return energy. Unlike a linear spring, where displacement is directly proportional to force, the resistance offered by the ankle changes with joint angle during stance in walking (i.e., 'nonlinear stiffening' behavior [2]). The biomechanical importance of the ankle's nonlinear stiffening behavior is evident; the ankle modulates its stiffness in response to changes in speed [2] and slope [3]. However, the influence of this nonlinear stiffness property on gait remains poorly understood. In this study, a range of ankle stiffness profiles are simulated in a wearable robotic prosthetic emulator to determine how varying degrees of nonlinearity affect the metabolic cost of walking.

Methods

1 healthy young adult (M, 25 yrs, 63.7 kg) participated in this study. The participant walked on an instrumented treadmill for 15 minutes at 1.25 m/s wearing a robotic prosthetic emulator (Humotech). The participant wore an immobilizer boot with the emulator rigidly attached at the distal end, and a lift shoe on the other foot (Figure 1). During gait, the emulator cycled through four ankle stiffness shapes while maintaining a constant overall ankle quasi-stiffness (0.0775 Nm/kg/deg). We calculated metabolic cost (W/kg) using a method for estimating instantaneous metabolic cost [4], where steady-state metabolic rate was estimated as the asymptote of an exponential curve fit to the metabolic data of each ankle stiffness profile.

Results

A nonlinear softening profile resulted in the highest net metabolic cost (6.05 W/kg) while a linear profile resulted in the lowest net metabolic cost (4.79 W/kg) (Figure 1). Data collection is ongoing.

Discussion

Preliminary results suggest the nonlinearity of the ankle during the loading phase of gait impacts metabolic cost. Findings from this study will contribute to the growing body of

knowledge on the complex ankle joint and may influence the design of prosthetic and orthotic devices to better replicate natural ankle function.

Adjustable Offloading Ankle-Foot Orthosis (AFO): Design and Evaluation during Walking

PhD Candidate Eshraq Saffuri, Assistant Professor Dana Solav Ph.D.

Technion – Institute of Technology, Haifa, North, Israel

Introduction

Numerous foot and ankle conditions may require partial or complete offloading of the affected areas using assistive devices for mobility. Crutches, though common, disrupt gait biomechanics, increase secondary injury risk, and immobilize the proximal affected leg. AFOs may offer a better alternative but can cause discomfort and abnormal gait [1]. This study proposes and evaluates a novel adjustable offloading AFO designed to improve gait dynamics and enable precise offloading levels.

Methods

Our AFO integrates several components designed to enhance functionality. A patient-specific shank brace is computationally designed from a 3D scan and fabricated using a 3D-printed polylactic acid core, externally laminated with carbon fiber, and internally fitted with a neoprene liner (Fig.1a). A height-adjustment mechanism enables precise load distribution between the shank and the foot. Medial and lateral rocker contact plates aim to compensate for the absence of ankle flexion by incorporating a roll-over-shape (ROS) derived from walking data. The ROS is computed by transforming the foot center-of-pressure trajectories to a shank-fixed coordinate system [2]. Evaluation on two healthy participants walking at self-selected speed measured plantar pressure distribution using Zebris FDM-2 walkway.

Results

Normal plantar forces during AFO walking increased progressively across five 4mm increment height adjustments (Fig. 1b), with foot impulses rising from 14%, 23%, 31%, 43% to 53%. Stance phase (SP) inter-limb symmetry index decreased from 13% at 0% load to 7% at 53% load. Contralateral SP shortened to 58% of the gait cycle, compared to 68% with

a prefabricated AFO [1]. Participants reported a comfortable, natural walking experience across all offloading levels.

Discussion

Our AFO facilitates a natural walking experience, even during complete offloading. Height adjustments resulted in a gradual reduction in offloading levels while maintaining mostly typical plantar force patterns. This advancement paves the way to enhanced rehabilitation from foot and ankle injuries. Future research will evaluate performance and long-term outcomes in clinical populations.

Characterizing Wheelchair Vibrations to Enhance Self-Motion Perception in Wheelchair Simulators

Pr Félix Chénier[1,2], Ms Julie Moison[3,4], Mr Baptiste Perrudin[3,4], Mr Mohammed El Abdoulli[3,4], M Clément Ghazouani[3,4], Pr Rachid Aissaoui[3,4]

[1]Université du Québec à Montréal (UQAM), Montreal, Quebec, Canada. [2]Centre for Interdisciplinary Research in Rehabilitation of Greater Montreal (CRIR), Montreal, Quebec, Canada. [3]École de technologie supérieure (ÉTS), Montreal, Quebec, Canada. [4]Centre de recherche du CHUM (CRCHUM), Montreal, Quebec, Canada

Introduction

Wheelchair simulators reproduce complex environment in stationary conditions, allowing users to safely train their propulsion skills. For training to be effective, users should feel as though they are moving in accordance with the simulation, even while stationary. Providing whole-body vibration during movement enhances this sense of self-motion, likely due to increased realism or by masking conflicting proprioceptive information, thus relying more on visual cues. A roller-based wheelchair simulator already generates vibrations caused by the rear tires interacting with the rollers. In this preliminary study, we measured the amplitude and frequency of these vibrations and investigated how they compare to different real-life conditions.

Methods

Four accelerometers were installed on the frame of a manual wheelchair near the axle of each wheel. The wheelchair was pulled at two constant speeds of 0.75 and 1.0 m/s over three surfaces: smooth vinyl flooring (indoor), concrete (outdoor) and grass (outdoor), while a person was seated in it. The same wheelchair was placed on a simulator with motorized rollers, and the speed of the rollers was matched to the overground conditions. The root-mean-square (RMS) and frequency spectrum centroid of the vertical acceleration were calculated separately for the front and rear wheels.

Results

The lowest vibration was observed on the vinyl surface, which most closely matched the vibration of the simulator's rear wheels. Both concrete and grass exhibited a higher vibration amplitude compared to vinyl; however, grass had a lower frequency centroid. In real-life conditions, the highest vibration was near the front wheels, whereas the opposite

was found on the simulator; this discrepancy was expected, as the front wheels were not rolling on the simulator. In every condition, higher speeds increased both the amplitude and frequency of the vibrations.

Discussion

The next step will be to generate additional vibration on the simulator using actuators, to replicate the characteristics of surfaces like concrete and grass. Both surface and speed should be considered, as they both impact vibration. The importance of reproducing or not the higher vibration at the front wheels should also be assessed, particularly for users with limited sensory perception near their feet.

Effects of Slip Intensity on Fall Rate Reduction during Repeated Standing-Slips

Ms. Susmita Bhandari, Dr. Caroline Simpkins, Dr. Feng Yang

Georgia State University, Atlanta, Georgia, United States

Introduction

Falls are a major public safety problem. Perturbation training has been shown to be useful in preventing falls. The slip intensity is a key parameter. Our previous study reported that higher-intensity slips induce more falls than lower-intensity slips on a novel slip among young adults [1]. The goal of this study is to examine whether slip intensity affects fall rate changes across five repeated standing-slips in young adults. We hypothesized that a high slip intensity would induce a fast fall rate reduction.

Methods

Twenty-one healthy young adults (23.8±4.4 years) were assigned to two groups: lower (11) and higher (10) intensity. They experienced five repeated standing-slips (S1-S5) under the protection of a safety harness connected to a loadcell on an ActiveStep treadmill. Peak belt speeds were 1.2 and 1.8 m/s for the lower- and higher-intensity profiles, respectively. The slip distance was 0.36 m for both groups. The slip outcome was classified as a fall if the loadcell force exceeded 30% of bodyweight and was visually verified by video files. The fall rate was calculated as the number of fallers divided by the total participants in each group for each slip. Fall-rate curves were log-fitted, and slope differences were tested with a Generalized Estimating Equation model in SPSS 29 with $\alpha=0.05$

Results

Both groups showed reduced fall rates over S1 to S5: 100% to 40% in the higher-intensity group and 36.4% to 0% in the lower-intensity group. The slope of the higher-intensity group's fall rate drop is significantly higher than that of the lower-intensity group (-42.11 vs. -21.32, $p<0.001$, Fig. 1).

Discussion

Our results showed that high-intensity slips initially caused more falls, but they also produced a strong motor learning effect, leading to a faster reduction in fall rate over

repeated slips. From a fall-prevention perspective, a high slip intensity should be prescribed for perturbation training. Notably, some participants in the high-intensity group did not recover by S5. This implies that our higher slip intensity may be overly strong for some individuals to adapt to. Future studies should further examine this observation.

Enabling the Multi-Session Comparison of sEMG Features Using a Novel High-Density sEMG Electrode Shift Tracking Algorithm

Mr Fraser Douglas, Dr Calvin Kuo

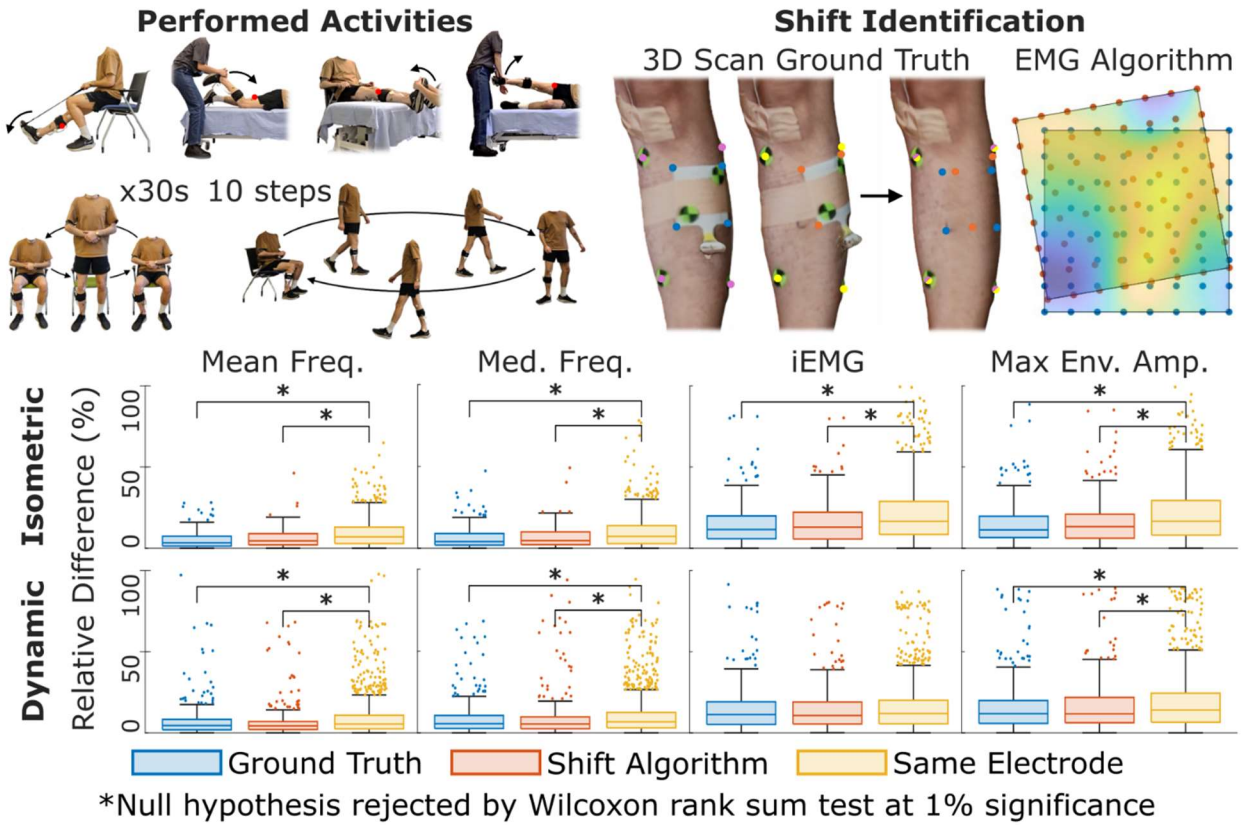
University of British Columbia, Vancouver, BC, Canada

Introduction

Surface electromyography (sEMG) enables direct measurement of muscle activity during exercise with signal features holding associations to muscle fatigue, firing rate, motor unit recruitment, and force production. Thus, sEMG holds potential supporting the recovery assessment of individuals suffering neurological and musculoskeletal disorders. Despite this, sEMG is highly sensitive to changes in electrode location [1], with palpation and anatomical landmarks often insufficient to ensure consistent placement across sessions. To support longitudinal sEMG-based assessments, we developed a high-density sEMG (HDsEMG) algorithm to determine electrode shift via correlation maps [2], hypothesising that through the algorithm's application effects of electrode shift on signal features can be mitigated.

Methods

12 healthy participants (ethics H22-02423) performed isometric and dynamic exercises with HDsEMG arrays (64 electrodes, 1cm-spaced 8x8 configuration) on four leg muscles. These were repeated, reapplying arrays at shifted locations to obtain four sets of data per muscle. 3D scans taken post-exercise were used to identify the ground truth shift between recordings, with our HDsEMG algorithm estimating this shift. We extracted mean and median frequency, integrated EMG (iEMG), and max envelope amplitude from HDsEMG data. Relative feature differences between closest electrodes across recordings per ground truth and algorithm shifts were determined, as well as differences using the same electrodes across locations.



Results

Isometric results demonstrate feature differences when accounting for shift using the HDsEMG algorithm are statistically similar to when using the ground truth. Furthermore, across features the relative difference for same electrodes pre- and post-shift were significantly greater than the ground truth and algorithm. These results, excluding iEMG, were consistent with dynamic exercises.

Discussion

The similarity achieved between ground truth and algorithm results compared to same-electrode results indicate the algorithm's application effectively mitigated electrode shift effects. This approach can facilitate more direct comparisons of features across sessions while allowing for imprecise sensor placement. Remaining differences post-shift can likely be attributed to variations in skin and electrode preparation, and discrepancies in participant effort. In sum, this work represents a promising step toward robust sEMG measurement for musculoskeletal and neurological recovery tracking.

Transfer Effects of Adaptive Propulsion Enhancement eXperience (APEX) Training on Gait Symmetry and Weak-Leg Joint Entropy During Overground Walking on Older Adults

Ms. Gaju Shin[1], Mr. Chihyeong Lee[1], Dr. Seoung Hoon Park[2], Dr. Beom-Chan Lee[2], Dr. Jooeun Ahn[1]

[1]Seoul National University, Seoul, N/A, Korea, Republic of. [2]University of Houston, Houston, Texas, United States

Introduction

Age-related gait asymmetry and increased stride-to-stride variability exacerbate mobility decline and falls in older adults, yet interventions targeting weak-leg propulsive deficits remain limited. The Adaptive Propulsion Enhancement eXperience (APEX) system, which incorporates an dual-belt treadmill that delivers real-time visual biofeedback (VB) of anterior ground reaction force (AGRF) with phase-specific belt-speed modulation to facilitate AGRF generation (propulsion-facilitating, PF), has been shown to enhance affected-leg propulsion after a single, short-term session (100 steps) in individuals post-stroke [1]. However, the efficacy of an intensified training protocol and the transferability of these biomechanical improvements to overgound walking remain unknown. This study investigates whether intensified APEX training elicits neuromotor adaptations in weak-leg and transfers improvements to overground gait symmetry and joint angle regularity in older adults.

Methods

Four older adults completed a single-session intensified APEX protocol, comprising baseline (30 steps), training (1000 steps), and post-training (30 steps) blocks. During training, the APEX system provided concurrent VB and PF to the participant's weaker leg. To evaluate transfer effects, a 10-meter overground walking tests were performed before and after the session. Bilateral kinematics (i.e., foot positions and knee joint angles) were recorded using a wearable motion capture system (MVN Awinda, Xsens Technologies, NL). Outcomes included the stance-time symmetry index (SI) to quantify gait symmetry and knee joint approximate entropy (ApEn) to characterize neuromotor regularity.

Results

Following the high-intensity training, participants improved tempoal gait symmetry, as demonstrated by a reduction in the stance-time symmetry index toward zero ($\Delta|SI| = 1.85 \pm 0.61$). Concurrently, knee joint angles exhibited increased requlrity and dynamic stability, quantified by a decrease in ApEn ($\Delta ApEn = -0.018 \pm 0.027$).

Discussion

The preliminary findings indicate that a single session of intensified APEX training elicits immediate transfer to overground gait in older adults. The concurrent improvements in stance-time SI and reduction in weaker-leg knee joint angle ApEn suggest that intensified training facilitated a short-term reorganization characterized by greater regularity and stability. Collectively, this proof-of-concept study demonstrates the potential of high-intensity APEX training as a viable intervention to mitigate gait asymmetry and restore gait regularity in older populations.

Thermal behaviour of transfemoral residual limbs in prosthetic sockets during rest, exercise, and recovery: a finite-element bioheat modelling study

Mrs Hadeel Alhamam, Prof Spyros Masouros, Prof Anthony Bull

Imperial College London, London, London, United Kingdom

Introduction

Heat buildup at the residual limb-socket interface remains a barrier to comfort and long-term prosthesis use, yet amputated limb thermoregulation within a socket is still poorly characterized. This study develops a finite-element bioheat model to quantify heat transfer and thermoregulatory responses in the transfemoral residual limb–socket system under realistic conditions.

Methods

MRI data from a unilateral transfemoral amputee were segmented into skin, fat, muscle and bone to form a multilayered geometry. This was abstracted into a 3D elliptical parametric model with preserved tissue thicknesses, including offset layers for the liner and socket. Thermal and physiological properties were assigned from literature. The Pennes equation governed heat transfer with convective, radiative, and evaporative boundary conditions. A transient three-phase protocol (rest, activity, recovery; 60 minutes each) was applied. Simulations were run under three ambient conditions: normal (24°C, 56% RH), hot–humid (32°C, 70% RH), and hot–dry (40°C, 24% RH). Prosthesis-OFF simulations allowed bare-skin heat exchange and were used to compare skin temperature against empirical data. Prosthesis-ON simulations blocked skin heat exchange and applied it to the socket exterior, testing two material configurations (silicone liner with carbon-fibre or thermoplastic sockets). A conductivity sensitivity analysis (±50%) was performed for the carbon-fibre configuration. Activity and recovery phases are still in progress.

Results

Model predictions agreed with empirical resting skin temperatures across all ambient conditions (R^2 = 0.97, RMSE = 0.36°C). Prosthesis use increased average skin temperature by ~1°C in normal conditions, with a slower temperature rise at hotter ambient due to the socket's insulating effect. Prosthesis use also altered the thermal gradient, with distal warming (~0.4°C) and greater proximal increases (~2.0°C). The proximal–distal gradient declined with increasing ambient temperature and reversed above ~37°C. For prosthesis-

ON simulations, carbon-fibre and thermoplastic material sets produced comparable temperatures. Varying conductivity by ±50%, exceeding realistic material ranges, produced minimal temperature change, demonstrating the limited thermal influence of material selection.

Discussion

This framework provides a reliable basis for residual-limb thermoregulation. Simulation findings indicate that thermoregulation-focused socket design may require active cooling rather than material changes alone, and future evaluations should include real-world ambient conditions.

Introduction

Exoskeletons are commonly designed to reduce mechanical demands on specific joints and muscles during gait [1]. Because walking emerges from coordinated interactions among multiple joints and muscles, it is important to understand how local assistance at the knee alters kinematics and muscle activation of other lower-limbs [2]. Downhill walking increases lower-limb joint loading and knee extensor demands [3], but it is still unclear how a passive knee exoskeleton affects knee kinematics or whether it induces compensatory changes. This study investigated how a passive knee exoskeleton influences knee kinematics and muscle activation of the thigh and shank during downhill walking.

Methods

Four healthy young men walked on a −6° treadmill under three 5-min conditions: no exoskeleton, adaptation with the exoskeleton, and steady-state exoskeleton walking. The

passive knee exoskeleton was worn on the right leg and provided assistance to the right knee during stance. Surface EMG was recorded bilaterally from eight lower-limb muscles, and the analysis focused on the right vastus lateralis and tibialis anterior. Ground reaction forces and three-dimensional kinematics were collected using an instrumented treadmill and a motion analysis system.

Results

Wearing the passive knee exoskeleton reduced peak right knee flexion during swing by 29.3% compared with the no-exoskeleton condition. At the muscle level, RMS EMG of the right vastus lateralis decreased by 22.8% with the exoskeleton, although this change was not statistically significant. By contrast, RMS EMG of the right tibialis anterior during pre-swing increased by 40.3% with the exoskeleton relative to the no-exoskeleton condition, representing the most pronounced and statistically significant phase-specific change in muscle activity.

Discussion

These findings suggest that a unilateral passive knee exoskeleton does not substantially unload the knee extensors but instead influences gait by mechanically limiting knee flexion. This mechanical constraint is accompanied by increased ankle dorsiflexor activation, a pattern consistent with a compensatory strategy to preserve toe clearance. Overall, unilateral knee assistive devices should be designed and evaluated with consideration for both local unloading at the assisted joint and compensatory adaptations in distal musculature and gait strategy.

Proprioceptive Feedback from a Compliant Biomimetic Ankle Joint

Mr James Clark, Dr Peter Ellison

The University of York, York, North Yorkshire, United Kingdom

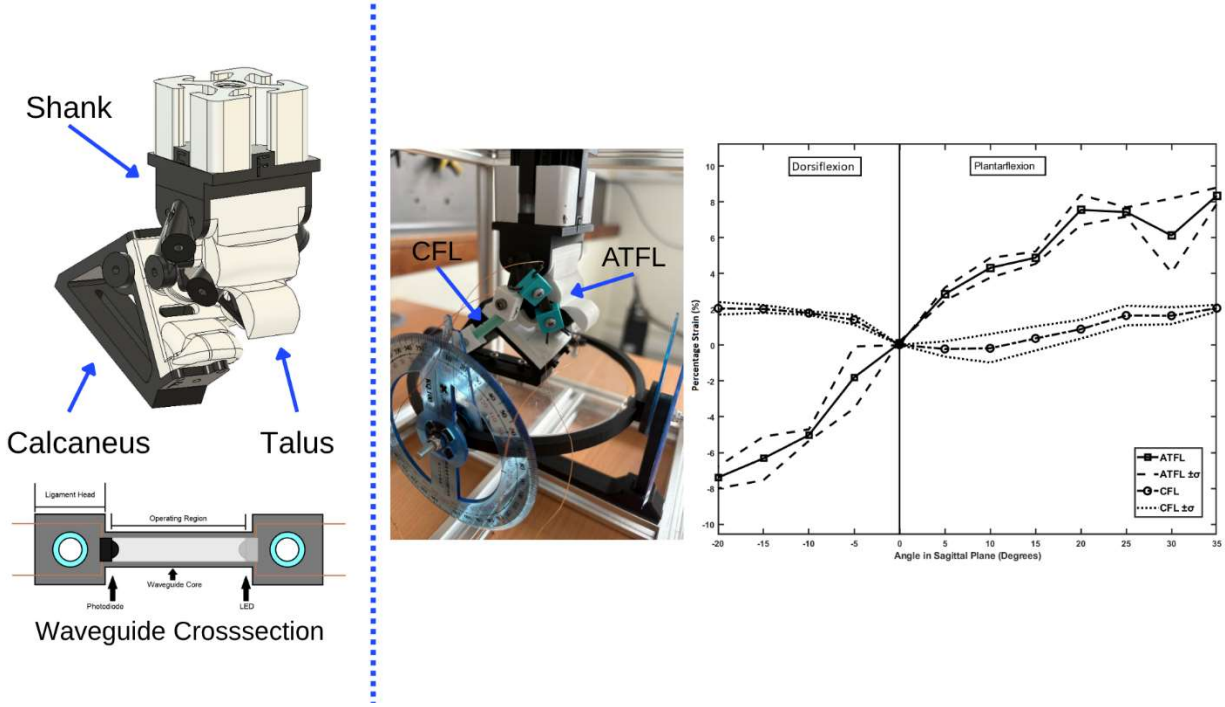
Introduction

Commercial ankle prosthetics primarily use one degree of freedom (DOF). Prior research has demonstrated that systems with two DOF improve user balance relative to one DOF devices [1]. However, pin-jointed designs lack the functional behaviour of a healthy ankle, primarily because they do not provide sufficient compliance or sensory feedback necessary for effective control. To address these limitations, we have developed an anatomically inspired ankle joint with motion constrained by soft multiplanar links analogous to ligaments.

Methods

An idealised version of the tibiotalar and subtalar joints was constructed to provide motion in the coronal and sagittal planes. Deformable waveguides were produced, representing the anterior talofibular and calcaneofibular ligaments, to provide stretch sensing. The waveguides were tested up to 10% strain, and the extension was approximated with linear regression. The joint was manipulated in dorsiflexion to 20° and plantarflexion to 35° in 5° increments. The resulting ligament stretch was recorded to establish the relationship between joint angle and ligament deformation.

Results



The linear regression fit produced R^2 values exceeding 0.996 between the operating range of 0-6% strain. During joint manipulation, the measured stretch of the lateral ligaments exhibited a mutually exclusive pattern across the discrete plantar direction of motion in both planes.

Discussion

The measured strain behaviour closely resembles the anatomical ligament strain profiles reported by Renström et al [2]. This indicates that the simplified joint model can replicate physiologically relevant deformation patterns, and the ligament analogues provide directional information about joint motion. In addition, the use of deformable ligament analogues inherently introduces joint compliance, offering a mechanical advantage over rigid pin-joint designs.

Because the system produces proprioceptive feedback through ligament stretch, it could be used to inform a controller for a powered prosthetic. The distinct stretch patterns of the ligaments across motion planes may allow the controller to infer joint position, serving a similar functional role to joint angle measurements in conventional control schemes. When combined with the joint's compliant behaviour, this sensing capability provides a pathway toward more adaptive, biomimetic control strategies.

Quantifying Human–Exoskeleton Conformity Using Hip Joint Gait Phase Portraits

M.D. Jehyun Yoo[1,2], Mr Yoonhwan Kim[2], M.D. Juntaek Hong[2], M.D. Junmin Cha[2], Mrs Yebin Cho[2], M.D. Ph.D. Dong-wook Rha[2]

Introduction

Wearable exoskeletons are increasingly used in industrial applications and rehabilitation. Despite their growing use, robot-assisted rehabilitation entails potential risks, due to the mismatch between standardized device designs and highly variable patient anthropometry. Such mismatch can result in improper fitting, malalignment, and inadequate timing and amount of torque assistance, reducing therapeutic effectiveness. Although interest in wearable exoskeletons is expanding, quantitative assessments of human–exoskeleton conformity remain limited. A major challenge is the difficulty in independently capturing human and device kinematics, as exoskeleton hardware often obscures anatomical landmarks required for marker-based motion capture.

In this study, we propose a novel approach for quantifying human–exoskeleton conformity by employing a hybrid motion capture setup that integrates IMU-based and marker-based systems. This dual-measurement strategy enables the independent acquisition of human and exoskeleton kinematics, allowing for a direct comparison. We also introduce new quantitative parameters specifically designed to evaluate the kinematic conformity between the user and the device.

Methods

Seven-healthy adults walked on a treadmill wearing a commercial exoskeleton(Angel Suit H10, Angel Robotics) at a self-selected speed for 3minutes. Human kinematics were measured using three IMUs placed on the pelvis and bilateral femurs, while exoskeleton kinematics were simultaneously recorded with a VICON system using three reflective markers per joint. Phase portraits of hip angle versus angular velocity were independently constructed, and similarity was computed using an area-overlap method:Similarity=$(A \cap B)/(A \cup B)$. The 3-minute trial was divided into three 1-minute intervals, from which the middle ten gait-cycles were analyzed. Additional metrics included point-wise Euclidean distance and centroid-drift of the phase portraits. Four torque levels(0%,30%,50%,70%)

were tested, and changes in similarity across torque and time were analyzed using linear mixed-effects models.

Results

Similarity significantly decreased as torque increased (slope = −0.02, $p < 0.05$), whereas no significant change was observed across early, middle, and late phases of walking.

Discussion

This study presents a novel quantitative framework for assessing human–exoskeleton conformity using independent kinematic measurements. Phase portrait similarity decreased with higher assistive torque, suggesting increased kinematic discrepancy. These conformity metrics may support individualized tuning of exoskeleton assistance and guide the development of patient-specific control strategies.

Uneven Terrain Training for Prosthesis Users: Interim Analysis of the First Cohort in a Phase I Clinical Trial

Dr. Jenny Kent PhD, CSci[1], Ms Katie Bricarell MS[1], Dr. Stefania Fatone PhD, BPO(Hons.)[2], Dr. Szu-Ping Lee PT, PhD[1]

[1]University of Nevada Las Vegas, Las Vegas, Nevada, United States. [2]University of Washington, Seattle, Washington, United States

Introduction

Persistent mobility deficits impact participation and quality of life of many lower limb prosthesis users (LLPUs). However, empirically-tested interventions to address these deficits are scarce. Exposure to uneven terrain (UT) may encourage exploration of new movement strategies, facilitate learning to respond to perturbations, and attenuate fears of the unknown. We aim to determine whether UT training can improve prosthetic skill and confidence. Here, we present findings from the first cohort of a Phase I clinical trial exploring UT training feasibility in LLPUs, following an established framework [1].

Methods

Training consisted of 12 sessions, during which LLPUs walked on a UT treadmill (UTT) or a flat terrain treadmill (FTT; to assess feasibility of control group only) for 12 two-minute bouts, wearing a safety harness. Handrail use, treadmill speed, and UT contour height were progressed to maintain level of challenge. Whole-body kinematics were collected via motion capture. Pre-post assessments included: Activities-specific Balance Confidence scale, Prosthetic Limb Users Survey of Mobility, L-test, Two-Minute Walk Test, Four Square Step Test, Single Leg Stand tests, and 7-day activity monitoring. Participant feedback was recorded throughout all sessions, and via an acceptability questionnaire.

Results

Eight individuals with unilateral amputation attended an average of 11.5 training sessions (Table 1). All could walk on their assigned treadmill. Session termination reasons included pain, fatigue, and time constraints. The handrail and harness system obscured biomechanical markers; remedied by careful camera placement. Several participants indicated that faster speeds made walking on the UTT easier. Activity monitoring periods did not reflect all participants' normal day-to-day activity.

Participants reported a positive experience. Of the seven who trained on the UTT, five agreed/strongly agreed that the training improved their balance, and six, their balance

confidence. While anecdotal reports of increased confidence and improved stumble recovery during daily life were provided, there were no changes in outcome measures.

Discussion

Individuals of all amputation levels demonstrated ability to participate in UT training, and described positive impacts. However, alternative outcome measures capable of detecting the impact of training described by participants must be identified before a Phase II clinical trial is conducted.

Smoother Ground Reaction Force Profiles while Ambulating with a Tensegrity Crutch: A Biologically Inspired Design for Compliant Mobility Assistive Devices

MS. Jingxian Gu, Dr. Dobromir Dotov

University of Nebraska Omaha, Omaha, NE, United States

MS. Jingxian Gu

Introduction

Six million people use crutches as mobile aids in the US. Crutches need to enable dynamic balance and efficient walking. They can be the only support of the body during the swing phase. Rigid designs with no axial mobility limit sensory feedback from the ground and lead to secondary injury on the upper joints. Spring-loaded designs offer compliance at the expense of dynamic stability.

We designed a crutch with compliance in multiple axes by using a structural principle studied in biology and robotics. Its tensegrity module consists of a closed network of pre-stressed compressive and tensile elements. Musculoskeletal systems exploit this principle for stability and proprioception. We compared commercial rigid, spring-loaded, and our compliant design in overground walking trials.

Methods

Young healthy adults (N=17) with no recent lower-body injury performed straight walking and turning trials (reported separately) at a comfortable self-selected pace. This was a within-subject design with random order of blocks of crutch type. A knee blocker simulated unilateral injury of the dominant leg. Integrated force plates and a 12-camera motion capture system collected ground reaction force (GRF) and kinematic data. Participants completed questionnaires of perceived effort, comfort, and tool usability.

Results

In straight walking, the compliant crutches with a tensegrity terminal module produced a smoother vertical GRF profile, expressed as a lower peak loading rate after initial contact with the ground (p<.05), see Figure 1. Axial stiffness was 10 kN/m in the spring-loaded crutch and 22 kN/m in our design which agrees with some participants' observation that

the spring-loaded type felt too soft and could bottom out. Upper body stability and kinematic gait parameters are being analyzed.

Discussion

Our innovative approach promises to improve crutch features that are associated with secondary injury and non-use which are linked to repeated falls in chronic users. The modular biomechanical design principle is generic and promises exciting possibilities for improving a range of other types of assistive devices.

Evaluation of Multiple Motion-Detection Algorithms and Thresholding Methods for In-Bed Exercise Tracking Across Individuals with Diverse Movement Capacities, Including Bedridden Patients

Ms. Jiwon Ryu[1], Mr. Cheoljae Lee[1], Ms. Gahyun Lee[1], Prof. Gwanseob Shin[1], Prof. Won Kim[2]

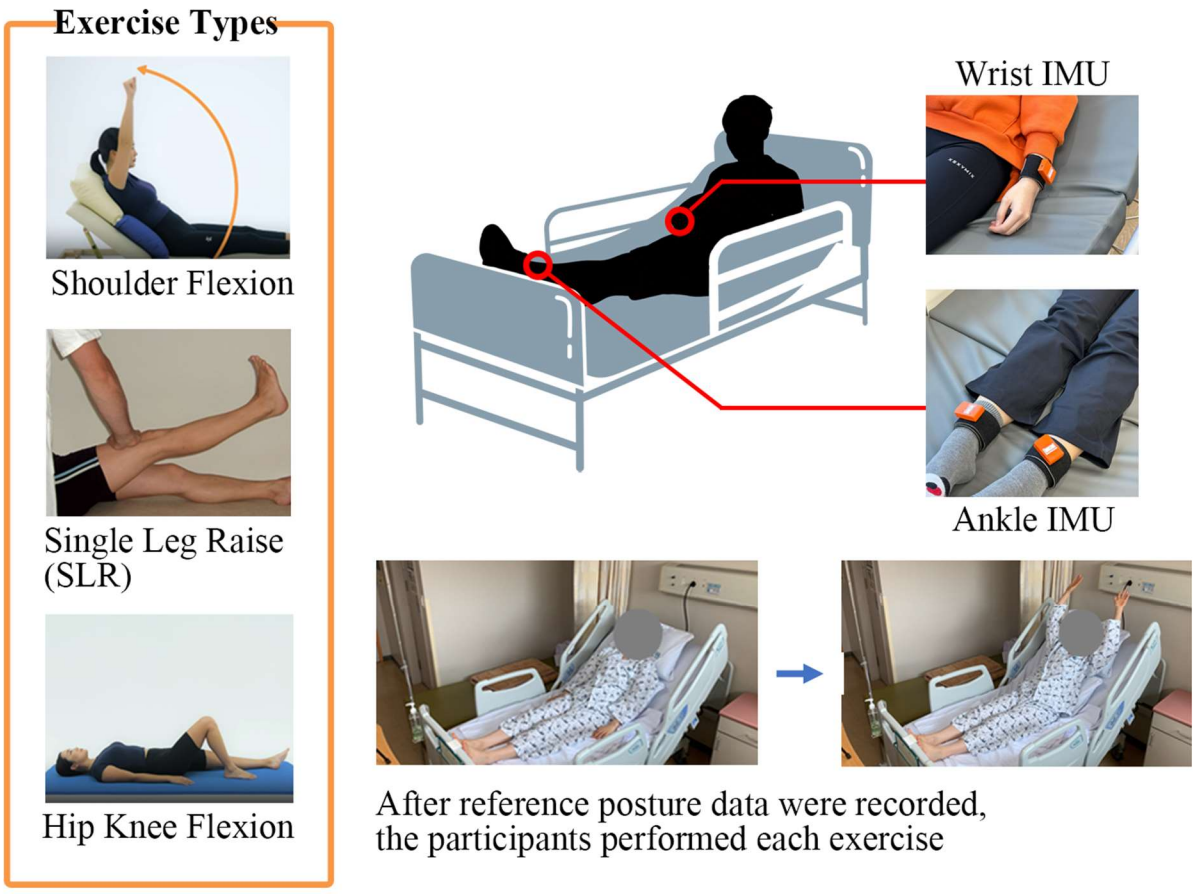
[1]Ulsan National Institute of Science and Technology (UNIST), Ulju-gun, Ulsan, Korea, Republic of. [2]Asan Medical Center, University of Ulsan College of Medicine, Songpa-gu, Seoul, Korea, Republic of

Introduction

The majority of bedridden patients become inactive, so a systematic and motivating exercise program is necessary. Motion-tracking exergames may offer a solution, however, most of the existing exergames require standing and highly active movements, which might be unsuitable for the inpatients. Furthermore, the movement patterns of the inpatients and movement capacity might be different from those observed in healthy individuals. As the first step of developing a suitable exergame for rehabilitating the bedridden patients, this study aimed to create a motion-detection algorithm which can track in-bed exercise motions across individuals with diverse movement abilities, including the bedridden inpatients.

Methods

Eight asymptomatic participants (4 females, 4 males) and four inpatients (1 female, 3 males) conducted three in-bed exercises: 1) shoulder flexion, 2) single leg raise (SLR), and 3) hip-knee flexion. The participants performed each exercise while lying on a hospital bed, with four inertial measurement units (IMUs) attached to both sides of wrists and ankles. The exercise motions were quantified at 100Hz. For the bedridden inpatients, the motion data were collected during regular rehabilitation sessions with clinical experts.



Results

The proposed algorithm utilized moving mean and moving variance of a vector magnitude of tri-axial linear acceleration for measuring movement intensity [1], combined with one principal Euler orientation angle. The algorithm first automatically determined thresholds of main parameters using the first few cycles of each exercise, then detected exercise and non-exercise segments in the remaining cycles. The algorithm achieved over 90% accuracy in identifying the exercise and non-exercise segments for both shoulder flexion and SLR motions across all participants. For the inpatients, the average accuracy was approximately 94% in shoulder flexion and 91% in SLR.

Discussion

The current study showed that the designed algorithm effectively detects the initiation and termination of major in-bed exercise movements from the people with various movement capacities, including the bedridden inpatients. Main findings of the study can be utilized as a core component for an in-bed exergame system. Future studies need to evaluate its performance with larger populations and additional exercises.

A Taxonomy for Ankle-Foot Orthosis Testing Methods

Ms Katherine Vaiciulis, Mr Zachary Williston, Dr Deema Totah PhD

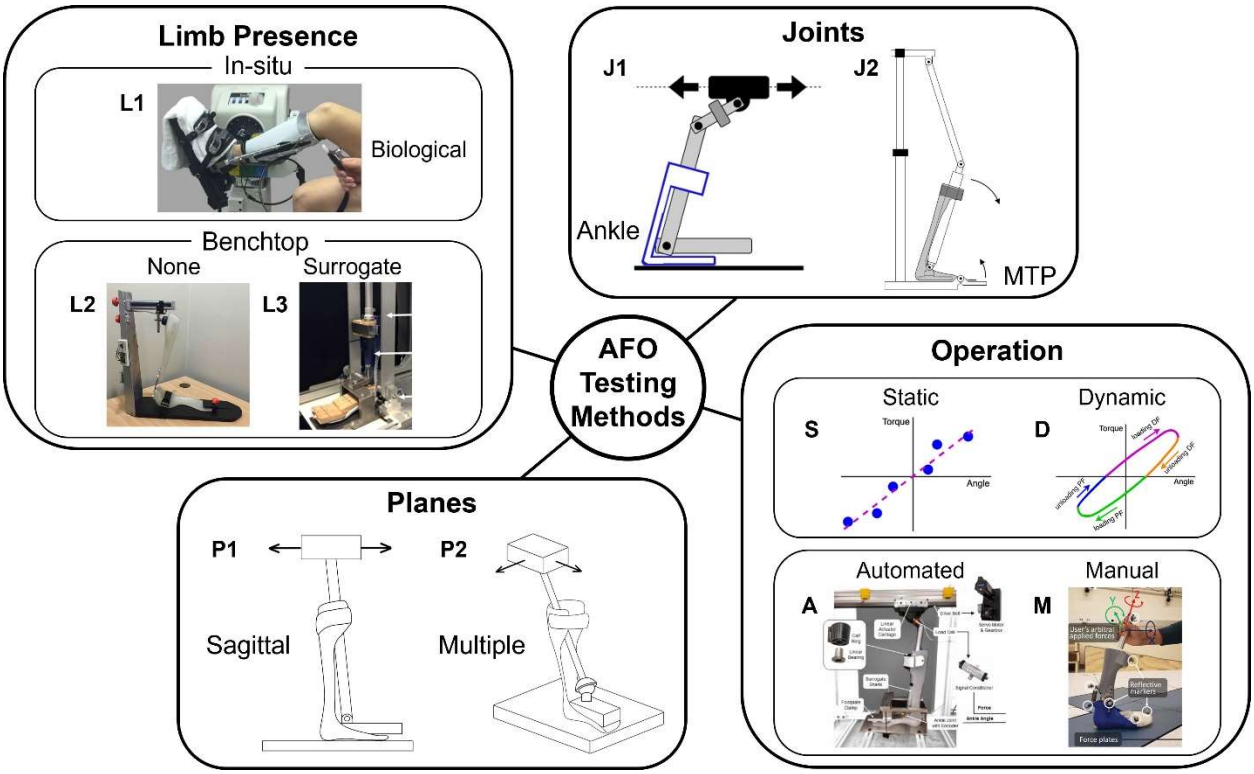
University of Iowa, Iowa City, IA, United States

Introduction

Ankle-foot orthoses (AFOs) are used by individuals with impaired gait. The amount of support AFOs provide largely depends on their mechanical properties, like stiffness. AFO stiffness is calculated from the slope of ankle flexion torque vs angle curve. Although individually optimizing AFO stiffness can improve gait [1], it is not quantified in clinical practice. Measurement techniques for AFO mechanical properties are not standardized, causing a significant lack of inter-method repeatability [2]. To address these challenges, this work performs a scoping review and introduces the first classification taxonomy for AFO mechanical testing to facilitate inter-study comparisons and guide future development.

Methods

A database search was conducted in PubMed, Engineering Village/Compendex, and Web of Science following the PRISMA guideline extension for scoping reviews. A snowballing search was conducted beginning from two published literature reviews. Articles that experimentally measure the mechanical properties of AFOs were eligible for inclusion. Exclusion criteria included insufficient details, using previously published testing methods, or measuring AFO properties using onboard sensors.



Results

Forty-six of 492 potential papers were identified for inclusion and analyzed to develop a taxonomy (categories in parentheses) for classifying AFO testing methods according to design and operation properties. Most methods use benchtop testing (L2,3), while a few in-situ (L1) methods involve a biological limb. Most methods deflect AFOs in the sagittal plane only (P1), while some deflect AFOs in multiple planes (P2). Most methods model the ankle joint only (J1), while a few also model the metatarsophalangeal (MTP) joint (J2). Methods also vary in operation, collecting static (S) or dynamic (D) data, through automated (A) or manual (M) operation.

Discussion

The proposed taxonomy provides the first framework for efficient categorization and comparison of specifications across AFO testing methods. Key elements that may affect measurements and would benefit from standardization include the ankle location, planes of motion, and testing speed. This work guides future standardization of methods and protocols for implementing AFO testing into clinical practice and quality control in manufacturing. This would support data-driven, individualized AFO prescription, design, and production towards optimized user outcomes.

Quantifiable Metrics of Saccadic Eye-Movement Improve With Time in Concussed Subjects

Miss Katherine Wiebe BSc., PhD candidate

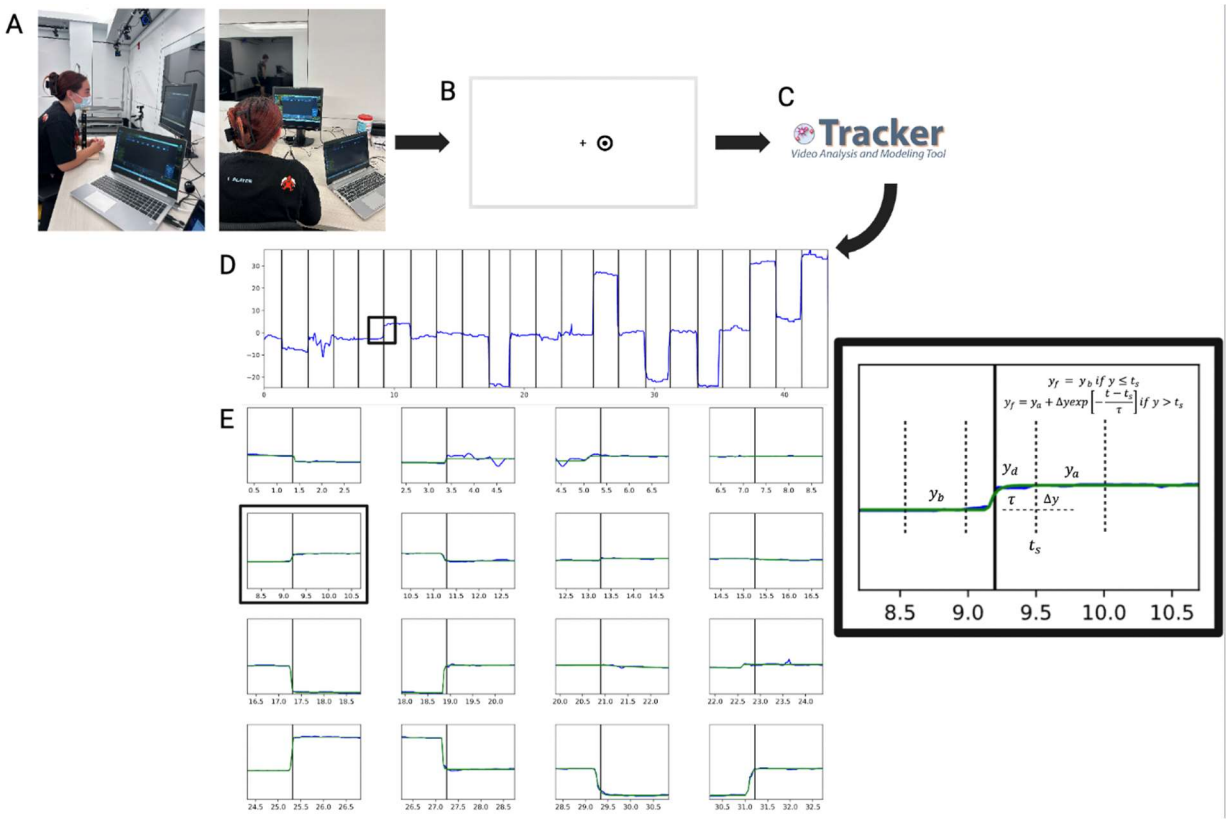
Carleton University, Ottawa, ON, Canada

Introduction

Current concussion assessment tools rely on qualitative and subjective methods. Our objective is to determine if saccadic eye-movements are correlated with the Vestibular Ocular Motor Screening (VOMS) test. A second objective is to compare commercial eye-trackers with open-source tools for this task.

Methods

Twenty concussed subjects performed the VOMS test and subsequently a saccadic eye-movement task, while being concurrently recorded using a webcam and a commercial eye-tracking tool. We developed analysis software for quantifying and comparing the eye tracking movements. Metrics of interest included the time constant (τ [ms]) of a transition event, and the concurrence of eye position before, during, and after each transition.



Results

A significant difference in all parameters between the control and concussed subjects, indicated that concussed subjects had slower transition time and difficulty fixating on a target. We discuss how the VOMS results may be correlated with eye-tracking. No significant differences were found between the calculated metrics from the webcam and the commercial eye-trackers.

Discussion

Correlations between eye-tracking metrics and VOMS test scores may call to question the specificity of the VOMS test in assessing concussions. This study supports the use of accessible eye tracking and open-source tools.

Model-based Reinforcement Learning for Personalized Hip Exoskeleton Assistance to Enhance Walking Mobility in Older Adults

PhD Candidate Ke Feng, Dr. Thomas Yang, Dr. Shuzhen Luo

Embry-Riddle Aeronautical University, Daytona Beach, Florida, United States

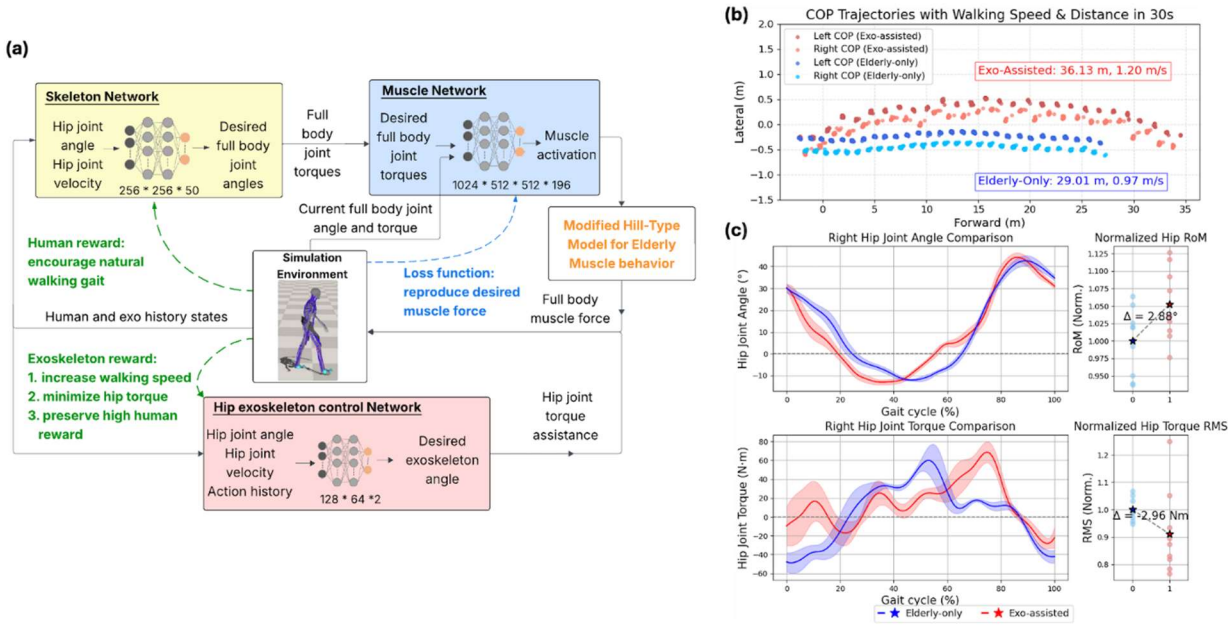
Introduction

Powered hip exoskeletons offer a promising solution for age-related mobility decline, as the hip joint contributes substantially to forward propulsion. User studies [1] show strong acceptance of lower-limb exoskeletons among older adults, with walking efficiency rated as the top factor influencing their acceptance. However, current hip exoskeleton controllers are designed mainly for healthy adults and require hours of human testing and parameter tuning to identify optimal torque profiles [2]. Phase-based controllers may also produce discontinuous assistance [3]. No prior work has developed personalized assistance specifically for older adults. Achieving truly "wear-and-go" assistance that adapts automatically without human-involved tuning remains a major challenge and is essential for community deployment.

Methods

Building on our Nature publication [4], this work presents a model-based reinforcement learning framework for personalized hip exoskeleton assistance. We incoporate a Hill-type muscle–tendon model with reduced maximum isometric force, increased passive stiffness, and slower activation dynamics, enabling the neuromusculoskeletal model to reproduce gait characteristics of older adults. A neural network controller is jointly trained with this personalized human model to optimize hip torque assistance and improve walking mobility. Through co-adaptation, the controller learns autonomous assistance aligned with user-specific neuromuscular coordination. Trained entirely in simulation, it autonomously delivers personalized torque assistance during real-world walking with no parameter tuning.

Results



Simulation results (Fig. 1c,d) showed that exoskeleton assistance increased gait speed from 0.97 to 1.20 m/s, improved hip range of motion by 7.2%, and reduced biological hip torque by 8.7%. In a pilot human subject test, the personalized controller increased hip

range of motion by 12.7% compared with the no-exoskeleton condition. Additional subject data are currently being collected for broader validation.

Discussion

This study shows that a simulation-trained, aging-informed controller can provide personalized hip assistance and improve mobility without human-involved tuning. By overcoming the simulation-to-reality gap and generalizing across exoskeletons and musculoskeletal conditions, it offers strong potential for rehabilitation and community mobility.

Effects of Agonist-Antagonist Myoneural Interface on Trunk Kinematics During Walking Among Individuals With Unilateral Transtibial Limb Loss

Mr. Kiichi Ash MS[1,2], Dr. Pawel Golyski PhD[2,3], Dr. Brad Hendershot PhD[2,3,4], Dr. Courtney Butowicz PhD[2,3,4]

[1]Henry M. Jackson Foundation for the Advancement of Military Medicine, Inc., Bethesda, MD, United States. [2]Walter Reed National Military Medical Center, Bethesda, MD, United States. [3]Extremity Trauma & Amputation Center of Excellence, Falls Church, VA, United States. [4]Uniformed Services University of the Health Sciences, Bethesda, MD, United States

Introduction

Traditional lower-limb amputation transects native agonist–antagonist muscle connections, reducing proprioceptive feedback and forcing greater reliance on vision during walking. The agonist–antagonist myoneural interface (AMI) procedure restores these muscle pairs, potentially improving proprioception and motor control. However, since this construct was designed for use with myoelectric prostheses that are not commercially available, it is unclear if AMI improves walking mechanics when using a conventional prosthesis. The purpose of this work was to evaluate postural control during walking with a conventional prosthesis, as quantified by trunk kinematics, during level treadmill walking in persons with unilateral transtibial limb loss (UTTLL), with and without AMI. We hypothesized that persons with AMI would exhibit reduced trunk–pelvis range of motion (ROM) compared to traditional amputation, indicating better postural control due to increased residual limb proprioception.

Methods

Seven service members with UTTLL donning passive-energy storing and returned ankle-foot prostheses, two with AMI (37.0 ± 2.8 y) and five without (38.0 ± 11.1 y), completed a one-minute, full-body gait assessment on a treadmill at controlled velocity of 1.0 m/s. Prosthetic-side strides were parsed and analyzed to compute trunk range of motion (ROM) using OpenSim (v4.4) and custom MATLAB (2024b) scripts. Group differences were assessed with independent-samples *t*-tests (α=0.05).

Results

Participants with AMI exhibited 48.93% and 29.27% smaller trunk–pelvis ROM in the sagittal ($p = 0.249$) and frontal plane ($p=0.219$), but 5.72% larger trunk–pelvis ROM in the transverse plane ($p= 0.838$).

Discussion

Individuals with AMI did not exhibit differences in trunk–pelvis ROM compared to traditional UTTLL. Individuals with AMI exhibited trunk–pelvis ROM comparable to uninjured individuals (4.4°±2.4° sagittal, 11.6°±4.0° frontal, 13.9°±5.2° transverse), versus individuals with traditional amputation techniques. This comparison may suggest that the benefits of AMI, particularly enhanced proprioception and improved prosthesis embodiment, may extend to users of conventional prostheses, improving stability by reducing compensatory movement. This may indicate a myoelectric prosthesis may not be required to obtain postural control benefits from AMI and the use of a conventional prosthesis with AMI should be further explored. However, given the small sample size, these results must be taken cautiously.

Images (Optional)

Evaluating Cortical Activation Patterns Associated With Auditory Biofeedback for Gait Retraining

MS, PT Luisa Cedin[1], MS Camilla Antognini[1], BS Emily Timm[1], . Emma Struck[1,2], PhD Christopher Knowlton[1], PT, PhD Joan O'Keefe[1], PhD Markus Wimmer[1]

[1]Rush University Medical Center, Chicago, IL, United States. [2]Case Western Reserve University, Cleveland, OH, United States

Introduction

Engaging the patient during gait retraining is an emerging strategy in rehabilitation. Auditory feedback is a promising approach as it enables rapid motor responses without constraining movements. We developed a musical feedback system to shift the center of pressure (CoP) through an intuitive, engaging auditory cueing approach [1]. A key concern of this technology is the involved cortical load. Therefore, this pilot study aimed to detect changes in motor planning and auditory cortical activation patterns of musical feedback while patients were cued to modify their gait line.

Methods

Ten healthy adults were asked to walk at a self-selected speed under four auditory conditions: silence (S), self-selected music (M), musical feedback (MF) and verbal feedback (VF). MF and VF were randomized and cued the subjects to either medialize or lateralize CoP. Musical feedback was provided by measuring real-time plantar pressure (Moticon ReGo insoles) to modulate a low-pass filter that muffled the music whenever lateral CoP exceeded 25% of baseline. Simultaneous functional near-infrared spectroscopy (fNIRS) data was recorded bilaterally from the superior and middle temporal gyri of the temporal lobe (TL), and the combined premotor cortex (PMC) and supplementary motor area (SMA) during all assessments.

Results

Compared to the silent condition (S), participants walked faster with longer step length when listening to music. VF led to slower gait and shorter stride. MF did not alter spatiotemporal parameters compared with S. Only VF increased PMC/SMA activation relative to S ($p = 0.044$, Table 1). A trend of higher TL activation ($p = 0.065$) was observed in M, while MF and VF seemed to elicit similar activations.

Discussion

This is first study that investigates the cortical load associated with auditory biofeedback for gait retraining. Music seemed to be motivating, increasing walking speed and attenuating the expected slowdown with learning a new walking pattern observed during VB. Motor planning area was more active with VF, while no significant increase in auditory processing activity was observed. Overall, MF imposed minimal additional recruitment of motor planning and auditory processing regions of the cortex relative to silent walking, supporting its suitability for gait-retraining applications.

Effects of transcutaneous spinal cord stimulation amplitude on gait in children with cerebral palsy

Ms. Madeleine McCreary BS, Mrs. Katie Landwehr-Prakel BS, MS, Dr. Anna Fragomeni PT, DPT, PCS, Dr. Heather Feldner PT, PhD, PCS, Dr. Katherine Steele PhD

University of Washington, Seattle, Washington, United States

Ms. Madeleine McCreary

Mrs. Katie Landwehr-Prakel

Dr. Anna Fragomeni

Dr. Heather Feldner

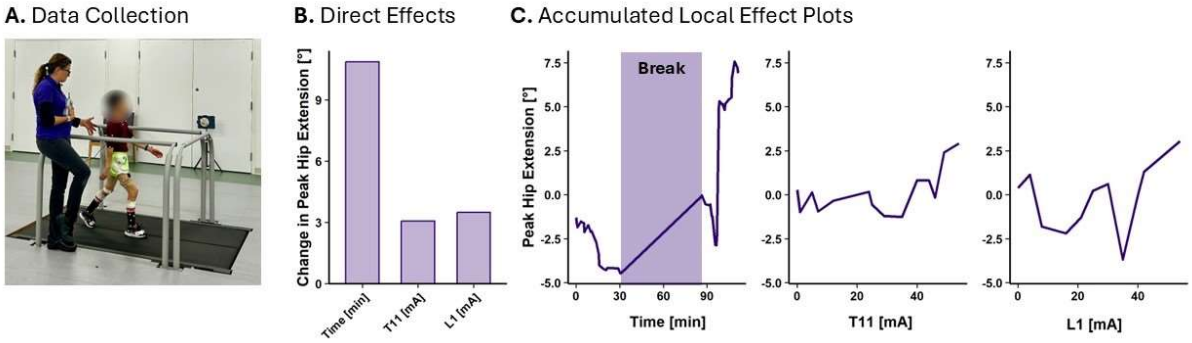
Introduction

Transcutaneous spinal cord stimulation (tSCS) is a noninvasive neuromodulation technique that, when combined with locomotor training, may improve gait function in children with cerebral palsy (CP). For a given session, stimulation is delivered to two vertebral locations at preset amplitudes. These preset amplitudes are typically determined by visual observation and trial-and-error, which is highly subjective and time-intensive. Thus, this study aimed to quantify the effect of tSCS amplitude on gait parameters in children with CP.

Methods

Three children with CP walked on a treadmill with tSCS for 24 one-minute stimulation conditions. The amplitudes at T11 and L1 vertebrae for each stimulation condition were determined via Latin hypercube sampling, and their order was randomized. For each gait cycle, step length, step width, peak hip extension, peak knee flexion, and quadriceps-hamstrings co-contraction were quantified. To quantify the effects of stimulation amplitude, we trained individual Bayesian additive regression tree models. Time into visit

was included as a covariate in the models to account for fatigue. Model fit was evaluated by R^2 values and accumulated local effect (ALE) plots were used to quantify individual parameter effects.



Results

Stimulation amplitude had the greatest influence on peak hip extension. For one participant, model fit was the highest for peak hip extension (R^2=0.34) and the lowest for step width (R^2=0.11). For all outcome measures, the direct effect of time was greater than the direct effect of T11 or L1 amplitude. The ALE plots indicate that peak hip extension increased as T11 amplitude increased above 40 mA and there were variable effects with L1 amplitude.

Discussion

Preliminary results indicate that minor changes in stimulation amplitude can alter gait outcome measures, such as peak hip extension. We expect results from additional participants will indicate that these effects vary across individuals due to the heterogeneity of CP. Determining whether there is an "optimal" stimulation condition to improve gait for a given individual remains an open question that needs to be addressed to maximize intervention effectiveness. These findings may be used to develop an evidence-based methodology to identify the appropriate stimulation parameters for future tSCS research, enabling consistency across sessions and institutions.

Is Exoskeleton-Assisted Walking Active? Evaluating Metabolic Cost and Weight-Bearing in Children with Cerebral Palsy

Miss Marita Cafazzo BASc[1,2], Dr. Tom Chau PhD, PEng[1,2], Dr. Virginia Wright PhD[1,2]

[1]University of Toronto, Toronto, Ontario, Canada. [2]Holland Bloorview Kids Rehabilitation Hospital, Toronto, Ontario, Canada

Introduction

Cerebral palsy (CP) affects 2–2.5 per 1000 children annually in Canada and is the leading cause of childhood physical disability. Children at Gross Motor Function Classification System (GMFCS) Levels III–IV have limited walking ability, often rely on wheelchairs for mobility, and consequently have few opportunities for physical activity, increasing their risk of cardiovascular disease. Motorized lower-limb exoskeletons, such as the pediatric Trexo Plus, offer a promising rehabilitation tool; however, the physical demands of robot-assisted gait training (RAGT) - particularly its potential as an exercise modality - remain insufficiently understood in this population.

This study aims to quantify the metabolic cost (MC) of Trexo-assisted walking in children with CP (GMFCS III–IV), assess their level of active engagement, evaluate weight-bearing during, and develop a predictive model of MC using accessible biomechanical markers to guide clinical decision-making.

Methods

This study involves 15 children with cerebral palsy (GMFCS III–IV) completing two visits involving anthropometric measurements, equipment familiarization, and metabolic testing during Trexo-assisted walking. Participants complete a seated 8-minute baseline followed by three 6-minute walking trials at increasing step rates while breath-by-breath oxygen consumption and carbon dioxide production are recorded, alongside weight bearing, external oblique engagement, head movement, heart rate, and perceived exertion. MC is calculated through Weir's equation, applied to a minute-long steady-state portion of each trial. Analyses include ANOVA, correlation testing, and predictive modeling using a hidden Markov model.

Results

Building on a pilot study (PRISM Lab, 2022–2024) that observed visual signs of fatigue during exoskeleton-assisted walking, this study will provide objective physiological measures of exertion and metabolic demand [1]. No results are available at this stage.

Discussion

Understanding the MC of Trexo-assisted walking will clarify the extent to which exoskeleton use facilitates meaningful physical activity for children with CP. Findings may support more effective therapy planning, expand opportunities for exercise participation, and ultimately enhance mobility and quality of life.

Prosthetic Proprioception: Complaint Ligaments for Joint Angle Estimation in a Robotic Bicondylar Knee

Mr Mark Wolstenholme, Dr Peter Ellison

University of York, York, North Yorkshire, United Kingdom

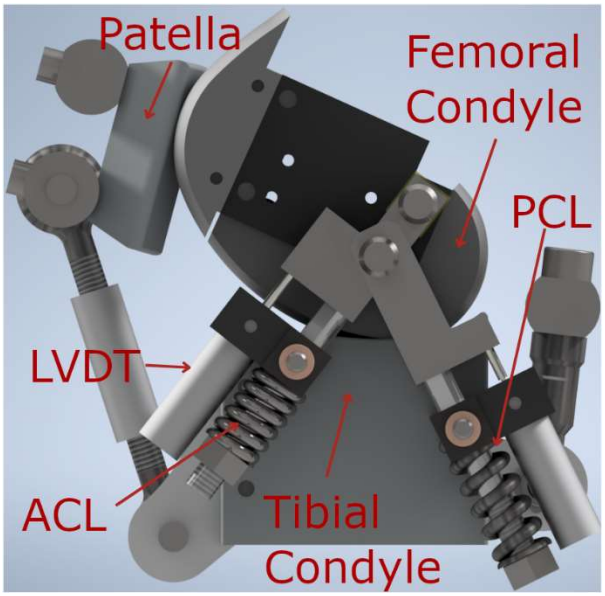
Introduction

Current designs of bionic knee are usually pin joined and rely on predefined control architectures to generate motion. Bicondylar designs modelled on anatomy have the potential to allow more natural motion for the user, however due to their compliant nature joint angle cannot be directly measured by encoders. Here we investigate the use of cruciate ligaments as a mechanism of estimating joint angle in a bicondylar knee design.

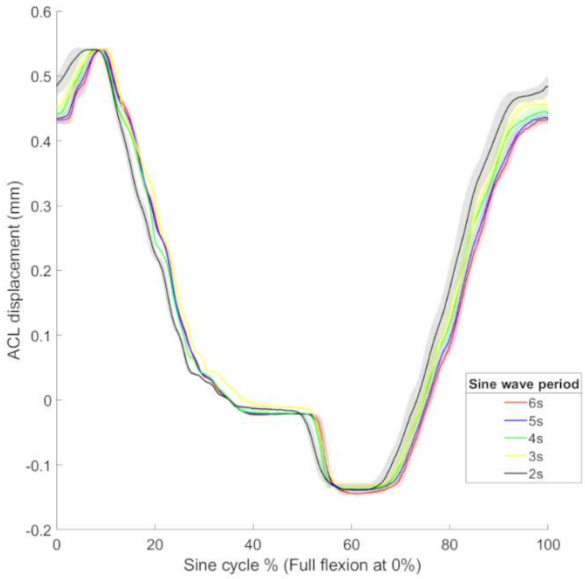
Methods

A robotic knee rig was used to simulate knee motion. A pair of LVDTs were used to measure the relative displacement of elastic mechanical ligaments while the joint was driven through a sinusoidal profile. The joint was driven between 30° and 110° flexion-extension at periods between 2 and 6 seconds. Results were averaged across 10 cycles for each dataset. The driving force was delivered by 2 servo motors attached to pulleys acting as quadriceps and hamstrings. The level of antagonistic co-contraction was varied from 22N to 154N.

Results



Ligament displacement was independent of joint speed, with no significant variation observed between datasets for the majority of the cycle. The most variation was shown by the PCL with 0.05mm difference at 56% cycle. ACL and PCL are affected by co-contraction level and ligament length. The ACL saw at maximum 0.094mm divergence between lowest and highest co-contraction level, and 0.143mm when varying ligament length . For the PCL, these values were 0.138mm and 0.252mm, respectively.



A predictor was constructed based on a Gaussian mixture model with means given by the two possible angles from each LVDT. The predictor achieved a mean square error of 250 deg^2 on test data.

Discussion

Cruciate ligament stretch provides a viable mechanism for estimating joint angle in a bicondylar knee design. A single ligament measurement provides two possible joint configurations, the combined stretch/displacement of the ACL and PCL enabled accurate estimation of joint position. Incorporating additional state variables such as speed or actuator force may further improve estimation accuracy. Overall, this study demonstrates a practical control strategy for compliant bicondylar joints and offers promising foundation for advancing prosthetic knee technologies.

Acute Effects of Whole-Body Transcutaneous Electrical Nerve Stimulation on Gait and Functional Mobility: A Mini-Longitudinal Case Study in Hereditary Spastic Paraplegia

Prof. Massimiliano Pau[1], Ms. Francesca Taccori[1], Dr. Micaela Porta[2]

[1]University of Cagliari, Cagliari, Sardinia, Italy. [2]Unibversity of Cagliari, Cagliari, Sardinia, Italy

Introduction

Individuals with Hereditary Spastic Paraplegia (HSP) typically present with a stiff, spastic gait featuring reduced knee flexion, limited ankle dorsiflexion, a generalized decrease in dynamic range of motion of all lower limb joints. Recently, transcutaneous electrical nerve stimulation (TENS) has been demonstrated beneficial in terms of lower-limb strength, joint range of motion, pain, and spasticity in neurological populations. Nonetheless, quantitative evidence supporting its effectiveness in HSP remains limited, underscoring the need for dedicated studies in this population.

Methods

A 60-year-old man with HSP presented with bilateral drop foot, right-accentuated forefoot drag, increased hip adductor and knee extensor tone. He routinely used the Exopulse Mollii Suit, delivering individualized low-intensity TENS for 60 minutes every two days. Over 100 hours, he completed two TENS sessions, with gait and functional mobility instrumentally assessed seven times to capture acute effects and washout. Gait was analyzed using an 8-camera motion-capture system, and functional mobility via an instrumented Timed Up and Go test.

Results

Main results are reported in Table 1. After the first TENS session, marked improvements in gait were observed: speed increased to 0.9 m/s and, similarly, increases in stride length and cadence were observed, together with a 16% reduction in double support. Dynamic ROM in the ankle joint of the more affected limb increased by 42%. These effects diminished after 48 hours (T74), returning to near pre-treatment values. In the iTUG test, performance improved in both sessions, with total time reductions of ~4 s and ~9 s, primarily driven by faster 180° turns. These benefits dissipated within two days, although second-session effects were more pronounced.

Discussion

This case study provides preliminary evidence that short-term full-body TENS via the Exopulse Mollii Suit can induce acute, clinically meaningful improvements in gait and functional mobility in HSP. A single 60-minute session led to increased gait speed, stride length, cadence, reduced double-support duration, and improved ankle ROM, with similar, reproducible effects after a second session. iTUG performance also improved, particularly during turning. These benefits were transient, returning to baseline within 48 hours, underscoring the need for repeated or sustained intervention and larger controlled studies.

Informing Exosuit Design: Analyzing Infant Reaching Duration and Coordination Strategies to Determine Actuator Operational Parameters

Miss Melanie Barahona Masters of Science Student, Bioengineering Dept, Miss Ipsita Sahin Ph.D Student, Bioengineering Dept, Miss Mehrnoosh Ayazi Ph.D Student, Electrical & Computer Eng Dept, Dr. Konstantinos Karydis Associate Professor, Electrical & Computer Eng Dept, Dr. Elena Kokkoni Assistant Professor, Bioengineering Dept & Electrical & Computer Eng Dept

University of California, Riverside, Riverside, CA, United States

Introduction

Reaching is a critical motor milestone fundamental to early environmental exploration [1]. Infants with or at risk of upper extremity impairments may face significant challenges in achieving this milestone. Wearable assistive technology, such as exosuits, offers a promising solution, as demonstrated in adult populations [2]. A key design element involves integrating fabric-based pneumatic actuators into the wearable exosuit. To optimize actuator performance, crucial information regarding reaching behavior is required. Specifically, we investigate the required actuator operating speeds (informed by reach duration) and coordination strategies (unimanual versus bimanual reaching based on targeted object size).

Methods

The KIRA dataset was used to extract this information. This dataset includes videos of infants up to 12 months of age reaching for objects in a sitting position in natural environments. The size and location of the presented objects varied. The final sample included eight infants exhibiting both unimanual and bimanual reaching actions, contributing 86 total reaches (24 being bimanual). Reaching duration was computed based on the annotated onset and offset frames. Object size categories were defined relative to the infant's hand size: small (equal to or smaller than one hand), medium (larger than one hand but smaller than two hands), and large (equal to or larger than two hands). Potential variations in reaching durations and coordination strategies were examined.

Results

Overall, reaching duration ranged from 0.2-1.8s, with the location of the object and the initial position of the hand contributing to variations. Unimanual and bimanual reaching duration was similar at 0.7s, while preliminary examination of object size did not seem to affect reaching duration or coordination strategy, in contrast to previous studies.

Discussion

Information on infant motor control is limited, yet critical for developing effective wearable actuator control systems. This work provides baseline data, essential for defining the operational parameters (speed and co-activation timing) of the exosuit's actuators.

Masters-Aged Runners With Knee Osteoarthritis Manage Symptoms With Load-Modifying Strategies to Continue Running: A Qualitative Inquiry

Ms Michaela Khan, Dr W. Ben Mortenson, Dr Jackie Whittaker, Dr Michael Hunt

University of British Columbia, Vancouver, BC, Canada

Introduction

Runners with knee osteoarthritis (OA) are a distinct subgroup of the knee OA population who remain highly functional. In our clinical experience, this group reports using various strategies to manage their knee symptoms, many of which appear to address the load experienced by the body. Given this has never been formally investigated, we aimed to qualitatively summarize load-modifying strategies that runners with knee OA use to manage their knee symptoms and continue running.

Methods

We used an interpretive description methodology [1] to identify patterns in strategies used by masters-aged recreational runners with a clinical diagnosis of knee OA. Participants were recruited - using intensity sampling - from a previous study examining responses of osteoarthritic cartilage to running. We collected data through one-on-one, semi-structured, videoconference interviews and analyzed using reflexive content analysis [2].

Results

We interviewed twelve runners who had either mild (n=10) or moderate (n=2) disease severity, and varied in age (50-76 years), gender (n=7 women), running experience (3-55 years), duration of knee symptoms (1-15 years), and current weekly running distance (0-50 km/week). Participants preferred running uphill and on soft surfaces, and modified their gait by reducing step length, increasing cadence, or running “softly”. They emphasized the importance of weight management but expressed mixed opinions about shoe selection and wearing a knee brace. Participants also balanced consistent running training with caution by incorporating rest days, shortening long runs, and slowing their pace.

Discussion

With a paucity of evidence to guide the education of runners with knee OA, our findings provide a foundation for quantitative research into load-modifying strategies for runners with knee OA. Some strategies (e.g., increasing cadence, running “soft”) align with evidence that they reduce load and improve pain, whereas others have not been linked to symptom management (e.g., running uphill). As masters-aged runners constitute the most

rapidly expanding group within the running community, and the incidence of knee OA is rising, clinicians, coaches, and runners should be aware of these experiential strategies. Future investigations should involve novice runners or those with more advanced knee OA disease.

Active Prosthetic Wrist and Multi-grip Control on Trunk Movement Compensations and Smoothness

Ms. Mira Mutnick M.S.E., Mr. Dylan Wallace, Dr. Paul Cederna M.D., Dr. Cynthia Chestek Ph.D., Dr. Deanna Gates Ph.D.

University of Michigan, Ann Arbor, MI, United States

Introduction

Commercial muscle-activated upper limb prostheses enable active grip selection but lack active wrist motion due to the lack of available musculature for control. Intramuscular electrodes coupled with a surgical construct, the regenerative peripheral nerve interface (RPNIs), provide additional control signals for more natural prosthetic hand movement. The ability to actively control the wrist unit might reduce the compensatory movement upper limb prosthesis users make to properly orient their hand to interact with objects. The purpose of this study was to assess the role of active wrist control with multiple grips during functional tasks on trunk movement compensations and smoothness.

Methods

One female with unilateral transradial amputation used a multi-grip myoelectric prosthetic hand with and without active wrist rotation to perform two functional assessments, the Coffee Task and the Clothespin Relocation Test, over eight sessions. Sequential pattern recognition classifiers were trained to decode either surface electromyography (EMG) or intramuscular EMG from residual muscles and RPNIs into multi-grip only or multi-grip and wrist rotation. Primary outcome measures were peak segmental trunk angles and range of motion (ROM), the number of submovements, the Speed Metric, and spectral arc length (SPARC). We compared the movement compensations and smoothness between wrist conditions using a Wilcoxon rank sum exact test (alpha = 0.05).

Results

For the pouring motion in the Coffee Task, including active wrist rotation had minimal effect on peak trunk angles and ROM. While the number of submovements was unchanged ($p=0.09$), the addition of wrist rotation decreased both the Speed Metric and SPARC ($p=0.04$). For the Clothespin Relocation Test, including active wrist rotation decreased trunk lateral lean and flexion/extension ROM ($p<0.02$) (Figure 1).

Discussion

While active wrist motion was available, it was hard to achieve consistent and precise hand position using these control approaches during object manipulation. This difficulty may have discouraged use of this feature, resulting in similar compensatory patterns. Future studies should iterate on the control approach used to activate the wrist to better improve compensatory movements.

Images (Optional)

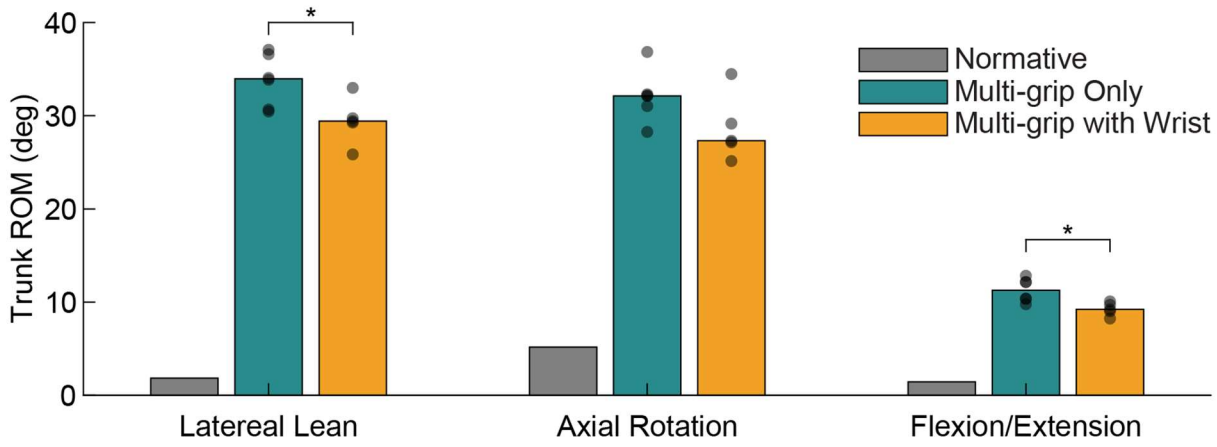

Figure 1. Three-dimensional trunk range of motion (ROM) when transferring a clothespin from a horizontal bar up to a vertical bar during the Clothespin Relocation Test with (gold) and without (teal) active wrist control. Normative angles (gray) from an individual without limb loss are provided for visual comparison. Dots represent the average ROM of all full attempted clothespin transfers using the controller during the session. Bars represent the median across controllers and sessions for each wrist condition. *p<0.05.

Introduction

People with lower extremity amputation (LEA) struggle with daily mobility, especially turning. Previous studies reported test time and forward walking spatiotemporal variables, but often omit other components of gait, such as turning, that are assessed in functional tests. The purpose of this study was to analyze spatiotemporal components of the Timed Up and Go (TUG) and the Three Times Figure Eight Test (3XF8T) for people with LEA.

Methods

Data were analyzed from a single visit. Participants completed clinical tests (10-m walk, TUG, 3XF8T) on a pressure-sensitive mat (Protokinetics Zeno Walkway, Havertown, PA) using their usual prosthetic foot. The total TUG and total 3XF8T were divided into components geometrically in MATLAB using exported footfall data. The TUG was split into (1) rising and sitting (excluded), (2) straight walking (footfalls away/toward the chair were averaged), and (3) turning. The 3XF8T was divided into right and left turns. Analysis compared the TUG and 3XF8T to each other and to the total test. Statistical analysis was conducted in RStudio using multiple linear regression methods, with interaction tests for amputation level and gait speed, and significance at $p < 0.05$.

Results

Sixty-one participants (bilateral (BA) = 13, K2 below knee (BKA) = 15, above knee (AKA) =33) were included. Spatiotemporal and regression results are in Table 1. Significant differences were found between the total, straight, and turning portions of the TUG. Except for stride width, there were no differences between the total, right, and left turns in the 3XF8T. Compared to AKA, BA was associated with slower stride velocity and longer stride and swing time for BA and BKA during TUG and 3XF8T. Generally, an increase in gait speed was

associated with increases in stride velocity and stride length and decreases in stride time and width.

Discussion

Gait varies across TUG components, and to a lesser extent, the 3XF8T, highlighting the importance of examining components of gait, such as turning, that mimic daily activities in LEA. Amputation level affects gait performance, and gait speed modifies spatiotemporal measures. Understanding both the forward and components of gait will help characterize gait patterns and improve knowledge of LEA's mobility.

Spatiotemporal Digital Biomarkers of Gait Impairment During Turning Phase of the Timed Up and Go Test

Mr. Muhammad Taimoor Adil PhD Student[1], Dr Parthasarathi Mandal Reader[2]

[1]University of Manchester, Manchester, Manchester, United Kingdom. [2]University of Manchester, Manchester, Mancehster, United Kingdom

Introduction

Turning strategy is an important predictor of fall risk in individuals with balance deficits [1]. It is a biomechanically demanding task that requires coordinated modulation of step placement, timing, and centripetal acceleration, yet remains far less studied than straight-line walking. The present study examined step-level spatiotemporal features during the turning phase of a Timed Up-and-Go (TUG) test to identify markers that differentiate normal from pathological gait with high fall risk.

Methods

Pose estimation was applied to video recordings from publicly available dataset [2] to reconstruct full-body kinematics. The turning phase and step events were identified using foot and pelvis trajectories. For each participant, mean and standard deviation of spatiotemporal parameters, together with centripetal acceleration, were computed. Participants were classified as normal (n = 10) or pathological (n = 7). Group differences were tested using t-tests or Mann–Whitney U tests, with Cohen's d quantifying effect sizes. An L1-regularised logistic regression model was then implemented to identify the subset of features most discriminative of gait pathology.

Results

Statistically significant differences ($p < 0.05$) were found for several parameters (Table 1). Participants with pathological gait took shorter, slower, and less variable steps, required more steps to complete the turn, and spent longer turning, thus, indicating reduced efficiency and impaired balance control. Multivariate analysis further showed that lower step-width variability, shorter step length, and reduced swing time, together with increased total turning duration, were the strongest predictors of pathological gait.

Discussion

The findings suggest that individuals with pathological gait adopt a conservative turning strategy that prioritises stability over efficiency. Reduced centripetal acceleration indicates limited capacity to generate lateral forces required for controlled redirection of the body during turning. Lower step-width variability further suggests a stiffer mediolateral control strategy that restricts foot placement to minimise balance threats. Detailed turning analysis within the TUG framework offers a practical means of extracting clinically relevant digital biomarkers of gait and may support early identification of mobility deficits. The small sample size remains a key limitation, warranting validation in larger cohorts.

Mobility Device Misuse and Fall Circumstances Among Older Adults in Long-Term Care

Ms. Brianna Reilly[1], Dr. Katherine Mayes MD, PhD[2,3], Dr. Damon Kuehl MD[2,3], Dr. Steve Rowson PhD[1], Dr. Nicole Stark PhD[1]

[1]Virginia Tech, Blacksburg, VA, United States. [2]Virginia Tech Carilion School of Medicine, Roanoke, VA, United States. [3]Carilion Clinic, Roanoke, VA, United States

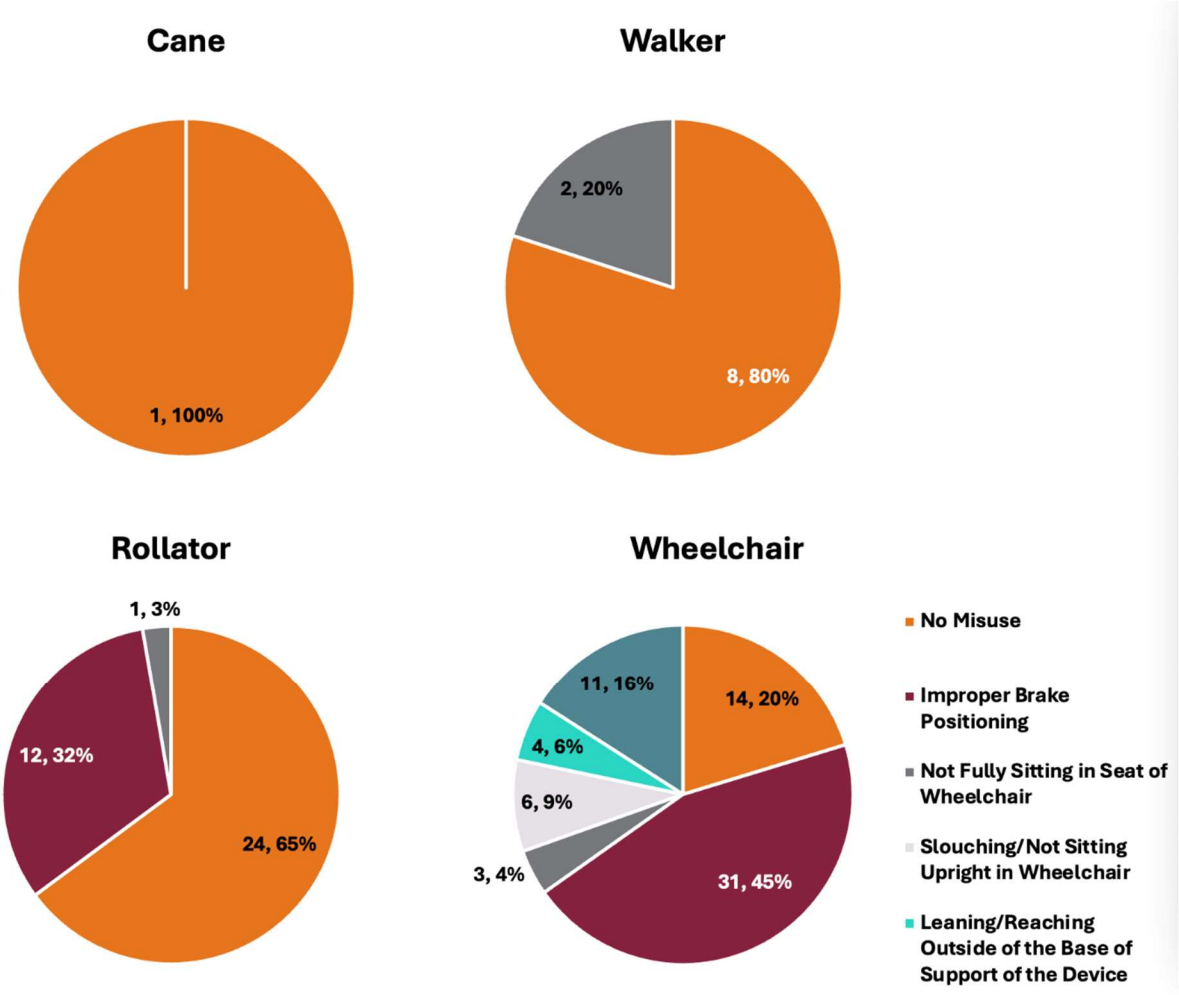
Introduction

The number of U.S. adults aged 65 and older is expected to nearly double, reaching 98 million by 2060. As the older adult population grows, understanding fall risk factors becomes increasingly critical [1]. Although mobility devices aim to improve safety, they can also pose new risks. This study uses video analysis to characterize how mobility devices contribute to falls among older adults living in long-term care (LTC) facilities.

Methods

A trained reviewer analyzed 300 open-access LTC fall videos, documenting fall characteristics, injury types, demographics, and clinical information [3]. Mobility devices were categorized by: cane, wheelchair, two-wheeled walker, and rollator. We examined the characteristics of falls, injury patterns, and instances of device misuse across these groups and compared them with falls that occurred without device use.

Results



Most falls occurred without the use of a mobility device, accounting for 60.7% (182 out of 300) of the incidents. Among device-related falls, 23.3% involved wheelchairs, 12.3% rollators, 3.3% walkers, and 0.3% canes. Nearly half of device-free falls occurred while walking (46.7%). Falls related to wheelchairs commonly occurred while the individual was seated/wheeling (38.65%) or during transfers (37.1%). Across all types of mobility devices, the most frequent causes of falls were improper transfers and incorrect weight shifting. Misuse of mobility devices was often observed, particularly among four-wheeled devices (Figure 1).

Among falls without mobility devices, 42.9% resulted in injury. Injury rates were similar for rollator users (45.9%) and walker users (40%), while wheelchair users had the lowest injury rate (24.3%).

Discussion

The main cause of falls involving wheeled mobility aids was improper braking, highlighting a design and usability issue. Wheelchair users often fell due to losing external support, indicating instability in the environment or difficulties during transfers. Rollator and walker users, like those who fell without devices, most frequently fall due to improper transfer or weight-shifting. These differences emphasize the need for targeted fall prevention strategies tailored to each type of mobility device, as falls among LTC residents vary greatly by device, with different mechanisms and misuse patterns.

Introduction

Virtual reality (VR) has gained popularity as a tool for motor learning and rehabilitation. This technology has advanced to the point that prosthetic controllers can be connected to virtual prosthetic arms, allowing users to train with them before owning a prosthesis. This

presentation details the development of a foot-based prosthetic controller, a VR environment for the controller, and the results obtained so far in using VR to train participants.

Methods

Ongoing participant recruitment is focused on users with (*n=10)* and without (*n=40)* a transradial amputation. These participants undergo a seven-week training program that consists of five weeks of VR sessions between two weeks of real-world baseline (week 1) and retention (week 7) sessions. Each session includes 3 trials with strict 10-minute rest. The participants are divided into 8 different training configurations defined by visual fidelity (*high (HV) or low (LV)),* cognitive demand (*high (HC) or low (HC)),* and adaptivity (s*tatic or adaptive*). Using a real-world foot-based prosthesis controller, participants sort an assortment of randomized blocks labeled with vocabulary terms under a given time limit.

The controller includes two components: an IMU-based controller unit and an insole inserted into a shoe for the participant to wear. Participants in adaptive VR conditions train across ten difficulty levels, where progressing to higher levels reduces available time and introduces blocks of varying sizes. Depending on condition and level, task time limits range from 5 to 15 minutes.

Results

Initial findings (*n = 11, all amputation-free*) suggest that VR training improves user performance, with participants showing rapid improvement over the course of five weeks. Faster completion speeds without sacrificing sorting accuracy demonstrated participants' increasingly reliable prosthesis control. Performance patterns also revealed clear condition-based effect: LC participants generally achieved higher speeds than HC participants, and HV participants outperformed LV, supporting our hypothesis about visual fidelity and cognitive demand.

Discussion

The outcomes of the participants' real-world retention sessions were comparable, demonstrating how VR training facilitates effective transfer to real-world applications. These findings highlight the potential VR can have as a scalable training platform and provides insight into condition-specific factors that shape learning trajectories for prosthesis control.

Development of Multidirectional Perturbations for Fall-Prevention Training Using the FLOAT Body Weight Support System

Ms. Nooshin Seddighi, Mr. Merrick Mar, Dr. Cecilia Monoli, Dr. Anna Render, Dr. Peter Fino

University of Utah, Salt Lake City, Utah, United States

Introduction

Improving reactive balance is critical for reducing falls in older adults [1]. However, few methods can safely and consistently deliver perturbations during standing and overground walking [1]. This study aimed to develop and evaluate the feasibility of controlled multidirectional perturbations using FLOAT, a 3D cable-driven robotic body weight support (BWS) system [2]. We evaluated the feasibility of using FLOAT's open-control mode by delivering perturbations of varying direction and magnitude during standing and overground walking.

Methods

Two healthy adults (female:30 years, 175.3cm, 83.9 kg; male:19 years, 177.8cm, 72.6kg) completed a validation protocol including standing and walking tasks. Thirty-Two perturbations were delivered at two magnitudes (standing:10% vs 15% BW; walking:7.5% vs 12.5% BW), two impulse durations (0.3 vs 0.5s), and eight directions in the transverse plane spanning 0-360° in 45° increments to assess directional stepping sensitivity. Baseline BWS was maintained throughout (standing:15%; walking:10% BW). Perturbations were randomized, and during walking, they were delivered at randomized intervals of 3-5m, ensuring variability in timing and direction. Perturbation-induced acceleration vectors, defined as the first peak magnitude of acceleration following each perturbation, were collected from inertial sensors mounted on the FLOAT bar, the participant's sternum, and lumbar. For each sensor, linear mixed-effects models assessed whether perturbation-induced accelerations differed by perturbation type (magnitude and intended direction).

Results

Preliminary data indicate that FLOAT successfully delivered perturbations at different magnitudes and directions during both standing and walking (Figure 1). During standing, acceleration of the bar, sternum, and lumbar sensors confirmed transmission of perturbations from the FLOAT to upper and lower trunk segments, but the acceleration

angle deviated slightly from the desired oblique directions. Perturbation-induced acceleration varied by magnitude at the bar (standing and walking: $p<0.001$), sternum ($p=0.01$), and lumbar ($p<0.001$) locations. The direction of perturbation-induced acceleration also differed by directional condition ($p<0.001$), confirming that the system can deliver perturbations in repeatable, different magnitudes and directions during standing and walking.

Discussion

This technical validation demonstrates that FLOAT with open-control mode can deliver controlled, multidirectional perturbations with adjustable parameters suitable for future perturbation-based training studies in older adults.

Images (Optional)

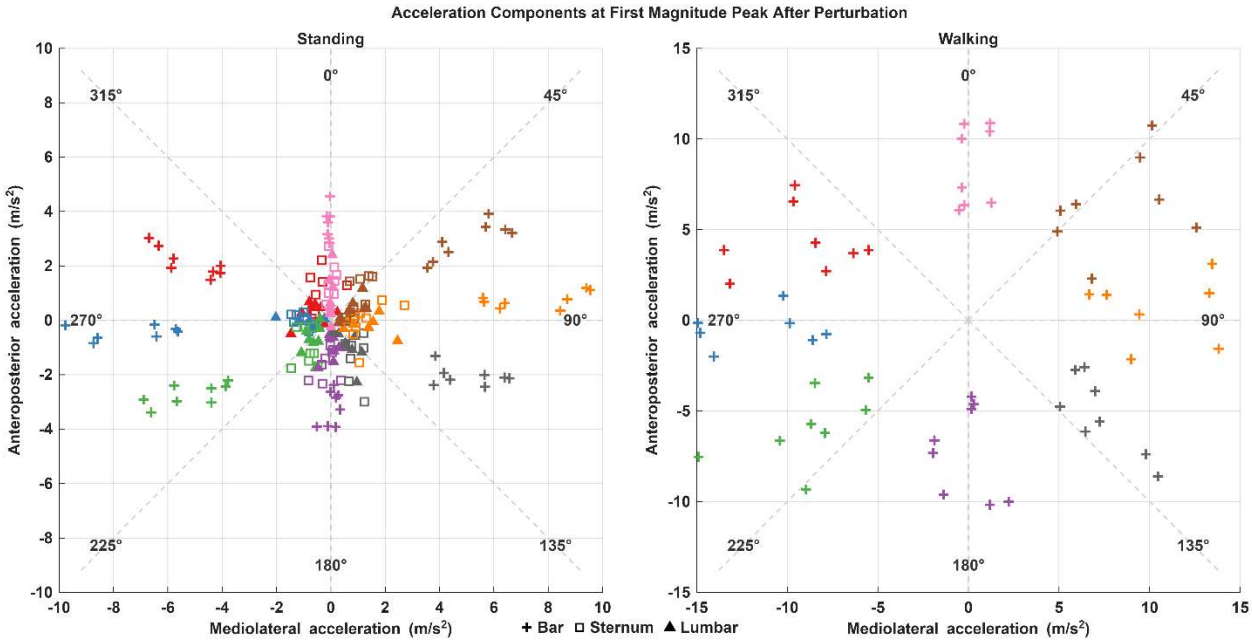

Figure 1. Perturbation-induced accelerations of the FLOAT support bar (−), participants' sternum (□), and participants' lumbar spine (▲) during standing (Left). The right panel shows walking responses, where (+) denotes the bar sensor. Colors indicate the acceleration direction relative to the participant. The main directions are anterior (0°), posterior (180°), right (90°), and left (270°). Diagonal angles correspond to combined directions: antero right (45°), antero-left (315°), postero right (135°), postero left (225°).

Effectiveness of a Contralateral Shoe Balancer on Reducing Gait Alterations in Achilles Tendon Rupture Rehabilitation Boots

Ms. Phoebe Cheung[1], Dr. Julie A. Stebbins[2,3], Prof. David J. Keene[2], Prof. Amy B. Zavatsky[1]

[1]Department of Engineering Science, University of Oxford, Oxford, Oxfordshire, United Kingdom. [2]NDORMS, University of Oxford, Oxford, Oxfordshire, United Kingdom. [3]Oxford Gait Laboratory, Oxford University Hospitals NHS Foundation Trust, Oxford, Oxfordshire, United Kingdom

Introduction

Achilles tendon rupture (ATR) patients wear an immobilization boot for about two months to facilitate healing, with the ankle transitioning from 30° plantarflexion (PF) to 0° over several weeks. To compensate for leg length asymmetry caused by the boot, a shoe balancer is occasionally worn on the uninjured (contralateral) side. Previous literature on balancer effectiveness only focused on boots with a neutral ankle position [1]. This study aims to determine the effectiveness of a balancer in reducing gait alterations when the immobilized ankle is at 30° PF.

Methods

Three healthy adult participants (ongoing study, target n=12) completed walking trials in two common ATR boots (VACOped and AirSelect) set at 30° PF and 0°, with and without a balancer (EVENup). Baseline walking data in shoes was also captured. Kinematic data was collected with marker-based motion capture (Vicon) using conventional model lower limb markers and processed with clinical protocols for calculating joint kinematics.

Results

Hip flexion-extension was selected for initial data analysis, as lower back and hip pain are most common in patients wearing rehabilitation boots [2]. Visual inspection of the preliminary data suggest that wearing a balancer partially reduces gait alterations at the hip (Figure 1). Greatest improvement is seen in the ipsilateral hip in the 30° PF configuration for both boots, with improved peak hip extension during stance. The balancer has little effect on contralateral hip motion.

Discussion

A study on the AirSelect at 0° reported that balancers partially restored kinematics towards the shoe baseline [1], while this study's initial findings show minimal visual change in this configuration. Upon completion of the study, the balancer's ability to reduce gait alterations at other joints and in other planes of motion will also be quantified, allowing the effectiveness of the balancer to be assessed fully. While the study is only observing the effects on healthy participants and does not consider pathological gait of ATR patients, its early results already reinforce the importance of wearing a balancer during the early stages of rehabilitation when the booted ankle is most plantarflexed.

Haptic Wheelchair Propulsion Training Using Real-Time 3D Inverse Dynamics and Reinforcement Learning Approach

professor Rachid Aissaoui RA[1,2], MSc Clément Ghazouani CG[1], MSc Manon Perez MP[1], PhD Philippe Nadeau PN[3]

[1]École de technologie supérieure, Montréal, Québec, Canada. [2]CRCHUM, Montréal, Québec, Canada. [3]University of Toronto, Toronto, Ontario, Canada

Introduction

Manual wheelchair propulsion (MWP) is an important form of mobility [1]. High prevalence of shoulder pain and injury are reported during MWP, but the exact cause-effect relation remains unclear [2]. Current wheelchair provision guidelines provide little insight into the biomechanical context about MWP efficiency while preserving from shoulder joint injury [3]. Recently, we developed a haptic wheelchair simulator [4,5] which has the capacity to estimate the bilateral 3D real-time inverse dynamics at shoulder, elbow and wrist joints as well as the physiological cost (PC) during MWP. The purpose of the present work is to train wheelchair user to modify their pattern of propulsion while enhancing their mechanical efficiency (MEF) and reducing their PC using real-time reinforcement learning approach.

Methods

Eighteen able-bodied subjects participated in this study. They were asked to propel the wheelchair at 1m/s onto the haptic simulator during 3 mn whereas the RL algorithm learn the pattern of their propulsion. Six conditions of training were applied randomly. 3D inverse dynamics of upper limb was assessed in a real-time using Simulink in Speedgoat computer. The dependent variables are the average and maximal value of MEF and PC during the push cycle of MWP for each condition at a controlled speed of 1m/s.

Results

Table 1 shows the 6 conditions with respect to the baseline. The results indicate that MEF was enhanced for all conditions of propulsion. RL training help reducing the joint moment at the shoulder level when using assistive/resistive condition.

Discussion

This work demonstrate that it is possible to enhance MEF while reducing shoulder joint moment. Any reduction of the shoulder joint moment is beneficial for the integrity of the shoulder complex as well as for the reduction of risk of glenohumeral joint injury.

Introduction

Research has described mixed outcomes for gait rehabilitation in virtual reality (VR), which may be related to the design of the VR experience itself [1]. Some design factors that might influence gait rehabilitation in VR include visual fidelity (i.e., visual realism) and cognitive demand (i.e., psychological realism). It is not known how the combination of these factors drives learning and/or enhancement of gait. Therefore, this study seeks to understand how systematically manipulating VR design factors affects gait biomechanics during a novel obstacle negotiation task.

Methods

Participants with and without stroke (anticipated n = 40 without and n = 10 with stroke) are being recruited for this ongoing study. Each participant performs an obstacle negotiation task while simultaneously completing a secondary cognitive task (simulating texting and walking). After a real-world baseline assessment, participants practice this task on an omnidirectional treadmill twice per week for five weeks in a virtual environment that differs in terms of visual fidelity (high (HV) or low (LV)) and cognitive demand (high (HC) or low (HC)). All participants then perform real-world retention and transfer tests. Inertial measurement units (IMUs) placed on the pelvis, legs, and feet are used to calculate spatiotemporal gait outcomes as well as obstacle negotiation mechanics.

Results

Preliminary results (n = 5, all without stroke) indicate that training in LV VR resulted in large increases in leading limb angles at the moment of obstacle negotiation, while training in HV VR resulted in large decreases in the same angle (Figure 1). There were no evident differences between training in HC and LC on obstacle negotiation mechanics. Very few differences in spatiotemporal outcomes were evident across all comparisons.

Discussion

Results indicate that VR realism can impact obstacle negotiation mechanics, highlighting the need for VR-based interventions to consider this factor when designing a training experience. Moreover, how an environment in VR is perceived has downstream effects on motor output. In total, this work describes how not all VR experiences are equal for skill learning, and thus better informs why the literature to date is mixed with regards outcomes in VR-based interventions.

Exercising With a Resistive Hip Exosuit Induces Stroke-Relevant Gait Aftereffects in Healthy Adults

Doctoral Student Sangwon Shin, Ph.D. Pieter Van den Berghe, Associate Professor Mukul Mukherjee, Associate Professor Philippe Malcolm

University of Nebraska at Omaha, Omaha, NE, United States

Introduction

Post-stroke walking leads to biomechanical deficits [1] such as asymmetric step length and propulsion, drop foot, insufficient toe clearance, hip hiking, and circumduction [2, 3]. Other groups have developed motorized devices to target stroke-relevant variables on each joint: e.g., split-treadmills to retrain propulsion [4], ankle exosuits to help with push-off and toe clearance [5], hip exosuits to help with circumduction and hip hiking [6]. We have developed a soft passive hip exosuit with quasi-force retractors asymmetrically spanning the hip joints. Our device made the aftereffect on step-length symmetry in healthy adults [7]. To expand this finding, this study aimed to evaluate whether an unpowered resistive device could alter stroke-relevant variables, such as trailing limb angle, propulsive/braking impulse, minimum toe clearance, hip hiking, and drop-foot angle, in healthy adults. We hypothesized that a passive hip resistive exosuit would affect sagittal hip kinematics but not other variables.

Methods

Eight healthy adults walked overground for 15 minutes while wearing an exosuit that applied 15% and 10% of body weight on the anterior right thigh and the posterior left thigh. Before and after this 15-minute bout, participants also walked overground for 15 minutes with the retractors disconnected. We measured stroke-relevant biomechanical variables using motion capture and ground reaction force measurement. We quantified the symmetry of these variables using the symmetry index [8], calculated as: We exponentially fitted phase evolutions and performed repeated measures ANOVA (*Baseline*, *Initial Adaptation*, and *Initial After*) and post-hoc tests using the Holm correction.

Results

The aftereffect on the trailing limb angle aligned with our hypothesis; however, immediately *after* disconnecting the exosuit, healthy adults increased trailing limb angle and braking impulse on the right side, coinciding with greater minimum toe clearance and drop-foot angle on the left side (Fig. 1). These aftereffects were not expected.

Discussion

A soft, passive hip exosuit produced significant aftereffects in four of six stroke-relevant gait parameters, challenging the joint-specific paradigm and indicating that a single-joint device can drive multi-joint adaptations. Future stroke trials are needed to determine how passive-resistance exosuits shape the rehabilitation of chronic stroke survivors.

Enhancing Passive Gravity Compensation in a Lower-Limb Exoskeleton with a CAM Mechanism

Ms. SeHee Jung MS Candidate, Prof. Ho Seon Choi Assistant Professor

Sejong University, Seoul, Seoul, Korea, Republic of

Ms. SeHee Jung

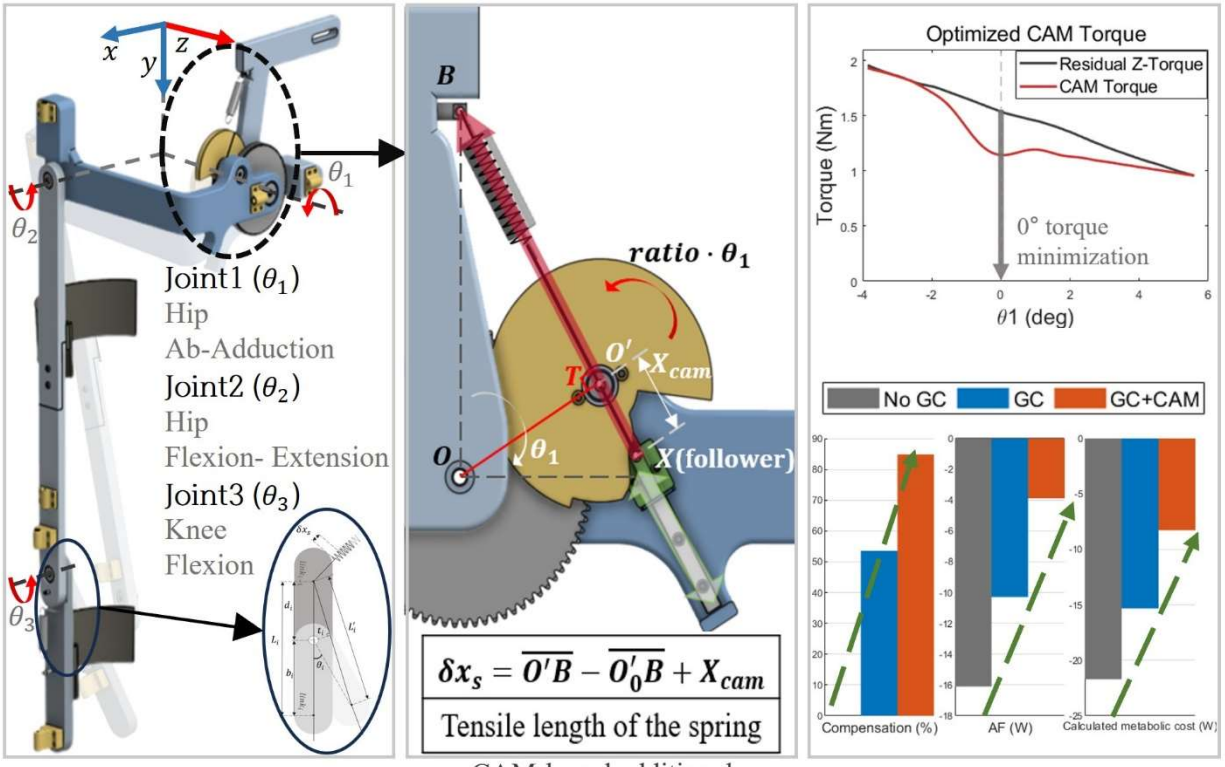
Introduction

As the weight of the exoskeleton may limit the performance of the walking assistance algorithm, we investigated a non-powered gravity compensation(GC) mechanism to mitigate this effect. However, the previous structure provided insufficient Z-axis compensation due to geometric constraints of the moment arm. Therefore, this study aims to enhance GC across all three axes by integrating a CAM-based additional compensation mechanism into Joint1 to directly address the residual Z-axis moment.

Methods

The compensation torque was calculated from the spring deformation and moment arm generated by each joint rotation in a 3-DOF passive exoskeleton with the GC mechanism located at the hip joint. The joint design parameters and spring constants were defined as optimization variables, and an optimization was performed to minimize the squared error between the gravity moment and the GC moment over the gait cycle. To address the insufficient Z-axis compensation, a CAM mechanism was additionally integrated into Joint1, and the CAM radius profile was obtained by inversely calculating the design variable x that satisfies the target torque at each angle. The target torque was generated through an optimization process incorporating slope and curvature limits, static torque minimization around 0°, and constraints to prevent overcompensation.

Results



A CAM profile capable of being tracked by a 3-mm follower was designed using curvature-constrained optimization, and the resulting CAM torque reliably followed the target torque while reducing overcompensation near 0°. Under a 2.9-kg exoskeleton load during walking for a 170-cm-tall adult, the moment compensation rate increased from 53.67% to 85.62% with the CAM mechanism. Furthermore, applying the AF–metabolic cost correlation

proposed by Mooney et al.[1] showed that the estimated metabolic cost loss decreased by 32.55%, from 15.34 W to 8.28 W.

Discussion

The proposed CAM-based additional compensation mechanism enhances the previously limited Z-axis compensation caused by the geometric constraints of the spring arrangement, achieving this improvement in a fully passive system. However, as the current findings rely on model-based optimization, further validation through prototype testing, including in-gait torque measurement and metabolic cost evaluation, is required.

Effects of Pain and Exercise Intensity on Lower Limb Asymmetry During Cycling

Ms. Sierra Sweeney BSc, Mr. Amirreza Hosseini, Dr. Shahram Rasoulian, Dr. Amin Komeili, Dr. Saied Jalal Aboodarda

University of Calgary, Calgary, Alberta, Canada

Introduction

Lower-limb pain is a clinical problem that disrupts movement, leading to compensatory motor strategies that increase biomechanical asymmetry and limit rehabilitation effectiveness [1]. Cycling is frequently prescribed in rehabilitation for individuals with lower limb asymmetry. Studying the effect of joint pain on physical performance using patients is challenging. This study aimed to develop an adaptive joint-pain induction protocol for varying exercise intensities and to quantify how unilateral lower-limb pain affects cycling performance in healthy adults. We hypothesized that pain would increase asymmetry and would be amplified at higher workloads.

Methods

Six healthy adults (2 female, 4 male) completed four randomized 2-min cycling trials: no pain at low-intensity (NPLI), with pain at low-intensity (PLI), no pain at high-intensity (NPHI), and with pain at high-intensity (PHI). Electrical stimulation over the right patella induced individualized pain levels applied during the downstroke, scaled to pedal force. Pedal kinetics were recorded using Sensix 3D force–torque pedals on a modified Echelon EX-5 ergometer. The Normalized Symmetry Index (NSI) was calculated to determine limb distribution. NSI from the first 25% and last 25% of each trial were averaged to assess early and late behavior. A three-way repeated-measures ANOVA (Pain × Intensity × Time) tested effects on NSI.

Results

Descriptive statistics showed greater asymmetry during trials with induced pain compared to those without pain. Additionally, NSI increased from **18.61 ± 10.38%** in PLI to **21.73 ± 8.26%** in PHI. The ANOVA revealed a **significant main effect of pain** (p=.027, partial η^2=.655). Intensity (p=.831) and time (p=.849) were not significant. A **Pain × Intensity interaction** was significant (p=.042, partial η^2=.595), indicating amplified asymmetry at higher workloads. No other interactions were significant (p>.33).

Discussion

Pain increased NSI values, and was amplified at higher workloads, consistent with evidence that nociception alters motor control [2]. This suggests that the proposed system can generate intensity-adaptive pain responses and capture compensatory loading strategies relevant to rehabilitation in individuals with lower-limb asymmetry. However, the small sample size limits generalizability, and ongoing studies in larger clinical populations are needed to validate these results.

Dr. Thi Bang Giao Nguyen

Dr. Chia-Lun Liu

Dr. Tsai-Yu Shih

Introduction

The recent motor training following stroke, such as transcranial Direct Current Stimulation (tDCS) hybridized with mirror therapy, requires coordination between motor preparation and execution stages, involving multiple cortical regions. Electroencephalogram (EEG) measures cortical activity, while kinematics assesses the two motor stages of preparation and execution. Identifying the coupling of cortical activity and kinematics can enhance our understanding of movement inefficiency and compensation during preparation and execution, which remains limited. This research examines how different brain cortical regions contribute to the motor control of these two stages before and after training.

Methods

Data for this project were obtained from a randomized, double-blind, placebo-controlled parent RCT involving 36 individuals with chronic stroke (FMA-UE score of 18–56). In that

trial, participants were allocated to the primary motor cortex, premotor cortex, or sham group and received 90 minutes of tDCS, mirror therapy, and functional task practice per day, five days a week, for four weeks. Outcome measures included EEG, specifically, beta-band event-related synchronization (ERS), dividing into low-beta (13-16 Hz), medium-beta (17-20 Hz), and high-beta (21-30 Hz) in central, frontal, and parietal regions; and kinematics involving reaction time (RT) and arm-trunk contribution slope (A-TCS) were extracted. Pearson and Spearman correlation analyses were conducted to examine the relationships between EEG measures and kinematic indices at baseline, and between post-pre change (Δ) in EEG measures and Δkinematic indices following training.

Results

At baseline, high-beta ERS in frontal and parietal regions correlated with RT; medium- and high-beta ERS in central, frontal, and parietal regions correlated with mid-phase A-TCS. After training, there was no significant correlation between Δhigh-beta ERS and ΔRT; Δlow-beta ERS in central and frontal regions was associated with Δmid-phase A-TCS, while Δmedium- and Δhigh-beta ERS in central, frontal, and parietal regions correlated with Δearly phase A-TCS.

Discussion

At baseline, arm and hand functions rely heavily on top-down control, extended motor preparation, and limited mechanical support from trunk compensation. After training, the shift from cognitive, time-based strategies to more automatic and spatially optimized strategies.

Differences in quadricep activation patterns through the knee range of motion between open- and closed-kinetic chain exercises

Ms. Tiffany Tiu PT, MScPT, BKin, CSCS

University of Toronto, Toronto, ON, Canada. The Pain and Wellness Centre, Vaughn, ON, Canada

Introduction

Rehabilitation following anterior cruciate ligament reconstruction (ACLR) includes regaining strength in the quadriceps. Existing research comparing open kinetic chain (OKC) and closed kinetic chain (CKC) exercises has used a single maximal electromyographic (EMG) signal in the movement to compare quadriceps activation between the exercises, without accounting for how muscle activation changes as the knee moves through its range of motion (ROM). During ACLR rehabilitation, 6-12 weeks are often needed to regain full knee ROM. Current research has not examined the interaction between muscle activation at different knee ROM during OKC and CKC exercises.

The purpose of this study is to compare quadriceps activation by knee angle between submaximal isokinetic OKC and CKC exercises and their different loading conditions.

Methods

Twenty-three healthy adults (18-40 years) performed OKC (unilateral knee extension (KE)) and CKC exercises (bilateral squat (SQ) and unilateral step-up (SU)) at body weight (BW/no added weight), with an added 10% BW load, and 25% BW load. Participants performed three trials of each condition in a randomized order. Surface EMG were collected from rectus femoris (RF), vastus medialis (VM), and vastus lateralis (VL), and reported as a percentage of maximum voluntary isometric contraction (%MVIC). Knee kinematics were quantified using an eight-camera markerless motion capture.

For each muscle (RF, VM, and VL) and each dependent variable (peak %MVIC and knee angle), two-way repeated-measures ANOVAs were performed: within-subject factors were exercise (KE, SQ, SU) and load (BW, 10%BW, and 25%BW). Post-hoc Bonferroni-adjusted pairwise comparisons were performed.

Results

KE provided the highest activations at more extended knee ranges (24-48°), while SQ and SU at more flexed ranges (99-123°) (p<.001). There was no difference between SQ and SU at the knee angles at which peak activation was achieved. SU elicited the most activation for all three muscles (72-121 %MVIC, p<.001).

Discussion

From an activation-by-knee-angle perspective, OKC and CKC exercises serve complementary roles in quadriceps strengthening. Within the ACLR patients' available knee ROM, both types of exercises are warranted to provide quadriceps strengthening through the knee's ROM. As a unilateral weight-bearing exercise, SU can be used early in rehabilitation to elicit high quadriceps activation, even at body weight.

Feasibility Study of a Custom Mixed-Reality Game Suite for Pediatric Motor Training

Mr. Tristan McCarty[1], Ms. Suhani Chaudhary[1], Mr. Weijia Zhang[2], Dr. Jiasi Chen[2], Dr. Elena Kokkoni[1]

[1]University of California, Riverside, Riverside, CA, United States. [2]University of Michigan, Ann Arbor, MI, United States

Introduction

Existing motor training interventions often rely on repetitive training tasks, which may lead to reduced motivation and adherence to motor training [1]. Mixed reality (MR) has emerged as a potential tool to enhance training by embedding motor tasks into immersive gamified environments. In contrast to screen-based systems, MR training environments allow users to move in a more naturalistic manner. By turning training into play, motor training paradigms for pediatric populations can become more engaging [2]. The efficacy of gamified training, however, also relies on how task difficulty is perceived and adapted over time [3]. Here, we report on a suite of four custom-designed MR games for use by children to train clinically relevant motor skills.

Methods

Our study design involves a single experimental session consisting of two blocks, with each block containing three minutes of exposure to each of the four MR games. One block retains a static pre-defined difficulty based on the participant's overall activity level, whereas the other uses a dynamic difficulty adjustment (DDA) algorithm to adjust task difficulty in real-time throughout exposure. The target population (children 5-9 years old) is exposed to the games via an MR head-mounted display, while multi-view video recordings are collected for annotation of events of interest. Electromyography (EMG) and inertial sensors are used to record muscle activity and limb acceleration, respectively.

Results

Literature-derived baseline metrics (gait speed and EMG root mean square) defined the initial in-game difficulty levels, with an average gait speed (~1.28 m/s) assigned to users and then adjusted towards the maximal and minimal difficulty values (two standard deviations) based on task performance. Ongoing efforts, including further data analysis

and collection of user and caregiver feedback, aim to identify potential areas of improvement in the system.

Discussion

This pilot study marks a significant step towards the development of an integrated MR-based DDA motor training system for children. It shows preliminary feasibility for use with pathological populations and provides feedback which can be used by clinicians to enhance training outcomes.

Effects of Hopping Directions on Knee Mechanics and Knee Extensors and Flexors Muscle Activation

PhD student Yu Gu, PhD student Wanyan Su, Dr. Yu Song

University of Kansas, Lawrence, Kansas, United States

Introduction

Single-leg forward and vertical hopping are widely used in clinics to evaluate knee function after anterior cruciate ligament reconstruction (ACLR). However, previous studies have shown that performance on these tasks demonstrates limited agreement with underlying knee mechanics and control. Therefore, a knee-specific clinical assessment is warranted. Recently, single-leg backward hopping has been proposed as a more knee-demanding task, given its greater knee power and work. Nevertheless, muscle activation across the knee joint aligned with the knee mechanics compared to forward and vertical hopping remains unclear.

Methods

Forty-eight injury-free participants (30 females and 18 males; 20.9 ± 0.7 yrs; 1.7 ± 0.1 m; 68.1 ± 12.0 kg) performed single-leg forward/vertical/backward hopping with motion, force, and surface electromyography (quadriceps, hamstrings, and triceps surae) data collected. Maximum voluntary contraction (MVC) was recorded for each muscle group. Peak knee flexion angles and moments during jumping were calculated. Peak and mean muscle activation during jumping were also calculated and normalized to MVC. One-by-three repeated-measures ANOVA was conducted to quantify the effects of hopping directions (p-value = 0.05).

Results

Forward hopping demonstrated significantly greater hamstring activation, but smaller knee angle/moment and quadriceps activation compared to vertical and backward hopping (Table 1). Vertical hopping showed the greatest knee flexion angle among hopping directions. Backward hopping showed the smallest muscle activation of biceps femoris/gastrocnemius medialis/soleus with the greatest knee moment compared to forward and vertical hopping.

Discussion

Single-leg forward hopping requires less quadriceps activation and knee engagement compared to vertical and backward hopping, indicating forward hopping alone may be insufficient to directly evaluate knee function. Vertical hopping, characterized by greater quadriceps activation and knee flexion angle, may be more appropriate for assessing quadriceps function and knee control. Backward hopping imposes the greatest knee moment while minimizing the involvement of hamstring and triceps surae, indicating its potential as an additional task to isolate knee extensors and identify knee deficits after ACLR. Further evidence from ACLR populations is necessary to support single-leg backward hopping as an additional rehabilitation assessment tool.

The Effects of Augmented Visual Feedback during VR-Based Motor Training of the Upper-Limb with Increasing Levels of Difficulty

Mr. Yu Shi, Ms. Sophie Dewil, Mr. Zachary Marvin, Dr. Raviraj Nataraj

Stevens Institude of Technology, Hoboken, NJ, United States

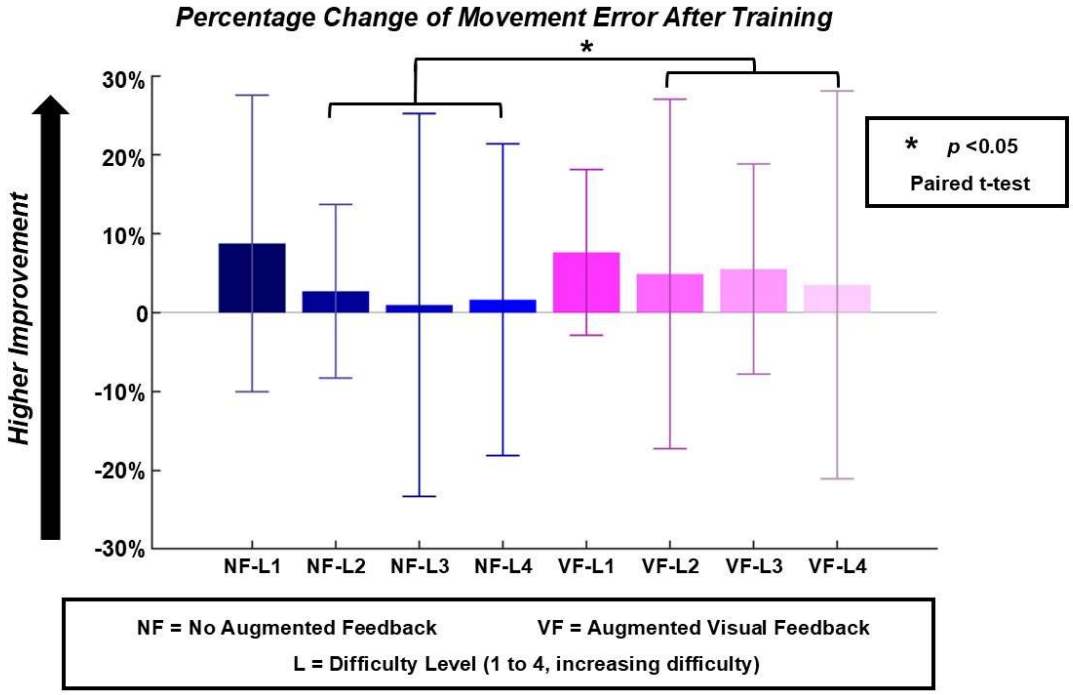
Introduction

Virtual reality (VR) can reduce the loss of training gains that accompanies repetitive rehabilitation after neuro-injury by making physical therapy more engaging. This study examines how VR-rehabilitation may be optimized through manipulation of two controllable training elements: augmented sensory feedback (ASF) and task difficulty. Visual ASF provides real-time, intuitive performance information and can yield substantial post-training gains [1], [2]. Task difficulty is tuned to match task complexity to the learner's capability, thereby supporting more effective rehabilitation gains [3]. This pilot study examined how post-training error reduction varies with difficulty in the presence of ASF with training.

Methods

Eight right-handed neurotypical participants controlled a spherical cursor in VR to trace trajectories by exerting forces with their dominant arm on a brace instrumented with a multi-axis load cell. The trajectories were either sinusoids (training trials) or semi-elliptical (testing trials, before or after training) to require persistent challenge in tracking curved paths. During training, difficulty levels were modulated by varying the amplitude of the sinusoidal trajectory. Training was repeated for two conditions (no ASF, visual ASF). Testing trials were conducted without ASF to evaluate training effects based on pre–post reductions in trajectory-tracking error.

Results



Motor performance was quantified as a percentage change in trajectory-tracking error, as shown in Figure 1. Performance gains generally declined with increasing difficulty for both training conditions; however, when comparing the three most difficult levels (paired t-test), visual ASF significantly preserved higher performance ($p = 0.0211$).

Discussion

The findings indicate that ASF and task difficulty jointly influence performance in this VR-based rehabilitation task. Although performance gains decreased as difficulty increased, a clear divergence emerged at higher difficulty: visual ASF reliably preserved training

benefits, whereas performance under no ASF declined more sharply. This suggests that visual ASF provides stabilizing guidance when error signals intensify, making it especially valuable for difficult tasks and an important component to prioritize in personalized rehabilitation protocols.

Nanoindentation and Correlative Microscopy to Evaluate Scaffold Degradation and Bone Micromechanics in Additively Manufactured 13-93 Bioactive Glass and Titanium Scaffolds in Ovine Critical Size Defects

Mr Benjamin Morrison[1], Dr Sarah Davis[1], Prof Gordon Blunn[2], Dr Roxane Bonithon[1], Dr Agathe Heyraud[3], Dr Francesca Tallia[3], Prof Julian R Jones[3], Dr Aikaterina Karali[1]

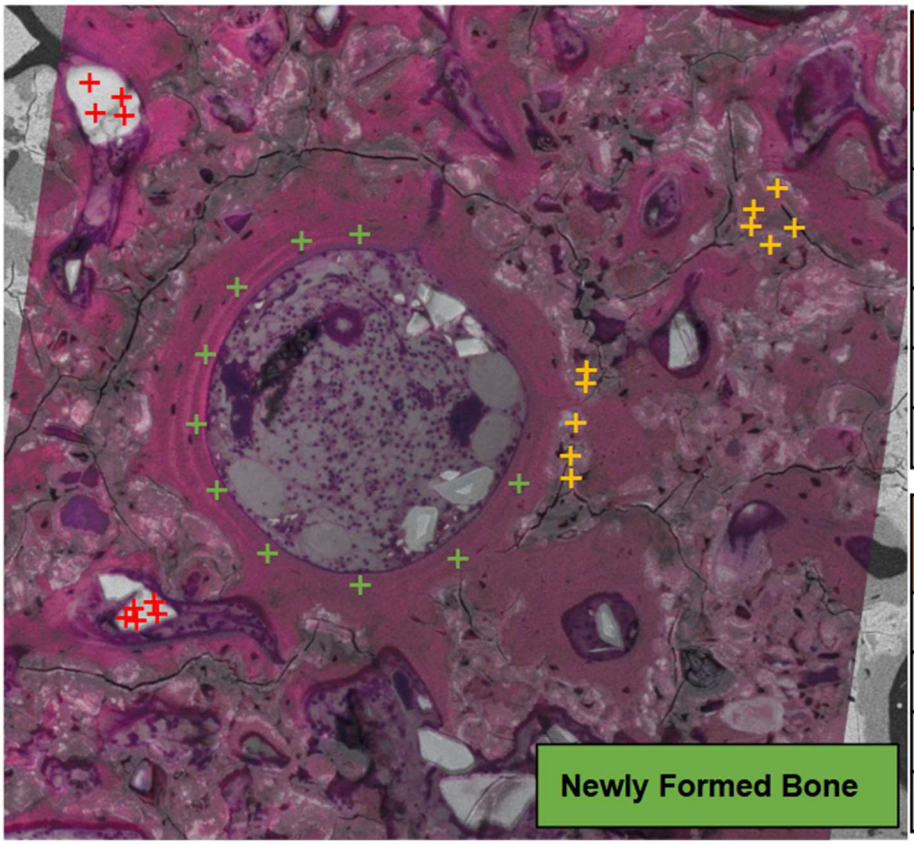
[1]School of Electronic and Mechanical Engineering, University of Portsmouth, Portsmouth, Hampshire, United Kingdom. [2]School of Medicine, Pharmacy and Biomedical Sciences, University of Portsmouth, Portsmouth, Hampshire, United Kingdom. [3]Department of Materials, Imperial College London, South Kensington, London, United Kingdom

Introduction

Additively manufactured biodegradable scaffolds can enhance bone formation in critical-size defects compared with metallic implants, as they can be replaced by new bone and have tuneable mechanical properties for better synergy with native tissue. Previously, 13-93 bioactive glass scaffolds have demonstrated substantial bone formation in a rabbit model, assessed using X-ray computed tomography[1]; however, the mechanical impact was not investigated. Here we compare micromechanics and mineralisation of newly formed bone and assess degradation of 13-93 scaffolds.

Methods

Defects (D=8 mm, H=12 mm) were created in the frontal plane of ovine femoral condyles and implanted with either Titanium (Ti) or 13-93 scaffolds, additively manufactured with log-pile geometry and 400-450um pores. Specimens with surrounding bone were harvested at 6 and 12 weeks (n=6/scaffold/time point). Samples were resin-embedded, sectioned transversely, and polished. Histomorphometry quantified osseointegration and local bone/soft tissue formation. Depth-control nanoindentation (Hysitron, Bruker) assessed bone maturation (10 nm/s, 500nm depth, 30s hold, 10×10 matrices, 10μm spacing), while load-control nanoindentation was performed on scaffolds (10,000μN, 30s loading/hold/unloading, 4×4 matrices, 10μm spacing). Sections were carbon-coated (10nm) and imaged using BSE microscopy (Mira 3, Tescan), with EDS (AZtec, Oxford Instruments, 20 kV, ~15 mm working distance). Corresponding histological sections were stained with modified Paragon (toluidine blue/fuchsin), imaged (AX10, Zeiss), and correlated to BSE microscopy (Fig.1).



Results

Bone formation was observed throughout 13-93 scaffolds, with 71% osseointegration at 12 weeks, whereas Ti scaffolds showed 15% bone integration , limited to the periphery. At T=12, newly formed bone stiffness was 28.8±16.7 and 38.2±3.1uN/nm for 13-93 and Ti, respectively. 13-93 scaffold stiffness and reduced modulus decreased from 104.5±6.9uN/nm and 80.3±6.8GPa at T=0 to 51.8±9.7uN/nm and 24.7±4.2GPa at T=12w. EDS of 13-93 revealed loss of Si, K, Na, Mg and increased Ca and P over time.

Discussion

13-93 scaffolds support extensive bone formation and osseointegration, while titanium scaffolds show limited peripheral growth. Declining 13-93 stiffness and modulus, together with elemental changes, reflect scaffold degradation and mineralised matrix formation. Work in progress includes quantitative BSE analysis to assess mineralisation of newly formed bone.

A Microstructure and Grain Orientation Based Framework for Predicting Corrosion in Magnesium WE43: A Phenomenological Approach

Mrs Fatemeh Karamifard

University of Galway, Galway, Ireland, Ireland

Introduction

Bioresorbable materials such as magnesium (Mg) alloys allow medical implants to safely degrade after completing their temporary function. However, Mg corrodes rapidly in physiological conditions, risking early loss of mechanical support before tissues have fully healed. Crystallographic orientation strongly influences corrosion, with basal-oriented grains showing higher susceptibility. In this work, we model a polycrystalline microstructure in which each grain has a defined lattice orientation, allowing corrosion behaviour to vary based on local crystallography. A phenomenological, statistically based finite element framework is used to examine how grain orientation affects corrosion initiation and propagation in Mg WE43.

Methods

A phenomenological corrosion model is employed, using a scalar damage field to represent degradation, implemented through a user-defined USDFLD subroutine in Abaqus. As shown in (Fig. 1(a–b)), the microstructure consists of 24 hexagonal HCP grains, each assigned a random crystallographic (basal plane) orientation. Orientation effects on corrosion are incorporated by weighting the local damage rate term, resulting in higher rates in the basal plane direction. Corrosion is initiated from a small surface pit representing local breakdown of the protective layer. Grain-specific corrosion then progresses preferentially on the basal planes, as guided by experimental observations.

Results

A sample of the modelling results are shown in (Fig.1(c)); corrosion initiates at a surface pit in a grain with horizontally oriented basal planes, and progresses layer by layer through the grain, and then spreads into neighbouring grains with orientations of approximately 45° and

90° (Fig.1(d)). Progression over time ultimately produces the non-uniform, multi-directional corrosion profile shown in (Fig. 1(e)).

Discussion

This study introduces a novel framework in which crystallographic orientation effects are incorporated into corrosion modelling, enhancing pitting corrosion prediction capability for Mg WE43. The model affords the assessment of how microstructure (grain size and orientation) influences corrosion progression, allowing for microstructural design recommendations to be made. Future work will implement a full 3D model informed by diffraction contrast tomography (DCT) to provide more detailed microstructural representation.

Host Response to Compliance Matching of Tissue Engineered Vascular Grafts is Sex Specific

Ms. Katarina Martinet, Dr. David Maestas, Dr. Keishi Kohyama, Ms. Jacqueline Avila, Mr. Leon Min, Ms. Reyhaneh Gholami, Dr. Kang Kim, Dr. William Wagner, Dr. Jonathan Vande Geest

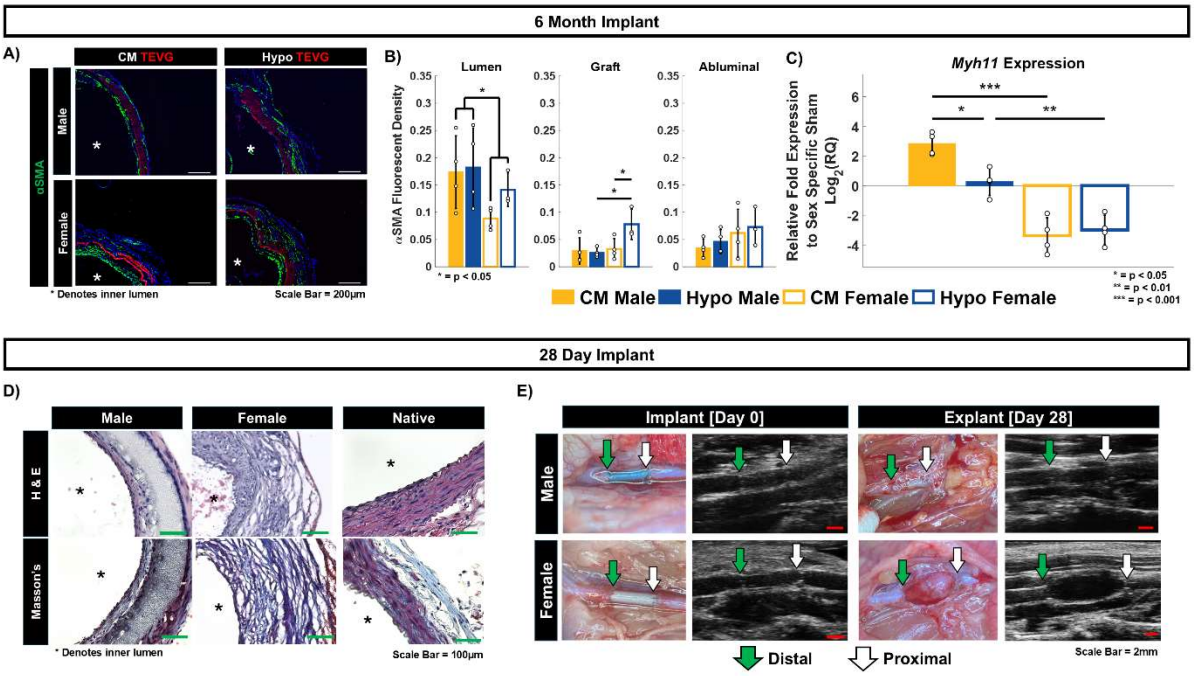
University of Pittsburgh, Pittsburgh, PA, United States

Introduction

Tissue engineered vascular grafts (TEVGs) are a promising solution to the challenges faced in small diameter vascular grafting procedures. Compliance matched TEVGs (CM TEVGs) have shown increased vascular smooth muscle cell (VSMC) presence in acute remodeling. There are known sex specific differences in VSMC behavior in vascular injury which are understudied in TEVGs. This study aims to understand if biological sex influences responses to compliance matching in CM TEVGs.

Methods

CM TEVGs and hypocompliant TEVGs (Hypo TEVGs) were fabricated via electrospinning polyester urethane urea:gelatin solutions with a non-thrombogenic inner layer of polyester sulfobetaine urethane urea – 50. TEVGs were confirmed to be compliant using a custom tubular biaxial device. Grafts were implanted as interposition grafts into the abdominal aortas of Sprague Dawley Rats. In short term studies, CM TEVGs and shams were implanted in n = 4 rats of each sex for 28 days. For long term studies, CM TEVGs, Hypo TEVGs, and shams were implanted for six months in n = 4 rats of each sex. Explants were analyzed with IHC, IF, 2P imaging, and qRT – PCR.



Results

TEVGs fell within their targeted compliance ranges. In acute studies, we saw increased degradation and increased collagen deposition in females over 28 days (A). This included one female sample that formed a pseudoaneurysm (B). After 6 months, there was increased degradation of the graft material in CM TEVGs (C). Female rats had significantly increased thickness over both graft types (Female: 58.22 ± 36.22 μm, Male: 16.41 ± 6.57 μm). A significant decrease in VSMC density (αSMA) was seen in female implants (D). Compliance increased contractile VSMC genetic marker expression in male rats (E).

Discussion

While compliance matching improves TEVG remodeling outcomes (increased remodeling of graft material), the degree of these effects is influenced by sex. Sex influences VSMC behavior, which is a major cell type involved in TEVG remodeling and formation of intimal hyperplasia. These responses to compliance matching can be captured acutely as well, allowing us to begin higher throughput studies looking at the role of how sex influences responses to changes in compliance.

Effects of Hydrogel-Based Mechanical Confinement on Morphological and Biochemical Characteristics of Cervical Cancer Spheroids

Mr. Kazuki Haneda M.S. Student, Mr Riku Akiyama B.S. Student, Dr. Shogo Miyata Ph.D.

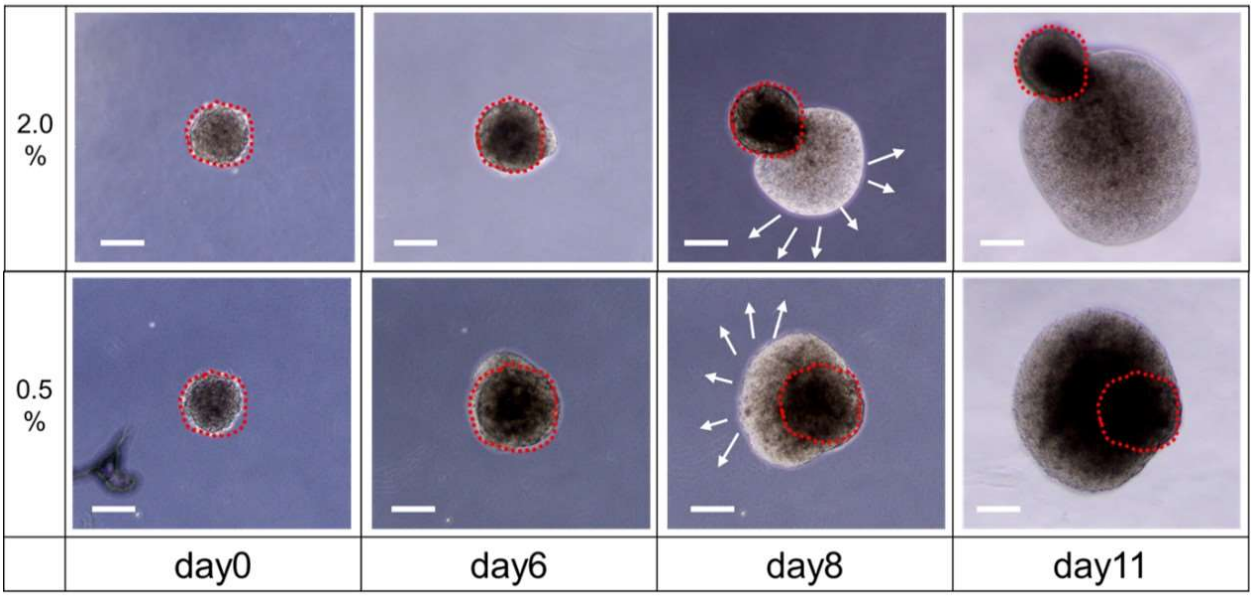
Keio University, Yokohama, Kanagawa, Japan

Introduction

Cervical cancer is the fourth most common cancer among women worldwide, with about 10,000 new cases and 2,900 deaths each year in Japan. Because diagnosis often occurs during pregnancy, understanding how the tumor grows in a controlled mechanical environment is important for protecting both mother and fetus. Mechanical microenvironments such as compressive stress have risks to cause phenotypical transition, which may increase tumor aggressiveness. Although earlier studies suggest that the mechanical environment affects tumor behavior, how confinement influences the earliest steps of cervical cancer invasion remains poorly understood. This study aimed to clarify how different stiffness levels affect the invasion dynamics and biochemical characteristics of cervical cancer spheroids.

Methods

HeLa cell spheroids were generated in U-bottom 96-well plates and embedded in 0.5% or 2.0% agarose gels to establish mechanically confined tumor models. Spheroid morphological changes were monitored by phase-contrast microscopy, and three-dimensional structures were visualized using confocal microscopy. Cytoskeletal organization and cell-cycle dynamics were further assessed by fluorescence microscopy.



Results

In both gel conditions, spheroids expanded isotropically until day 7. Thereafter, protrusive growth regions extended into the agarose, with more pronounced directional growth observed in the 2.0% gel. The protrusive regions were thicker and more widely spread in the 0.5% gel, whereas spheroids in the 2.0% gel exhibited larger centroid displacement. Actin staining showed more developed cytoskeletal structures at the invasive edges, particularly in the stiffer gel. Cell-cycle staining further indicated rapid cell-cycle progression within the spheroid interior, while cells at the periphery and in the protrusive regions predominantly remained in the G1/G0 phase.

Discussion

These results indicate that gel stiffness modulates both the growth patterns and cellular responses of cervical cancer spheroids. Softer matrices permitted greater vertical expansion, whereas stiffer gels facilitated more pronounced directional extension. At the invasive edges, cytoskeletal structures were more developed, which is consistent with an enhanced migratory and invasive potential. In addition, cells remaining in the G1/G0 phase at these regions suggest a transition toward a motility-associated phenotype. In summary, these findings demonstrate the importance of the mechanical microenvironment in regulating early invasive behavior in cervical cancer.

Improving Reconstructed Dermal Skin Through Shear Wave Mechanical Stimulation

Ms Koloina Randrianavony[1,2], Mrs Coralie Privet-Thieulin[1,2], Mrs Lara Jobeili[3], Mrs Dominique Sigaudo-Roussel[3], Mr Hassan Zahouani[1]

[1]Ecole centrale de Lyon, Ecully, Auvergne Rhône Alpes, France. [2]LyRIDS, Paris, Ile de France, France. [3]LBTI, Lyon, Auvergne Rhône Alpes, France

Introduction

Reconstructed skin is an in vitro model widely used to study skin's biological behavior and tissue maturation. Contrary to human skin, it allows invasive measurements. It also enables to have a neutral baseline without interindividual variability. The dermal layer, mainly composed of extracellular matrix (ECM) and fibroblasts, provides the skin's load bearing capacity. The fibroblasts produce collagen and elastin fibers responsible for the skin's rigidity and elasticity. In this study, we propose to stimulate the reconstructed dermal skin with a Shear Wave Stimulation device (SWS) [1], a non-contact device using air pressure to mechanically stimulate it with shear and compression waves. The impact of different air pressures on collagen production is studied.

Methods

The study was performed on reconstructed dermal skin cultured for 14 days. Primal dermal fibroblasts of a 29-year-old woman was used. The samples were stimulated for 2 min twice a day separated by 6 hours, for 2 days. An opening time of 10ms (closing time 490ms) was chosen and the SWS was done with two different air pressures: 0.5 and 0.7 bar. 24 hours after the last stimulation, the samples were fixed and then undergone immunofluorescence (IF) collagen type I staining. A mechanical model was developed to characterize the effect of internal tissue forces on image pixel morphology, expressed for each pixel by an intensity, a spatial frequency, and a wavelength in Fourier space. Three tension indices are quantified before and after stimulation.

Results

The deformation induced by the stimulation along the X and Y axis has been computed with DX=0.17 and DY=0.3, which indicates that the stimulation caused an extension along the two axis. The stimulation improved the mechanical tension of the reconstructed skin by 5 times compared to the control group (IT index). The stimulation also impacted the number of fibroblasts cells (-15%) and collagen production (+13%) with the apparition of hyperdense collagen fibers on the surface.

Discussion

These results are certainly the response of fibroblasts from mechanical stimulation leading to mechanotransduction and a mechanical effect on the ECM.

Images (Optional)

Mechanobiology-Driven Reinforcement of Bioactive Cement for Enhanced Hard-Tissue Function and Antibacterial Performance

Frau Lilly Völkel[1], Dr Sabina Karacic[2], Prof. Dr.rer.nat Christoph Bourauel[1], Priv.-Doz. Dr. Lamia Singer[1]

[1]Oral medicine Technology, University Hospital Bonn, Bonn, North Rhine–Westphalia, Germany. [2]Institut für Medizinische Mikrobiologie, Immunologie und Parasitologie, University Hospital Bonn, Bonn, North Rhine–Westphalia, Germany

Introduction

Glass-ionomer cement (GIC) is a clinically used bioactive cement capable of chemically bonding to mineralised tissues and releasing ions that support hard-tissue integration. However, brittleness, moisture sensitivity, and insufficient antibacterial protection limit long-term performance in load-bearing or infection-prone environments. Reinforcing GIC with biologically relevant fillers has emerged as a promising strategy to enhance its suitability for hard-tissue repair. Hydroxyapatite (HA), the main mineral component of bone and dentine, may improve biological interaction, while nanodiamonds (ND) and hexagonal boron nitride (BN) offer enhanced mechanical integrity and microbial resistance. This study aimed to evaluate the mechanical, physical, antibacterial, and bioactivity characteristics of GIC modified with HA alone and combined with either ND or BN to support improved performance in tissue engineering applications.

Methods

Four formulations were prepared: Control (unmodified GIC), GIC+HA, GIC+HA+BN, and GIC+HA+ND. Powders were homogenised with additives before mixing with liquid. Compressive strength was measured following ISO 9917-1; flexural strength via three-point bending; and Vickers microhardness by indentation. Water sorption and colour stability (ΔE) were assessed after 7-day storage at 37 °C in aqueous media. Bioactivity was examined by immersion in simulated body fluid (SBF) for 14 days to assess surface apatite formation. Antibacterial activity against *Streptococcus mutans* was evaluated using agar

diffusion. Mechanical tests used 10–15 specimens per group; micro-scale tests in triplicate. One-way ANOVA identified significance ($p < 0.05$).

Results

Both nanoreinforced groups demonstrated significantly improved performance compared to the Control and HA-only groups ($p < 0.05$). HA+ND achieved the highest flexural strength (21.8 ± 2.7 MPa), compressive strength (130 ± 6.3 MPa), microhardness (74.8 ± 3.1 VHN), and antibacterial inhibition zone (12.4 ± 0.9 mm). HA+BN exhibited the lowest water sorption (21.6 ± 1.8 μg/mm^3) and greatest colour stability. Both dual-reinforced groups showed increased apatite formation after SBF immersion, confirming enhanced remineralisation potential.

Discussion

Reinforcement of bioactive cement with HA combined with ND or BN significantly improved its mechanical resilience, antibacterial activity, and biological response. ND offered the strongest strengthening and antimicrobial benefits, whereas BN improved environmental stability. These modified cement systems show promise for durable restorative and craniofacial hard-tissue repair within tissue engineering applications.

Comparison of Micro- and Macro-Mechanical Responses of α- and β-Phase 3D-Printed Titanium Alloys for Biomedical Applications

Ing. Petr Bočan, Ing. Jiří Němeček, prof. Jan Vorel, doc. Aleš Jíra

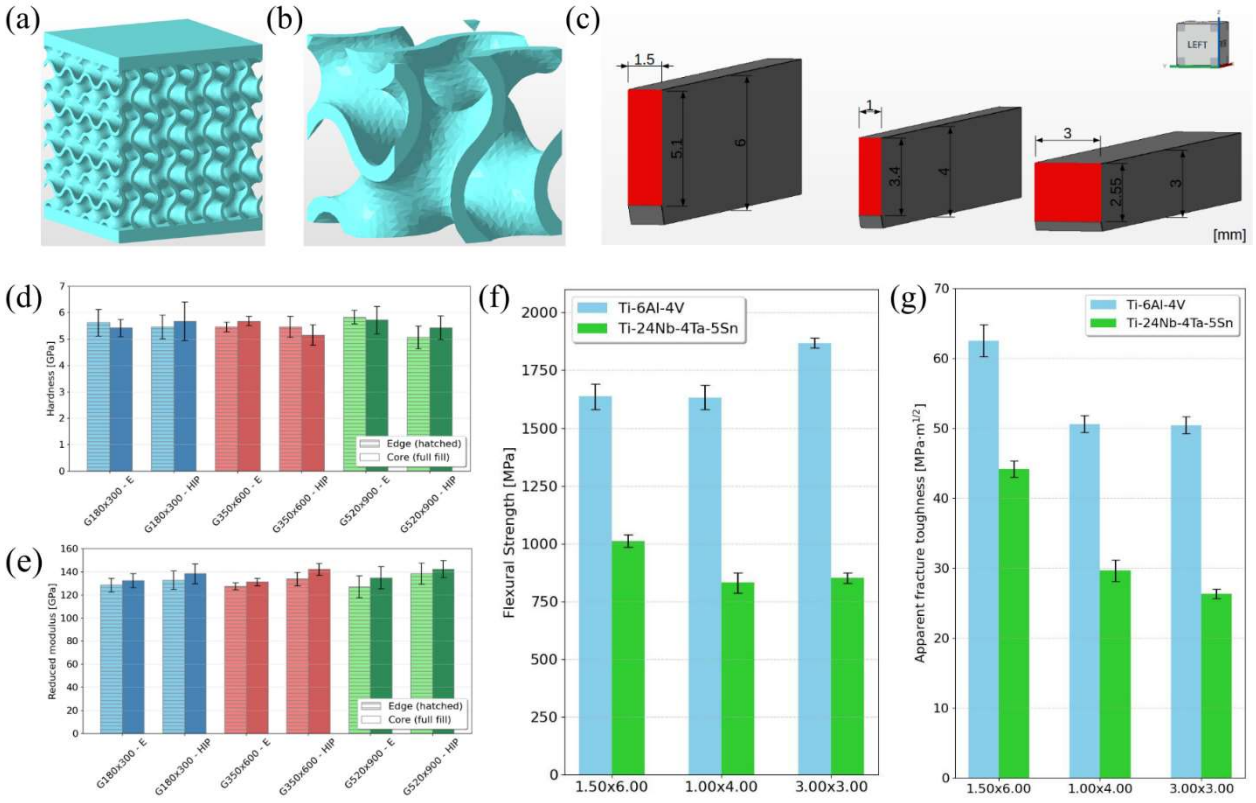
Czech technical university, Prague, Czech republic, Czechia

Introduction

The increasing use of porous architectures on implant surfaces enhances osseointegration by enabling bone ingrowth and improving mechanical compatibility at the bone–implant interface. Additive manufacturing, particularly Selective Laser Melting, enables precise control of pore size, geometry, and mechanical behavior, though clinical adoption is still limited by material certification. The widely used α-phase alloy Ti-6Al-4V offers high strength but has drawbacks such as high stiffness and concerns regarding aluminum and vanadium cytotoxicity. The β-phase alloy Ti-25Nb-4Ta-8Sn provides improved biocompatibility and a lower elastic modulus closer to bone, making it a promising alternative for next-generation implants.

Methods

This study evaluates the macro- and micro-mechanical behavior of these two alloys. Three-point bending tests were performed on thin notched beam specimens of three geometries (Figure (c)), using a 3D micro-DIC system to measure strain fields. Flexural strength and apparent fracture toughness were determined, supported by numerical simulations mirroring the tests. Micro-mechanical analysis focused on Ti-6Al-4V, using nanoindentation on three 3D-printed gyroid lattices (Figure (a), (b)) to assess hardness and reduced modulus in both surface and internal regions.



Results

Ti-6Al-4V showed higher flexural strength (1630–1870 MPa) than Ti-25Nb-4Ta-8Sn (830–1010 MPa) (Figure (f)). Apparent fracture toughness was also higher for the α alloy (50.5–62.5 MPa$\sqrt{m}$) compared with the β alloy (26.3–44.2 MPa$\sqrt{m}$) (Figure (g)). Numerical simulations agreed closely with experimental load–deflection results. Nanoindentation of Ti-6Al-4V gyroids revealed hardness values of 5.06–5.83 GPa and reduced modulus values of 125.8–142.3 GPa, with only minor variation between edge and core regions (Figure (d), (e)).

Discussion

These findings confirm the superior mechanical performance of Ti-6Al-4V for load-bearing applications but highlight the improved biocompatibility of Ti-25Nb-4Ta-8Sn, suggesting its potential where lower stiffness is advantageous. The consistent microscale behavior of Ti-6Al-4V gyroid lattices supports their use in surface architectures designed to promote bone ingrowth. Future work will include microscale testing of β-phase structures and expanded evaluation of lattice-based surfaces to optimize material–architecture combinations for implants requiring reliable mechanical performance and enhanced biological integration.

Degradation-Induced Changes in Mechanical Properties of Resorbable Implant Materials.

Dr. Steffen Braun, B.Sc. Leonie Thiele, B.Pro. Jonas Dresen, B.Sc. Jan Marc Schehl, B.Eng. Lisa Veeser, Dr. Tobias Wolfram

KLS Martin SE & Co. KG, 78570-Mühlheim, Baden-Württemberg, Germany

Introduction

Resorbable biomaterials are subject to high requirements in terms of biocompatibility and controlled biodegradability with sufficiently long-lasting mechanical stability. The aim was to investigate the degradation behavior of resorbable implant materials while evaluating their mechanical strength.

Methods

In this study, bioresorbable implant materials PDLLA, PDLLA+$CaCO_3$, PLLA+PGA, WE43 as a magnesium alloy, and PEEK were investigated. After sterilization, samples were incubated in DMEM (pH7.4; 37°C) for zero (T0), four (T1), six (T2), and eight (T3) weeks to simulate degradation [ISO-13781]. Mechanical characterization was performed at defined time points using standardized tensile tests [EN-ISO-527], with polymers being loaded in medium at 37°C.

Results

The stiffness of resorbable polymers ranged from 3927 MPa (PDLLA) to 5234 MPa (PDLLA+$CaCO_3$) and decreased by up to 82% (PDLLA+$CaCO_3$) after four weeks. PDLLA showed an linear 35% reduction from T0 to T2. PDLLA+$CaCO_3$ (−82%) and PLLA+PGA (−40 %) exhibited the greatest decline after four weeks, with PDLLA+$CaCO_3$ reaching −90% over the entire period. WE43 and PEEK showed a 17% decrease in tensile modulus after eight weeks (WE43: 103,635 MPa; PEEK: 6045 MPa).

Tensile strength decreased particularly sharply after eight weeks in PLLA+PGA (−90%) and PDLLA+$CaCO_3$ (−84%) (PDLLA: −58%). After four weeks, PDLLA and PLLA+PGA decreased by 23–37%, while PDLLA+$CaCO_3$ had already reached −72%. WE43 started at 296 MPa (8.3× higher than polymers) but fell 28 % after four weeks. PEEK showed a 5.4% loss over eight weeks, with 4 % after four weeks.

PDLLA showed a significant increase in elongation at break from 5.35% (T0) to 372.70% (T1). PDLLA+$CaCO_3$ increase slightly from 4.48% (T0) to 9.83% (T3), while PLLA+PGA

dropped from 10.74% to 0.28%. WE43 decreased from 9% to 2.03%, and PEEK from 36.60% to 20.50%.

Discussion

All materials showed changes in mechanical properties due to simulated degradation. In polymers, this results from hydrolytic chain decomposition and loss of structural integrity. Salts in DMEM and additive manufacturing may influence degradation of PEEK. In vitro results are only partly transferable to in vivo conditions but provide key insights for material modification in the develop ment of implant materials.

Effect of Manufacturing Process on the Mechanical Performance of Resorbable Implant Materials in Simulated Biological Environments

Dr. Steffen Braun, B.Sc. Sofie-Josephine Scheuch, B.Eng. Lisa Veeser, B.Sc. Jan Marc Schehl, B.Pro. Jonas Dresen, Dr. Tobias Wolfram

KLS Martin SE & Co. KG, 78570-Mühlheim, Baden-Württemberg, Germany

Introduction

Resorbable materials offer new therapeutic options in craniomaxillofacial surgery. Complex physiological conditions demand high biocompatibility, controlled biodegradability, and mechanical stability. The aim was to investigate the influence of different manufacturing processes on the mechanical properties of resorbable materials.

Methods

This study examined bioresorbable implant materials poly(-ε-caprolactone) (PCL) and poly(D,L-lactide) (PDLLA), with Polyetheretherketon (PEEK) as a non-degradable control material. Samples were produced by milling, injection molding, and 3D printing. Degradation studies (PBS solution: pH7.4; 37 °C) were conducted in a biologically relevant environment [1,2] at three time points (T0: 0 weeks; T1: 1 week; T2: 4 weeks). Characterization included microscopy (LM, SEM), thermal analysis (DSC) [3], and mechanical analysis with standardized tensile [4] and bending tests [5].

Results

Standardized tests [4,5] on PEEK confirmed method validity through comparability with material data sheets. Injection-molded PDLLA samples showed significantly higher tensile strength than milled samples (58.1 vs. 54.0 MPa), while bending properties were similar. After one-week, tensile modulus (injection molding: -30%; milled: -23.5%) and tensile strength (injection molding: -28%; milled: -12.0%) decreased significantly, accompanied by a significant increase in elongation (injection molding: +26%; milled: +19%). Bending properties of injection-molded PDLLA samples declined after one week, whereas milled samples showed this effect only after four weeks.

Additively manufactured PCL samples showed significantly lower tensile strength (19.0 MPa vs. 23.9 MPa) and bending strength (18.9 MPa vs. 32.6 MPa) than milled samples. Degradation reduced tensile modulus (−8%) and strength (−2.5%) in milled PCL samples, while additively manufactured samples remained more stable in tensile strength. Bending properties remained almost unchanged in both groups.

DSC analysis revealed higher crystallization and melting peaks in additively manufactured samples, suggesting a strong influence of manufacturing process on thermal properties.

Discussion

Results indicate a significant impact of manufacturing processes on material properties, degradation behavior, and kinetics. Injection molding and 3D printing showed the most pronounced changes in mechanical parameters during degradation. These findings provide an important basis for assessing biomaterial performance under biologically relevant conditions and guide the selection of suitable manufacturing processes for medical implants.

Guidance of Cell and Matrix Morphology in Fiber/Hydrogel Composite Scaffold

Mr. Takumi Asakawa, Dr. Pen-hsiu Grace Chao

National Taiwan University, Taipei, Taiwan, Taiwan

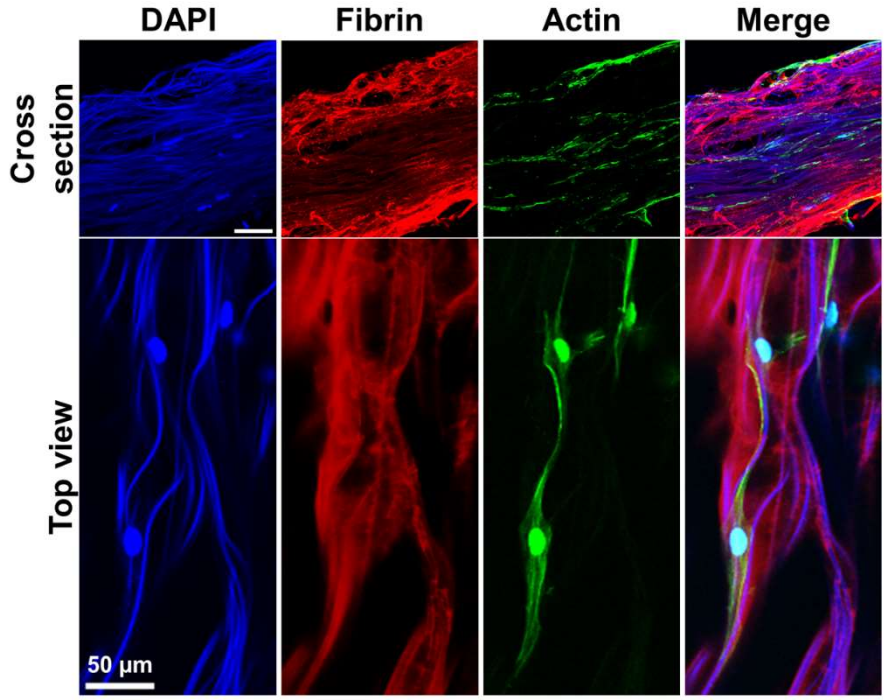
Introduction

Electrospun fiber scaffolds are widely used in tissue engineering as they can recapitulate the structural and mechanical performance of native tissues. However, their lack of bioactivity limits matrix remodeling and graft integration [1]. Conversely, fibrin hydrogel can offer bioactive signals that drive cell-mediated remodeling but lack the mechanical integrity and structural cues of fibrous materials [2]. Here, we fabricated a composite construct by incorporating fibrin into electrospun fibrous scaffolds and investigated the influence on cell morphology.

Methods

Type I collagen-coated poly-L-lactide (PLA) scaffolds were fabricated as described previously [3]. Adipose-derived mesenchymal stem cells were suspended in fluorescently labeled fibrinogen solution. This suspension and thrombin solution were absorbed into the scaffolds from both sides and incubated for gelation and culture.

Results



Cross-sectional images confirmed infiltration of the fibrin throughout the scaffold. The fibrin network organized along the polymeric fiber structure (Figure). Cells were localized on the construct surface on day 1 (data not shown), migrated to the center of the composites by day 7, and followed the fiber/fibrin structure with an elongated morphology.

Discussion

We have previously found laminating electrospun fibrous scaffolds with fibrin gels not only increased construct size, but improved matrix deposition and mechanical properties of engineered ligament tissue, demonstrating the interactive role of fibrin with fibrous scaffolds [3]. We also reported synergistic effects of fibrin and growth factor supplementation, confirming the role of fibrin for growth factor binding and stabilization [2, 3]. In the previous study, however, fibrin was added after one week of culture and limited to the scaffold surface. Here, we fully incorporated the fibrin within the fibrous scaffold. Notably, the fibrin gel formed networks that closely followed the collagen-coated fiber structure, consistent with previous findings that collagen fibrils guide fibrin network formation [4]. Thus, the composite provides contact guidance from both fiber and fibrin

while supporting a bioactive environment. Current studies are investigating the long-term effects on matrix deposition and tissue development.

Images (Optional)

Representative maximum projection confocal micrograph of the composite scaffold in cross section and top views. PLA fibers can be seen in the DAPI channel due to autofluorescence.

[3]Leeds Institute of Medical Research, School of Medicine, University of Leeds, Leeds, West Yorkshire, United Kingdom

Introduction

Anterior cruciate ligament ruptures occur at an estimated annual rate of ~80 cases per 100,000 individuals in the general population [1], typically requiring surgical reconstruction using autografts or allografts. Decellularised porcine tendon offers a promising graft alternative, creating an immunologically compatible scaffold through removal of native cellular components [1]. Recent research in our group compared a novel 4-day decellularisation protocol with an established 26-day process, demonstrating that the shortened protocol better preserved the tissue's tensile and viscoelastic properties. Further, Picro-Sirius Red staining demonstrated altered collagen organisation and birefringence following decellularisation. Similar variations have been reported previously in the literature, although their underlying causes have been interpreted differently. This study employed Raman spectroscopy, second harmonic generation (SHG), and scanning electron microscopy (SEM) to characterise microstructural changes in the tissue following decellularisation. We hypothesised that this multimodal imaging approach would provide enhanced sensitivity to alterations in collagen and other extracellular matrix components.

Methods

Three tendon groups (native, 4-day, and 26-day processed; n = 3 each) were imaged using a Stellaris 8 microscope with multimodal chemical imaging capabilities including coherent anti-Stokes Raman spectroscopy (CARS), stimulated Raman spectroscopy (SRS), 2-photon fluorescence and SHG. Samples were imaged hydrated in phosphate-buffered saline. One sample from each group was examined using a Tescan AmberX Plasma FIBSEM following cryofracture, freeze-drying, and carbon coating.

Results

SRS symmetric stretching at ~2935 cm^{-1} imaged proteins, ~2850 cm^{-1} imaged lipids and SHG imaged collagen organisation (fig.1.A-C). Results from all imaging techniques demonstrated that the 26-day group exhibited pronounced microstructural changes, including lack of definition and consistency of fibrils, smoothing of crimping, and reduced organisation (fig.1.B,E). In contrast, the 4-day group more closely resembled the native tendon (fig.1.C,F). Stronger signals of lipids were visible in the native group when compared to the decellularised groups.

Discussion

In conclusion, Raman spectroscopy and SHG provide non-destructive imaging of hydrated biological tissue without fixation, offering detailed insights into tendon microstructural changes following decellularisation. SEM findings corroborated these observations. This study confirms the new 4-day decellularisation process better preserves the native tendon microstructure than the 26-day process.

Image-guided Microstructural Mechanical Evaluation and Quantification of Cartilage Under *In Situ* Compression

Ms. Xi Chen PhD Candidate[1], Dr. Catherine Disney PhD[2], Dr. Brian Bay Associate Professor[3], Dr. Kathryn Stok Professor[1]

[1]The University of Melbourne, Melbourne, Victoria, Australia. [2]University of Manchester, Manchester, North West England, United Kingdom. [3]Oregon State University, Corvallis, Oregon, United States

Introduction

A novel validated device, FELIX, enables image-guided micromechanical evaluation of complex soft tissues [1]. This opens up opportunities to explore heterogenous, depth-dependent fibre architecture in loaded (compressed, fluid pressurised) environments that bulk measurement and isotropic models fail to capture [2]. Characterising fibre mechanics under load helps explain how microstructure give rise to the macroscopic response. In this proof-of-concept study we combine data from FELIX with a point-cloud digital volume correlation (DVC) approach to directly visualise and quantify collagen deformation under compression *in situ*.

Methods

Stepwise, unconfined stress relaxation with 5% and 15% strain was carried out on 6 bovine auricular discs of 3 mm diameter, using FELIX. Volumetric images (512 x 512 x 65, 0.9943µm x 0.9943µm x 1µm) were captured using second harmonic generation (SHG) on a two-photon microscope (Olympus FV-MPERS), Figure 1A. Fibres were segmented using custom code (MATLAB, R2024b), and a point cloud was populated among the fibres for analysis using DVC (ver25.00) [3]. Displacement fields were computed and converted to Green-Lagrange strain tensors to quantify maximum, minimum and shear strain within the collagen network (Figure 1B, C).

Results

Preliminary results demonstrate fibre-scale displacement fields can be quantified from SHG volumes, showing a clear heterogenous response. Localised clusters of higher strain coincided with regions of higher fibre density, and regions with more chondrocytes exhibited lower strains. Shear strain had the highest average, compared to maximum and

minimum strain. This suggests that fibre re-alignment occurred and is consistent with reported collagen deformation mechanisms [4].

Discussion

This study demonstrates feasibility of combining SHG imaging, *in situ* compression and DVC to directly visualise and quantify cartilage microstructural mechanics. Sample preparation was kept to a minimum using non-destructive loading and non-labelling. Future work includes implementing confined compression to capture deformation with fluid pressurisation, enabling a thorough evaluation of this biphasic material. This will provide insight into substructural micromechanics for improving engineered cartilage constructs.

In Vitro Culture Model Mimicking Mechanical Environment of Spontaneous Pneumothorax to Elucidate Frictional Force-Induced Cellular Response

Mr. Yu Akiyama Master's Student, Prof. Shogo Miyata Ph.D.

Keio University, Yokohama, Kanagawa, Japan

Mr. Yu Akiyama

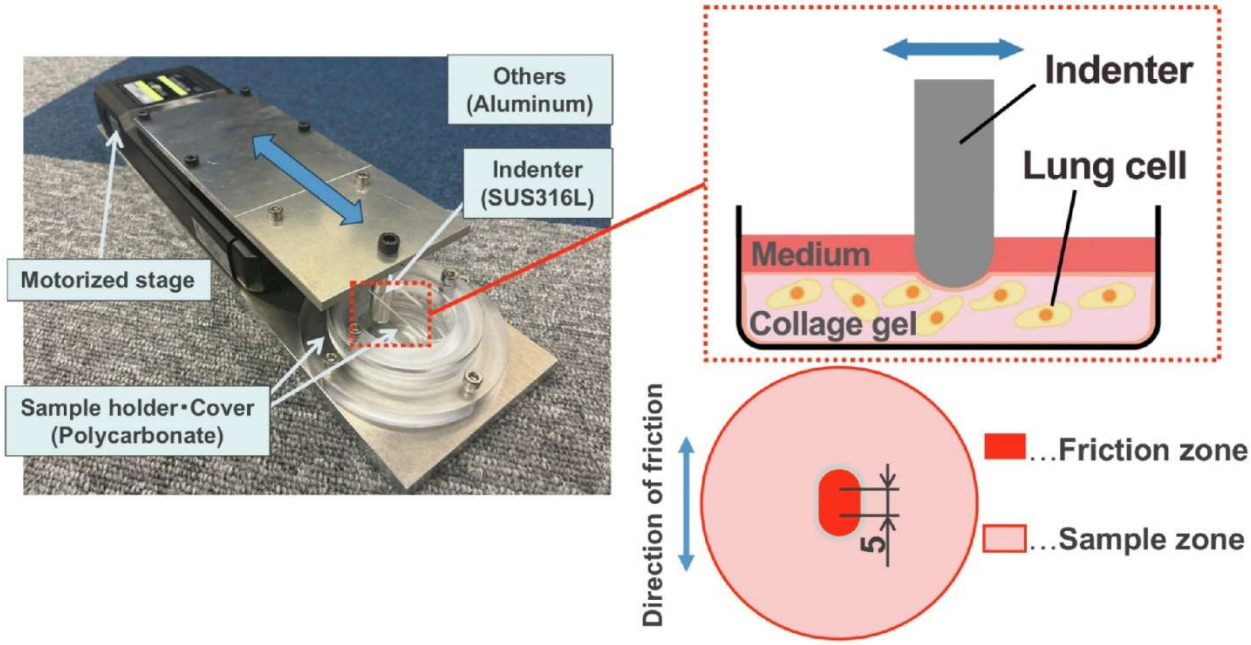
Introduction

Primary spontaneous pneumothorax (PSP) occurs suddenly in individuals without underlying lung disease, caused by air leakage from the visceral pleura leading to lung collapse and dyspnea. PSP is associated with the formation and rupture of blebs and bullae, predominantly in the apex of the lung, although the mechanical triggers remain unclear. PSP mainly affects tall, thin young males and shows a high recurrence rate, reducing quality of life. Previous studies reported that patients exhibit an elongated, laterally expanded, and anteroposteriorly flattened thoracic shape, resulting in up to 20 times higher tensile stress in the apex of the lung than in other regions. This study hypothesized that strong frictional force in the narrow apex of lung induces the degeneration of lung tissues resulting in rupture of blebs and bullae. To elucidate the pathogenesis of PSP, we developed an in vitro cell culture model mimicking the mechanical environment and evaluated effects of frictional forces on lung-derived cells.

Methods

Human fetal lung–derived fibroblasts were embedded in type I collagen gel at a density of 4.0×10^5 cells/mL and incubated for 24 h before stimulation. A custom-made culture device with motorized linear stage was developed to impose frictional stimulation on the cell-containing collagen gel. Frictional displacement for 5 mm was applied at 0.262 Hz for 24 h. Cell viability and morphology were evaluated by fluorescence microscopy with Calcein-AM and PI staining. Cell responses in regions with and without frictional stimuli were evaluated.

Results



Cell viability was maintained in both regions with and without frictional stimuli throughout the culture period. However, cell aggregation was observed exclusively in regions subjected

to frictional stimulation, and a higher number of dead cells was detected around the aggregation sites compared with other regions.

Discussion

From results of this study, frictional stimuli could be imposed on the cell-laden collagen gel without direct cellular damage. Moreover, the cell aggregations under frictional stimuli was considered to indicate the cellular degeneration mimicking those in spontaneous pneumothorax.

Modeling Solute Transport and Clearance in Synovial Joints: Implications for Predicting Cartilage Penetration of Injectable Therapeutics in Preclinical and Clinical Models

Ms. Aiyana Fortin M.S., B.S., Ms. Zongyin Dong B.S., Dr. Ulrich Wiesner Ph.D., Dr. Lawrence Bonassar Ph.D.

Cornell University, Ithaca, NY, United States

Introduction

The effectiveness of intra-articular (IA) drug delivery approaches for osteoarthritis is hindered by rapid synovial clearance and the dense, avascular cartilage matrix that limit therapeutic penetration. Particle-based delivery vehicles yield modest improvements in drug residence time, but joint retention in large animals and humans has not been optimized (**Fig.1A**). Recently, solute transport properties in cartilage were found to correlate with molecular weight (MW). However, there is no unifying framework that combines synovial kinetics and cartilage transport. Our objective was to examine the relationship between clearance kinetics, diffusivity and cartilage penetration following IA injection.

Methods

PubMed was searched (terms: injection, intra-articular, knee) to find studies with longitudinal clearance data following an IA injection. Models of exponential decay ($y=Ae^{(-t/\tau)}+c$ or $y=A_1e^{(-t/\tau)}+A_2e^{(-t/\tau_2)}+c$) and linear regressions ($\log(y)=b*\log(x)+a$) were fit in Origin Pro. Half-lives were calculated: $t_{1/2}=\ln(2)*\tau$. Diffusivities (D) were estimated using a power-law relationship. Penetration depths were calculated: $Z_{penetration}=\sqrt{(2D\tau)}$. General linear F tests, ANCOVA, and Tukey's post-hoc tests were performed in RStudio ($\alpha=0.05$).

Results

IA half-lives of solutes and vehicles were predicted by MW and hydrodynamic radius (r_h) via a power-law relationship (solutes: $y=0.52x^{0.269}$, $R^2=0.29$, $p=0.00013$; vehicles: $y=9.9x^{0.321}$, $R^2=0.20$, $p=0.0016$). Half-lives in rats were 10-fold greater than in rabbits (**Fig.1B**, $p<0.001$). Clearance kinetics in mice were poorly correlated with MW (**Fig.1B**, $p=0.79$). Clearance kinetics of untargeted vehicles correlated with r_h (**Fig.1C**, $p=0.002$), but targeted vehicles did not ($p>0.6$). Large vehicles ($r_h>30$nm) penetrated <500μm in cartilage while small vehicles ($r_h<30$ nm) diffused >500μm (**Fig.1D**).

Discussion

Vehicles exhibited 10-fold greater half-lives than solutes. Given that clearance and diffusion kinetics are both linked to r_h, further investigation of smaller vehicles (r_h<30nm) may enhance cartilage targeting and joint retention (**Fig.1D**). Nearly all vehicles penetrated the full thickness of mouse cartilage (~50μm) but few would penetrate human cartilage (~1.5mm) before being cleared (**Fig.1D**). These data partially explain why many IA therapies are successful in rodents but translation to larger animals and humans is lacking. This model of IA transport highlights the value of large animal models to predict therapeutic efficacy in humans.

Images (Optional)

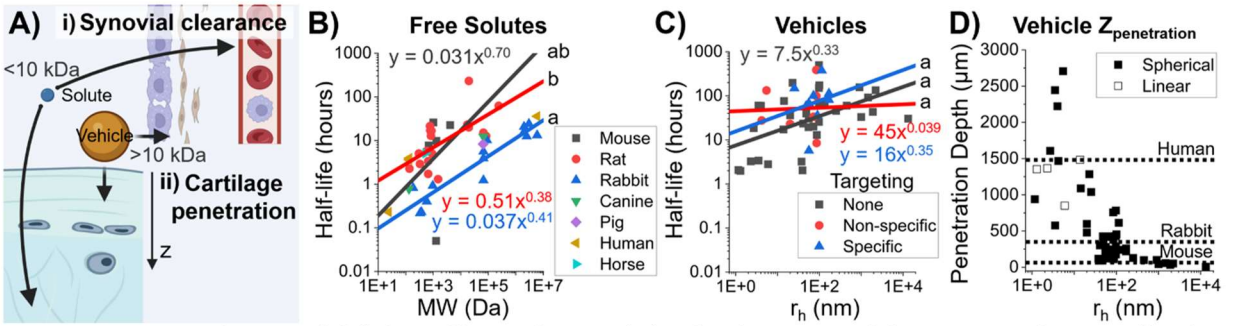

Figure 1: (A) (i) The synovial lining offers a size-restrictive barrier to material transport, where small solutes (<10kDa) clear rapidly (long arrow) and large solutes (>10kDa) clear slowly (short arrow). **(ii)** Similarly, diffusive transport in cartilage is also size-dependent: small solutes (<10kDa) diffuse rapidly (long arrow) and large solutes (>10kDa) diffuse slowly (short arrow). **(B)** Solute half-lives exhibited a 10-fold increase over 4 orders of magnitude in MW. Half-lives were 10-fold greater in rats than in rabbits. **(C)** Vehicle half-lives exhibited a 10-fold increase over 4 orders of magnitude in size. Surface functional groups (i.e., 'non-specific' indicates cationic surface charge; 'specific' indicates reversible binding with cartilage is possible) obscured the relationship between vehicle size and clearance kinetics. **(D)** Cartilage penetration of vehicles decreased with r_h in this model. Smaller vehicles (r_h<30nm) can diffuse farther into tissue than larger vehicles, exceeding full-thickness penetration in human cartilage (i.e., 1.5-2mm). Shared letters between groups denote no significant difference (α=0.05).

Laser-Templated Microvascular Construction With Predefined Geometries via Flow Stimulation and Initial Cell Introduction Control

Mr. Akira Ono[1], Mr. Ryo Aoyama[1], Mr. Masahiko Suda[1], Mr. Keisuke Shibata[1], Dr. Tadahiro Yamashita[1,2], Dr. Yoshihiro Taguchi[1,2], Dr. Ryo Sudo[1,2]

[1]School of Integrated Design Engineering, Graduate School of Science and Technology, Keio University, Yokohama, Kanagawa, Japan. [2]Department of System Design Engineering, Keio University, Yokohama, Kanagawa, Japan

Introduction

In tissue engineering, capillary networks play a crucial role in delivering oxygen and nutrients into 3D parenchymal constructs, and each organ has a distinct capillary architecture. For example, the hepatic lobule contains a radial vascular network called sinusoids, whereas the kidney contains densely packed spherical capillary structures in the glomerulus. Therefore, constructing capillary networks with organ-specific geometries is essential for recapitulating organ-specific metabolism.

In this study, we established a method to construct capillary-scale vasculature with pre-defined geometries. We demonstrated that flow stimulation and the manner of initial cell introduction into the template channels immediately after seeding are critical for successful vascular formation. These findings offer a promising approach for engineering organ-specific microvasculature for tissue regeneration.

Methods

For hydrogel preparation, a type I collagen prepolymer solution was injected into the hydrogel port. Cylindrical hollow channels with straight, linear geometries, serving as templates, were fabricated inside the hydrogels using a femtosecond laser. For template-guided microvessel construction, human umbilical vein endothelial cells (HUVECs) were seeded onto the hydrogel surface by injecting a cell suspension into the medium port.

Results

With a 20-μm-diameter template, which falls within the size range of native capillaries, HUVECs failed to form vascular structures under static conditions. In contrast, under

interstitial flow, the cells covered the entire luminal surface, leading to the formation of straight vascular structures along the channels.

To further regulate early cell introduction, narrowed constriction structures were created within the hydrogel channels. The position of these stenotic structures influenced the rate and extent of vascular formation.

Discussion

Overall, we demonstrate that the application of interstitial flow, together with controlled initial cell introduction, is essential for robust vascular formation. We hypothesized that successful formation along the template requires sequential processes: initial cell adhesion, establishment of cell–cell junctions, and subsequent collective migration.

The primary advantage of this methodology is its ability to reproducibly generate capillaries with predefined geometries. Such reproducibility is crucial for investigating vascular remodeling in vitro and holds significant potential for tissue engineering applications aimed at regenerating organ-specific vascular networks, such as those in the liver and kidney.

A Confined Dynamic Compression Framework for Characterizing Melt Electrowritten-PVA Composite Scaffolds for Articular Cartilage Repair

MSc Alessio Amicone[1], Dr. Remco Doodkorte[2], Prof. MD ScD Keita Ito[2], Prof. Dr. Stephen J. Ferguson[1]

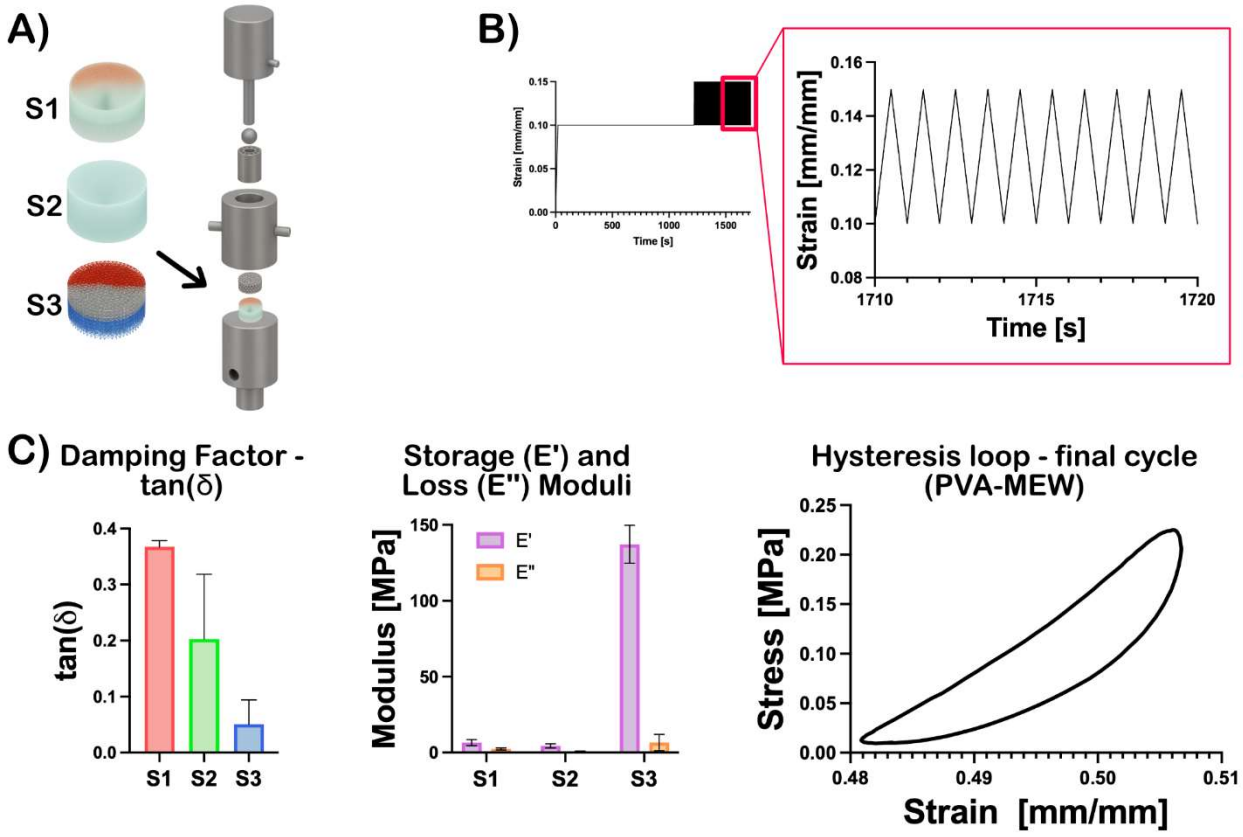
[1]ETH Zurich - Institute for Biomechanics, Zurich, Zurich, Switzerland. [2]Eindhoven University of Technology - Orthopaedic Biomechanics, Eindhoven, Noord-Brabant, Netherlands

Introduction

Articular cartilage withstands intense cyclic loading through a collagen-rich network and poroviscoelastic fluid pressurization. Mimicking this dual mechanism in engineered constructs remains challenging: hydrogels lack reinforcement, while scaffolds must ensure mechanical stability and load distribution. Prior studies show that porous polymer scaffolds filled with PVA hydrogels improve performance under compression [1], and melt electrowritten (MEW) architectures offers tunable structural reinforcement by limiting lateral expansion [2]. Despite the relevance of confined compression in cartilage biomechanics [3], MEW-hydrogel composites remain underexplored in such settings. This study quantifies the viscoelastic response of tri-layer MEW scaffolds, with and without PVA, under confined dynamic compression.

Methods

Tri-layer scaffolds were fabricated via MEW using medical-grade poly(ε-caprolactone), mimicking cartilage zonal architecture. Constructs (8 mm ø) were prepared as PVA-only (S2), MEW-only (S3), or MEW-PVA composites (S1) via gel infiltration and freeze-thaw cycling. Confined compression testing followed Patel's cartilage protocol [3], adapted to scaffold mechanics (Fig.A). After applying a 2N tare load, samples were compressed 10% at 2 mm/s and held for 1200s (stress-relaxation), then cycled at ± 5% strain, 1Hz for 500 cycles (Fig.B). Viscoelastic parameters were extracted through Matlab analysis.



Results

Relaxation curves were fit to a bi-exponential model (mean R^2=0.91), with $\tau_1 \approx$ 1-24s and $\tau_2 \approx$ 100-590s. MEW-only (S3) had high stiffness (E' = 128-146 MPa) and low damping ($\tan\delta \approx$ 0.02-0.08). PVA-only (S2) was softer (E' ≈ 3.4-5.4 MPa), while MEW-PVA (S1) showed intermediate stiffness (E' ≈ 3.5-8.0MPa) and greater damping (E'' ≈ 1.4-2.9MPa, $\tan\delta \leq 0.4$). Hysteresis in a representative S1 sample confirmed energy dissipation (Fig.C).

Discussion

Mechanical trends reflect construct structure. The excessively high modulus in S3 (Fig.C) likely reflects fluid incompressibility in the open MEW structure, rather than an intrinsic stiffness. S1 composites combined elastic reinforcement with damping, evident in modulus values and hysteresis. Compared to native cartilage (7-40 MPa, tanδ ≈ 0.1-0.2 at 1Hz [4]), S1 approaches physiological damping. These preliminary findings support the value of MEW-PVA systems for cartilage scaffolds and confined compression for evaluating cartilage-mimetic mechanics.

A Multi-Modal Bioreactor System Designed for Characterising Chondrogenic Effects of Dynamic Mechanical Stimulation in Cartilage Tissue Engineering

Mr. Jiaqi K. Shen, Ms. Cecily X. Chen, Prof. Kathryn S. Stok PhD

Department of Biomedical Engineering, The University of Melbourne, Parkville, Victoria, Australia

Introduction

Dynamic mechanical stimulation is a central pillar in cartilage tissue engineering, yet progress in the field is hindered by the lack of standardised platforms for delivering and tuning mechanical cues essential for cartilage matrix development [1]. A recent systematic review by the authors revealed that current studies report chondrogenic outcomes without characterising the applied mechanical stimulus at sub-tissue scales, and the substantial heterogeneity of custom-built bioreactors further limits cross-study comparison [2]. This work aims to develop a multi-modal bioreactor system capable of delivering controlled mechanical stimulation under standardised *in vitro* conditions to enable comprehensive mapping and comparison of chondrogenic responses across conventional loading modalities.

Methods

A traceable, evidence-based engineering design process was implemented to ensure mechanical feasibility, biocompatibility, and operational robustness. The platform integrates configurable stimulation modules that support compression, shear, tension, hydrostatic pressure, fluid-induced shear, and combined loading. Standardised protocols were defined for tuning mechanical inputs and quantifying biological outputs, forming the basis of a parametric analysis workflow for mechanically stimulated chondrogenesis.

Results

The resulting multi-modal bioreactor system (Figure 1) consists of: (a) mechanical actuation for direct-contact stimuli, (b) fluid actuation for fluid-mediated stimuli, (c) a circulation subsystem to maintain nutrient transport, and (d) gas exchange to regulate incubation environments. Together, these subsystems provide a modular infrastructure for delivering reproducible mechanical inputs under consistent conditions. A culture chamber has been prototyped and assembled (Figure 1) to initiate functionality tests using a dual-

piston pump, which allows for dynamic modulation of 0-10 MPa fluid pressure as well as a tuneable range of 0-400 ml/min continuous flow to induce fluid shear stimulation.

Discussion

While further validation and refinement are ongoing, this multi-modal bioreactor presents a viable framework for cross-comparison under a unified experimental workflow. The successfully prototyped culture chamber confirms the technical feasibility of the bioreactor design. Overall, this device serves as a foundation for standardising mechanically stimulated cartilage tissue engineering, generating reliable mechanobiological datasets, and supporting optimisation of stimulation strategies toward future regulatory acceptance of engineered cartilage constructs for regenerative medicine.

Advancing Articular Cartilage Regeneration: A Multiscale Scaffold Approach And Physical Characterisation

MSc Elisa Bissacco[1], MPhil Neeraj Sakhrani[2], Dr. Jack Rogot[2], MS Haoyu Zhang[2], Prof. Dr. Clark T. Hung[2], Prof. Dr. Gerard A. Ateshian[2], Prof. Dr. Stephen J. Ferguson[1]

[1]ETHZ, Zürich, Switzerland, Switzerland. [2]Columbia University, New York City, New York, United States

Introduction

Articular cartilage (AC) degeneration remains a major clinical challenge. Tissue engineering integrates cells, growth factors, and biodegradable scaffolds to support its repair. Here, we developed bilayered PCL scaffolds via Solution Electrospinning (SES) and Melt Electrowriting (MEW), embedded in porous SBMA-GelMA-quaternized chitosan hydrogels, and evaluated gel morphology and the influence of fiber geometry on mechanical properties, solute diffusivity and tribological response.

Methods

SBMA-GelMA-qChitosan (Gel) hydrogels were formulated at 4%, 6%, and 2.4% (w/v), respectively. Bilayered PCL scaffolds were produced via SES and MEW in three architectures differing in wall spacing (WS) and fiber orientation: O-WS500, O-WS150/350, and X-WS500 (Figure1A). Preliminary characterization of Gel and Gel+O-WS500 included compression testing under 60% strain and SEM analysis of pore size and fiber-gel integration. Tribological performance was assessed by measuring the coefficient of friction (μ) under reciprocating sliding (contact stress of 130 kPa) against bovine tibial cartilage in synovial fluid for 120 min at 1mm/s [1]. Diffusion was quantified by Fluerescence-Recovery-after-Photobleaching (FRAP) using 70kDa FITC-dextran.

Results

Compression testing showed an elastic modulus of 41.6±20.4kPa for Gel and 432.8±76.5kPa for Gel+O-WS500. Gel and Gel+O-WS500 exhibited average pore sizes of 91.4±22.8μm and 82.0±18.3μm, respectively. μ_{avg} values were 0.032±0.009, 0.040±0.012, and 0.089±0.036 for Gel+O-WS500, Gel+O-WS150/350, and Gel+X-WS500, respectively (Figure1C). Gel displayed significantly higher solute diffusivity (113.7±15.4$\mu m^2/s$) compared to Gel+O-WS500, Gel+O-WS150/350, and Gel+X-WS500 (58.6±15.9, 49.1±19.8, and 58.2±13.6$\mu m^2/s$, Figure1D).

Discussion

As expected, incorporation of PCL fibers substantially increased the mechanical stiffness of the hydrogel, reaching the lower range of physiological compressive modulus for AC. SEM analysis revealed good gel-fiber integration and homogeneous pore size distribution, suitable for chondrocyte infiltration. Tribological testing showed relatively stable coefficients of friction across all scaffold geometries, with μ_{avg} approaching the upper range of AC values. FRAP analysis indicated that solute diffusivity was higher in Gel, suggesting that increased volume fraction due to fibers reduces molecular transport. Overall, all constructs exhibited diffusivity values comparable to AC [2], supporting their suitability for cell and growth factor delivery.

Investigating the Mechanical Efficiency of Genipin Crosslinking on Demineralized Cancellous Bone Scaffolds for Articular Cartilage Repair

Mr. Shengming Hu B.M.E.[1], Dr. Andreja Zupan Ph.D.[1], Dr. Darryl Dickerson Ph.D.[2], Dr. Eric Nauman Ph.D.[1]

[1]University of Cincinnati, Cincinnati, Ohio, United States. [2]University of New Mexico, Albuquerque, New Mexico, United States

Introduction

Articular cartilage injuries in the knees affect approximately 900,000 Americans annually. Due to its avascular nature, cartilage has limited healing potential and current repair strategies have long recovery times largely because they don't adequately support the damaged area while facilitating nutrient transport. We evaluated the mechanical properties of a Genipin-crosslinked, regionally-demineralized cancellous bone scaffold to enhance stiffness, provide structural support, and facilitate nutrient delivery.

Methods

Crosslinking was performed after osteoinductivity removal and before sterilization. Genipin powder was diluted in 99.5% ethanol. Scaffolds were then submerged in the Genipin solution for 24 hours at 37 ºC, and rinsed in deionized water.

A Biomomentum MACH-1 was used to record compressive forces up to 30% strain at rates of 0.05, 0.5, 5, and 50%/s. The 30% strain level was chosen based on MRI scans of knee cartilage deformation under load and the highest strain rate approximated the knee cartilage deformation rate during moderate-intensity walking. Six unconfined cyclic compression loads were applied to each 7 mm diameter, 2.5 mm thick sample (12 each of control, 0.5% Genipin, and 2% Genipin) for each strain rate.

Results

Estimated peak knee joint force was 385% of body weight and the mean unloaded contact area was approximately 210 mm^2. Under loading, contact areas increased by 24%. The estimated stress values were 5.65 MPa for females and 6.54 MPa for males under a double-leg stance. For comparison, the peak stresses measured in the Genipin crosslinked samples ranged from 12.7 – 164 kPa (Table 1). As expected, 2% Genipin crosslinking significantly increased the peak stress more than 10-fold greater that of controls, though still less than the stresses experienced during normal activities.

Discussion

With 2% Genipin, the peak stress increased more than 10-fold, but the peak stress remained lower than the estimated stresses in the knee condyle. In vivo testing will be required to determine whether this is sufficient to promote the restoration of the cartilage-bone interface.

Development of Articular Cartilage Model Considering Fiber Orientation Using Particle Method

Ms. Fuyu Mima B.S.[1], Prof. Yoshimori Kiriyama Ph.D[1], Prof. Katsumasa Tanaka Ph.D[1], Prof. Salvatore Federico Ph.D[2]

[1]Kogakuin University, Shinjuku, Tokyo, Japan. [2]The university of Calgary, Calgary, Alberta, Canada

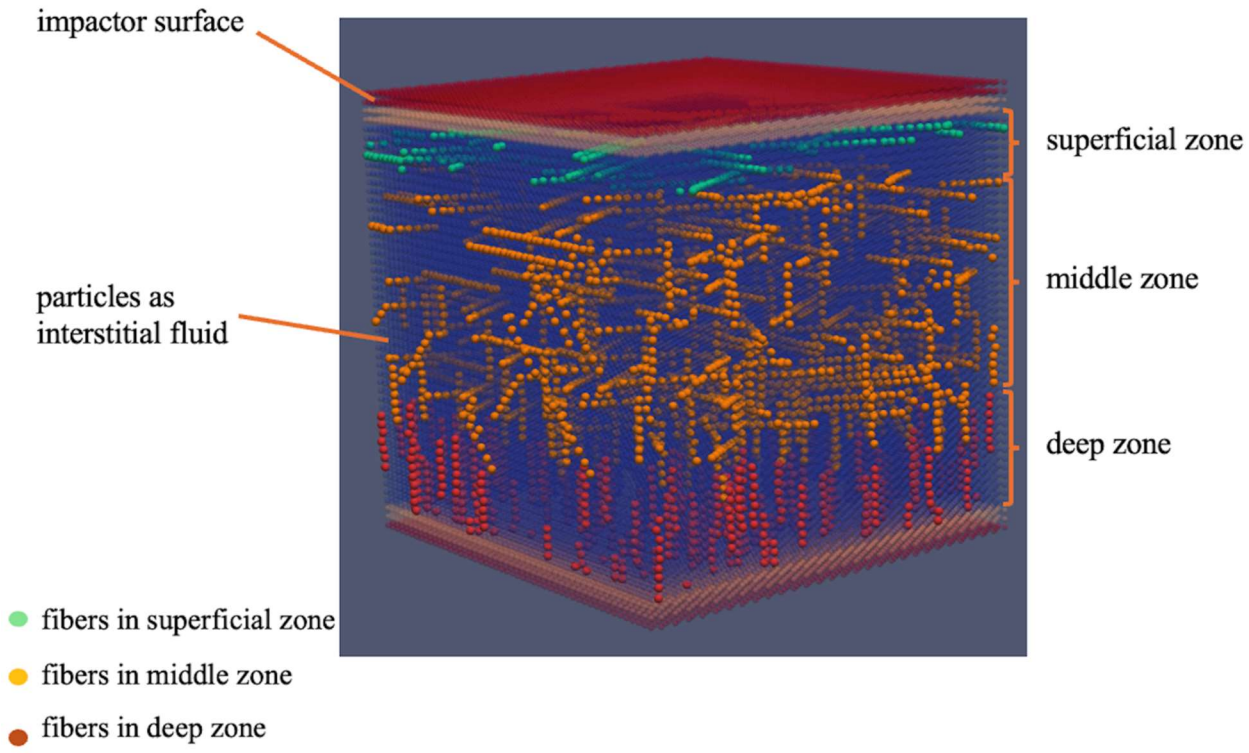
Introduction

Collagen fibers in the articular cartilage exhibit a depth-dependent architecture, transitioning from a horizontal orientation in the superficial zone to a vertical orientation in the deep zone. The mechanical behavior of cartilage arises from the interaction between the collagen network and interstitial fluid. In osteoarthritis, fiber rupture and fibrosis are frequently observed, highlighting the need for models that represent fiber behavior and failure. In this study, we developed an articular cartilage model based on a particle method in which collagen fibers and interstitial fluid are expressed as particle assemblies, enabling mechanical response failure.

Methods

This study employed the Moving Particle Semi-implicit (MPS) method. Collagen fibers were modeled as linearly elastic solids, whereas the interstitial fluid was treated as incompressible. The fibers were represented by particles connected in straight chains, with the spacing set to the mean collagen fiber diameter (20 μm). Tentative positions are first calculated explicitly and then corrected using the pressure among the particles obtained implicitly. Fiber deformation was evaluated from the corrected positions to assess the behavior and rupture. A uniaxial compression test was simulated by prescribing a vertical displacement at the top surface.

Results



A three-dimensional articular cartilage model was constructed. The fiber particles were statistically distributed to reproduce the histological depth-dependent collagen architecture: in the superficial zone, fibers ran parallel to the articular surface; in the middle zone, they ran obliquely and intersected; and in the deep zone, they ran vertically toward the subchondral bone plate. Under vertical compression, fluid particles moved

laterally while continuing to transmit vertical stress, indicating that the characteristic compressive response of the cartilage was reproduced.

Discussion

The proposed model reproduces the native tissue structure and depth-dependent fiber orientation, enabling individual fibers to deform under compression. This allows a detailed analysis of the depth-wise differences in fiber behavior and rupture. Incorporating a mechanism by which multiple fibers aggregate and form fibrosis into the particle framework enables the reproduction of stepwise tissue-level failure. Therefore, this model could be useful for elucidating the histopathological progression of osteoarthritis.

P2-365

A Thermodynamic Framework for Coupled Electromechanical Bone Remodeling, Damage, and Healing

Dr Ibrahim Goda

University of Lorraine, Metz, 57073, France

Introduction

Bone is a complex hierarchical material whose structural evolution is governed by the interaction of mechanical loading, electrical fields, and biological regulatory mechanisms. This interdependence motivates the need for predictive mathematical models capable of capturing these coupled effects.

Methods

In this work, a unified thermodynamically consistent formulation is developed within the theory of irreversible processes in order to model coupled internal and external bone remodeling, damage progression, and healing in brittle bone tissue under simultaneous mechanical and electrical stimulation. The approach relies on irreversible thermodynamics and Eshelby-type configurational forces, with internal remodeling described by density evolution driven by the trace of the Eshelby stress and external remodeling represented through a surface growth law derived from a surface potential that depends on elastic surface strain and the local normal vector [1], while healing is incorporated through a scalar or tensorial variable interpreted as a negative counterpart to damage. Numerical simulations are performed on multiple geometric configurations including individual hexagonal trabeculae, clusters of trabeculae within a representative region of analysis, and macroscale bone samples, and electromechanical coupling is included to account for the piezoelectric behavior of bone and the associated conversion of mechanical stress into electrical potential.

Results

The simulations reveal that mechanical and electrical stimuli, whether applied separately or simultaneously, enhance bone formation, facilitate healing, and generate bone density distributions that are consistent with radiographic observations and experimental evidence.

Discussion

The findings suggest that the proposed unified framework is able to reproduce key mechanobiological mechanisms driving bone adaptation and recovery and thus provides a

robust platform for assessing the influence of natural and therapeutic electromechanical environments on bone remodeling, damage repair, and long-term structural evolution.

Development of Two-Photon Biofabricated Tissue-Engineered Vascular Graft

Ms. Jacqueline L. Avila[1], Dr. Jonathan P. Vande Geest, Ph.D.[1,2,3]

[1]Department of Bioengineering, University of Pittsburgh, Pittsburgh, PA, United States. [2]McGowan Institute for Regenerative Medicine, University of Pittsburgh, Pittsburgh, PA, United States. [3]Department of Mechanical Engineering and Material Science, University of Pittsburgh, Pittsburgh, PA, United States

Ms. Jacqueline L. Avila

Introduction

Coronary artery disease (CAD) is characterized by plaque buildup in the coronary arteries, leading to vessel narrowing and reduced blood flow to the heart. CAD results in about 610,000 annual deaths in the United States and in advanced cases, it is treated surgically with coronary artery bypass grafting (CABG). Although autologous vessel grafts such as the saphenous vein are the current gold standard, they have limited availability and have high failure rates of about 50% at 10 years. Tissue-engineered vascular grafts (TEVGs) offer a promising alternative. However, conventional fabrication methods such as electrospinning have limitations, including reduction of pore size due to compacted fibers, which hinder cell infiltration. Two-photon polymerization (2PP) supports high-resolution, three-dimensional fabrication with feature sizes ranging from hundreds of nanometers to centimeters. The objective of this study was to utilize 2PP to fabricate a small-diameter TEVG that mimics key geometrical features of the extracellular matrix (ECM), including fiber orientation, porosity, and topology.

Methods

A cross-section of a Sprague-Dawley rat abdominal aorta was imaged using an Olympus BX51 upright laser-scanning microscope. The resulting two-photon image was processed in MATLAB to generate a binary input image that guided TEVG fabrication (**Figure 1A**). The photoresin IP-S was used to fabricate a tubular construct by 2PP using the 4X objective on the same microscope. After fabrication, a grayscale image of the TEVG was acquired, binarized, and compared to the original input image using the Dice similarity coefficient (DSC) to evaluate spatial overlap (**Figure 1B**).

Results

The TEVG was successfully biofabricated in 2h 1m 52s, with an inner diameter of 0.694 mm, an outer diameter of 1.214 mm, and a length of 12.67 mm (**Figure 1C**). A DSC of 0.6027 was obtained between the input and output binary masks, indicating substantial geometric similarity between the designed and fabricated structures.

Discussion

Future work will include fabricating grafts using a biodegradable gelatin-based photoresin (Hydrobio INX N400) to improve biocompatibility and promote tissue remodeling. Mechanical testing will assess compliance matching to native vessels, a critical factor in preventing graft failure. Subsequently, TEVGs will be interpositionally implanted in Sprague-Dawley rats to evaluate *in-vivo* remodeling, patency, and long-term functionality.

Optimization of a Custom-Designed Perfusion Bioreactor for Human Bone Tissue Culture

PhD Mahsa Zojaji[1], BSc Annelise Grace Pageau[1], BSc Teodora Maluckov[1], MSc. Eng. Johannes Eichwalder[1], PhD Corey Daniel Smith[2], MD, FRCSC George Athwal[2], PhD, PEng Louis Miguel Ferreira[3,2], PhD Nikolas Knowles[1]

[1]Department of Kinesiology and Health Sciences, University of Waterloo, Waterloo, Ontario, Canada. [2]Roth McFarlane Hand and Upper Limb Centre, London, Ontario, Canada. [3]Department of Mechanical and Materials Engineering, Western University, London, Ontario, Canada

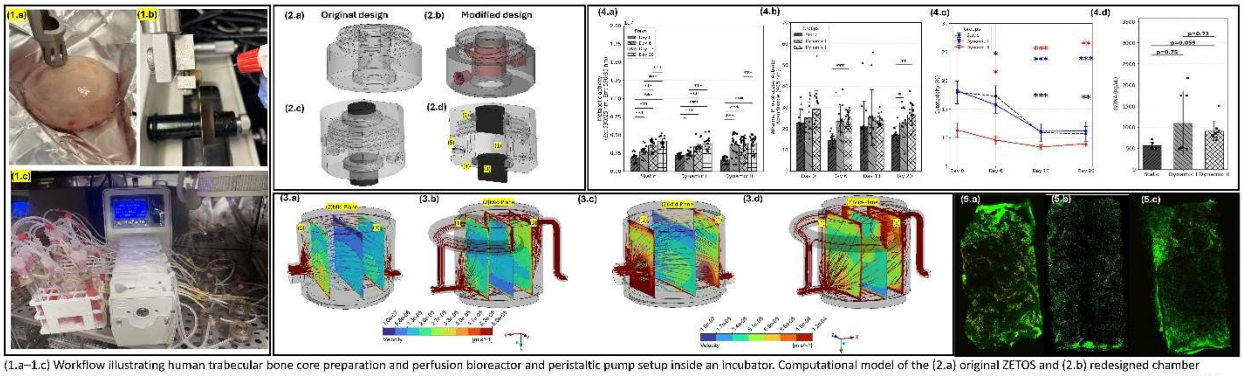
Introduction

Perfusion bioreactors maintain trabecular bone culture by preserving marrow and the native extracellular matrix by providing continuous fluid flow under osteogenic conditions [1]. Previous studies using this system have reported increases in apparent bone stiffness [2-3]. A recent modification enabled larger bone cores though perfusion was not optimized for these samples [3]. This study developed a redesigned, 3D-printed ZETOS bioreactor with three internal inlet channels to improve multidirectional perfusion. Computational simulations optimized the design and flow rate, and experiments evaluated cell viability, metabolic activity, and osteogenic function in human osteoarthritic bone samples.

Methods

Human trabecular bone cores (Ø9.15±0.14×9.5±2.0mm, n=22) obtained from four arthroplasty patients (Fig.1) were cultured for 21 days under static or dynamic (two perfusion rates;252 and 752µL/min) conditions. Metabolic activity, cytotoxicity, and osteogenic markers were measured throughout culture, with live/dead cell distribution visualized via confocal microscopy and genomic content (dsDNA) quantified on Day 21. Micro-computed tomography characterized bone microstructure, and computational simulations evaluated fluid flow through the porous tissue at both perfusion rates.

Results



Computational analysis demonstrated that the modified bioreactor increased mid-plane velocity and wall shear stress relative to the original ZETOS design, reducing the surface-to-center velocity drop by 50% and nearly doubling intrachamber pressure (Fig.2&3), thereby

improving fluid infiltration into trabecular regions [4]. Experimentally, metabolic activity rose in all groups, with the highest increase in the faster perfusion group (Fig.4a). Cytotoxicity decreased earliest under perfusion, and pH remained within physiological ranges (Fig.4b/c). Osteogenic activity was elevated in perfused groups at Days 6 and 20, and dsDNA trended higher with flow (Fig.4d). Live/dead imaging confirmed widespread cell viability throughout the explants (Fig.5).

Discussion

The findings demonstrate the redesigned 3D-printed bioreactor enhances fluid distribution, sustaining cell viability and osteogenic activity in human trabecular bone explants. This platform provides a physiologically relevant model for mechanobiology studies and lays the groundwork for future investigations incorporating cyclic mechanical loading and long-term bone adaptation.

Images (Optional)

(1.a–1.c) Workflow illustrating human trabecular bone core preparation and perfusion bioreactor and peristaltic pump setup inside an incubator. Computational model of the (2.a) original ZETOS and (2.b) redesigned chamber featuring three internal inlet channels to enhance multidirectional perfusion. (2.c) Bioreactor assembly and (2.d) cross-section showing: (1) bone chamber within the body component, (2) bioreactor cap, (3) load applicators at the top and bottom, (4) X-ring/O-rings preventing fluid leakage at both ends, and (5) integrated luer fitting for external connection to tubing. Computational fluid dynamic simulations comparing (3.a , 3.c) the original and (3.b , 3.d) redesigned bioreactors under Dynamic I (252 µL/min, a,b) and Dynamic II (752 µL/min, c,d) perfusion; mid-plane velocity fields and streamlines demonstrate improved flow uniformity, increased mid-plane velocity, and enhanced fluid penetration into central trabecular regions in the new design. (4.a–4.d) Biological responses of bone cores cultured under Static, Dynamic I (252 µL/min), and Dynamic II (752 µL/min) perfusion for 21 days: (3.a) metabolic activity, (3.b) alkaline phosphatase activity (ALP), (3.c) cytotoxicity, and (3.d) genomic content (dsDNA) on Day 21. Metabolic activity increased significantly over time in all groups, with Dynamic II showing the earliest and largest rise by Day 6. ALP as indicator of osteogenic differentiation varied with perfusion, with Static significantly lower than Dynamic I and II at Days 6 and 20. Cytotoxicity significantly under dynamic culture by day 6, whereas in static culture, no significant change was observed until day 13. Total dsDNA content trended higher in Dynamic II versus Static ($p = 0.059$) while no significant difference was found among groups. Representative live/dead confocal images (2x) showed cell viability throughout trabecular cores under (5.a) Static, (5.b) Dynamic I, and (5.c) Dynamic II confirming that bone cutting and coring did not compromise cell survival at the bone surfaces. All data were tested for normality using the Shapiro-Wilk test; within-group changes over time were analyzed using the Wilcoxon signed-rank test, and between-group comparisons were analyzed using Kruskal-Wallis tests.*$p < 0.05$, **$p < 0.01$, ***$p < 0.001$.

EFFECT OF Porosity Gradients on the Mechanical Performance of SLA 3D-Printed TPMS Scaffolds

Ms Catalina Araya Student[1], Mr Benjamín Rodríguez Student[2], PhD Luis Pérez Assistant Professor[3], Mr José Contreras PhD (c)[2], PhD Ameet Aiyangar Senior Researcher[4], Mr Bernhard Weisse Deputy Head of Laboratory[4], PhD Juan Vivanco Associate Professor[2]

[1]Federico Santa María Technical University, Valparaíso, Valparaíso, Chile. [2]Adolfo Ibañez University, Viña del Mar, Valparaíso, Chile. [3]Adolfo Ibañez University, Valparaíso, Valparaíso, Chile. [4]Swiss Federal Laboratories for Materials Science and Technology, Zurich, Zurich, Switzerland

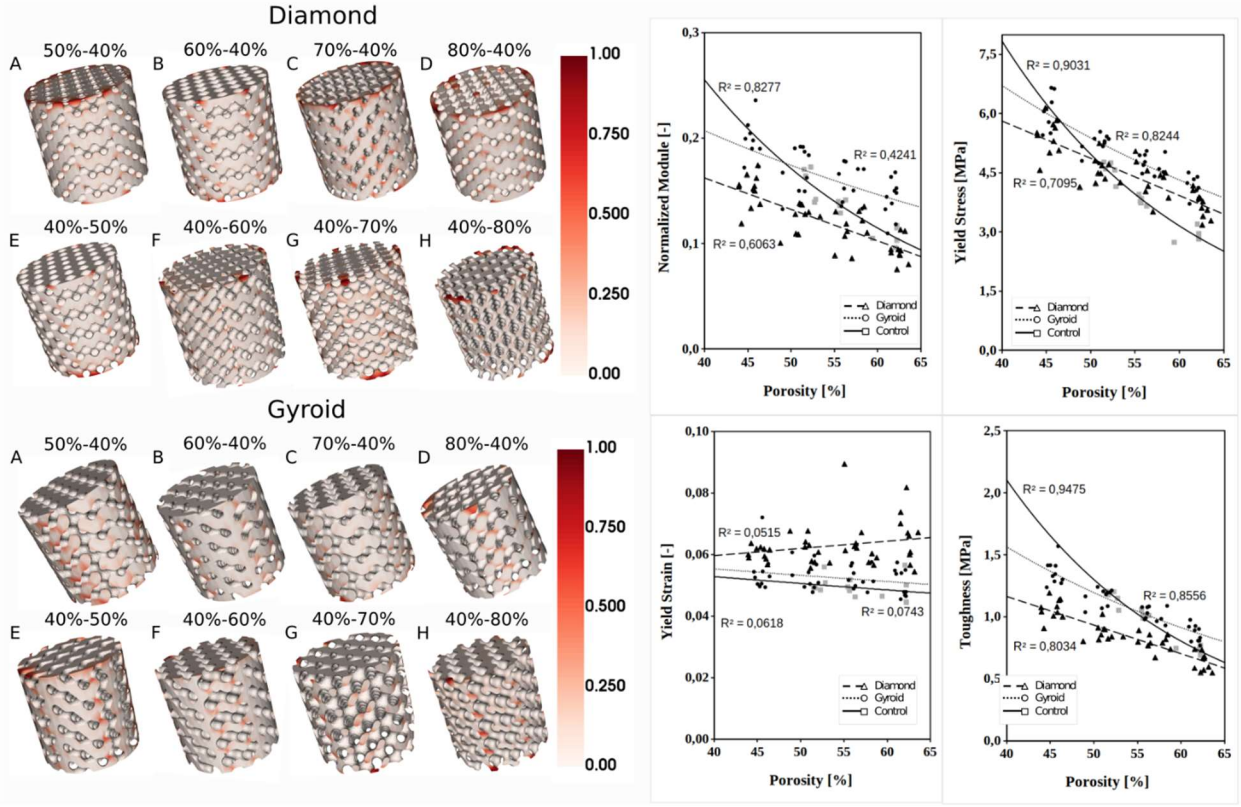
Introduction

Triply periodic minimal surfaces (TPMS) have gained significant interest in the biomedical field due to their potential in bone tissue engineering. Prior studies have shown the promise of TPMS structures, demonstrating strong mechanical performance and biocompatibility [1,2]. Three-dimensional porous scaffolds with graded porosity can better mimic the natural bone architecture [3]. However, the influence of radial porosity gradients on SLA 3D-printed TPMS structures remains insufficiently explored. This study evaluates the mechanical performance of Diamond and Gyroid TPMS designs with functional porosity gradients, focusing on their elastic modulus, yield strength, and toughness.

Methods

Diamond and Gyroid TPMS structures with four radial porosity gradients (ranging from 40% to 60%), including increasing and decreasing configurations, and a uniform-porosity control group, were fabricated using stereolithography (SLA) printing with Creality's high-precision 8K UV resin. Outer dimensions and porosity were measured experimentally. Compression testing was performed in accordance with ASTM D695-15, reporting elastic modulus, yield strength, and toughness. Micro-computed tomography (MicroCT) imaging was used to validate internal architecture and assess geometric accuracy through surface distance analysis.

Results



Fabricated samples showed high printing fidelity, with porosity within 5% of theoretical values. Micro-CT analysis and surface distance measurements confirmed high geometric accuracy (95%HD: 0.17 ± 0.04 mm). Diamond scaffolds exhibited lower error (0.15 ± 0.02

mm) than Gyroid scaffolds (0.20 ± 0.04 mm). Radial gradients remained below 0.25 mm, indicating minimal impact on geometric accuracy. Gyroid structures demonstrated higher mechanical properties than Diamond. Radial porosity gradients had little influence on TPMS scaffold mechanical performance, producing limited changes in the elastic modulus.

Discussion

Distinct responses between structures show that geometry primarily drives mechanical behavior. Micro-CT confirms that differences arise from intrinsic design features rather than printing errors, validating the reliability of SLA-printed TPMS scaffolds. The minimal impact of radial porosity gradients suggests that stronger or multi-axis gradients may be needed to generate measurable effects. Overall, the results support TPMS scaffolds for bone engineering and encourage exploring gradients along additional axes.

Investigation of the Protective Effect by Pressurized Dissolution of Argon Gas Under Cold Storage of Monolayer Cells

Mr Kenshi Mimura[1], PhD Kazuhiro Yoshida[2,1], PhD Rina Sakai[3,1], PhD Masanobu Ujihira[3,1]

[1]Kitasato University Graduate school of Medical Science, Sagamihara, Kanagawa, Japan. [2]Kitasato University Shcool of Allied Health Sciences, Sagamihara, Sagamihara, Japan. [3]Kitasato University Shcool of Allied Health Sciences, Sagamihara, Kanagawa, Japan

Introduction

Currently, all organs, as well as many tissues and some cells are typically maintained under cold storage at 0 to 4°C due to occurrence of cellular damage below 5°C. The purpose of this study was to investigate cellular protective effect by pressurized dissolution of argon gas under cold storage in rat cardiomyocytes monolayer.

Methods

The cell monolayers in a culture dish incubated for 24 h were prepared as test samples and control. Dulbecco's Modified Eagle Medium which has poor effect on cold protection, was used as the cold storage solution. First, the samples were pressurized in 0 to 1.0 MPa in argon gas, then preserved at 2 to 6°C for 24 h. Secondly, the samples were similarly, they were pressurized in 0 and 0.8 MPa in argon gas, then preserved at 6°C for 0 to 72 h.

Results

The first results showed that there was low, regardless of applied pressure at 2°C. It increased with increasing the pressure at 4 to 6°C, but plateau or decreased at pressure of higher than 0.8 MPa. Furthermore, the highest value was observed under 6°C and 0.8 MPa. The second results showed that there decreased significantly within 24 h when no pressure was applied. Although the value remained high for up to 24 h, decreased thereafter at 0.8 MPa. Pressurized storage at any time points between 24 and 72 h showed significantly higher than the case of 0 MPa.

Discussion

The relative cell viability at 4 to 6°C showed a plateau at pressures higher than 0.8 MPa, suggested that 0.8 MPa is the optimal pressure for maximum cell protection. In our previous studies using xenon gas, it was considered that argon gas has optimal dissolution

amount like xenon gas. The relative cell viability at 6 °C was higher than that observed at other temperatures, 6°C is considered to be the optimal storage temperature in this study.

Novel Nested Transwell for Developing Lung Immuno-Organoids

Ms Lara Herlah, Dr. Luc Mongeau

McGill University, Montreal, Quebec, Canada

Introduction

Organoids often lack immune cells; a key component when studying disease. Monocytes and macrophages are the most common immune cells found in the lung and play a significant role in homeostasis and pathological conditions. Including these cells is essential to accurately mimic respiratory infections. This study employs an heterogenous lung organoid that shows markers of the proximal and distal lung. We aimed to establish a lung organoid and monocyte co-culture to investigate the role of monocyte migration and activation in infected organoids. The infiltration of monocytes was performed using a nested transwell, which was designed and validated. The organoid sits in one transwell and THP-1 monocytes are added to a second transwell. Upon infection, the organoid releases chemokines, attracting monocytes toward the organoid. Monocytes extravasate through the transwell membrane making the model more representative than direct co-cultures.

Methods

A 3D-printed nested transwell system was designed and validated through cell compatibility and extravasation assays. An indirect co-culture of monocytes and the lung organoid was established and optimized. The organoid and THP-1 co-culture was infected with H1N1 to compare the response of organoids to H1N1 with and without monocytes. Monocyte extravasation and differentiation into macrophages were assessed using qPCR, flow cytometry and fluorescence imaging.

Results

3D-printed transwells were found to be biocompatible (1% dead cells in Live/Dead assay), functional (75% of monocytes extravasated within 3 hours when exposed to CCL-2) and allowed for a physical separation between organoids and monocytes. Studies related to immuno-organoid infection are still in progress.

Discussion

This approach establishes a framework for immune-integrated lung organoids that better recapitulate the lung. The nested transwell can be useful in a variety of other organoid or cell studies, e.g when studying inter-organ communication or immune-organoid crosstalk. Additionally, by adding macrophages, the organoid may be used for tuberculosis

infections as tuberculosis primarily infects macrophages; a future study will include TB infections. While there is a diverse set of immune cells active in the lung, monocytes were the only immune cells added to the organoid; future studies should look at incorporating other immune cells, like T- and B-cells to further improve the lung model.

Biocompatibility Assessment of 3D Printed Hydroxyapatite/Polycaprolactone Composites for Intra-oral Bone Regeneration

Ph.D. Candidate Margaryta Ivanets[1], Postdoctoral Researcher Sandy Anania[1], Senior Scientist Christine Kermel[2], Program Manager Stéphane Hocquet[2], Postdoctoral Researcher Bernard Staumont[1], Associate Professor Dorien Van hede[1], Professor France Lambert[1], Full Professor Liesbet Geris[1]

[1]University of Liège, Liège, Liège, Belgium. [2]Belgian Ceramic Research Centre, Mons, Hainaut, Belgium

Introduction

The loss of one or more teeth is frequently associated with alveolar bone resorption, which can compromise the placement of dental implants. To address this issue, a procedure known as guided bone regeneration (GBR) was developed several decades ago. This technique promotes bone regeneration through the combined use of a barrier membrane and a bone graft material, supporting bone cell attachment and bone neoformation (osteoconduction). While deproteinized hydroxyapatite (HA) xenogeneic particles are clinically used as bone grafts for GBR, they lack structural integrity and show limited performance to repair large and complex defects. Therefore, in line with regenerative and personalized medicine, research increasingly focuses on synthetic biomaterials for bone regeneration with self-supporting, patient-specific, and three-dimensional shapes. Building on this progress, our objective is to develop bioactive 3D-printed synthetic composite biomaterials with enhanced efficacy for intra-oral bone regeneration.

Methods

In this study, pellet additive manufacturing (PAM) 3D printing was used to print composite HA/polycaprolactone (PCL) disks. Contact angle measurement and scanning electron microscopy (SEM) were performed to evaluate surface wettability and microstructural features of the disks. Human mesenchymal stem cells and L929 fibroblasts were seeded onto disks composed of pure PCL, HA (20% v.v)/PCL, HA (41% v.v)/PCL, pure HA, and cultured up to 21 days. Cell-seeded disks were subsequently assessed for viability (Live/Dead staining, LDH assay), proliferation (DNA quantification), and morphology (SEM).

Results

Correlations were identified between HA content and contact angle measurements. SEM imaging showed that cells displayed a spread morphology in all compositions, including pure PCL (Figure). All groups demonstrated viability levels exceeding 80%, and DNA quantification indicated an increase in DNA content over time for each composition.

Discussion

To evaluate the suitability of the PAM printing method and HA/PCL compositions, in vitro studies were performed on 2D disks. The initial results confirmed the biocompatibility of the PAM-printed HA/PCL composites. The next step will be to assess whether the different formulations can induce osteogenic differentiation. Compositions demonstrating the most favorable outcomes in terms of viability, proliferation, and differentiation will subsequently be implemented in 3D gyroid scaffolds to investigate extracellular matrix deposition and early bone tissue formation.

Engineering Reproducible Vessel-Like Constructs: Optimizing FRESH Bioprinting and Mechanical Characterization of Alginate–Gelatin Hydrogels

Prof Michele Conti[1], Dr. Franca Scocozza[2], Dr. Delgrosso Elena[2]

[1]University of Pavia, Pavia, Italy, Italy. [2]University of Pavia, Pavia, IT, Italy

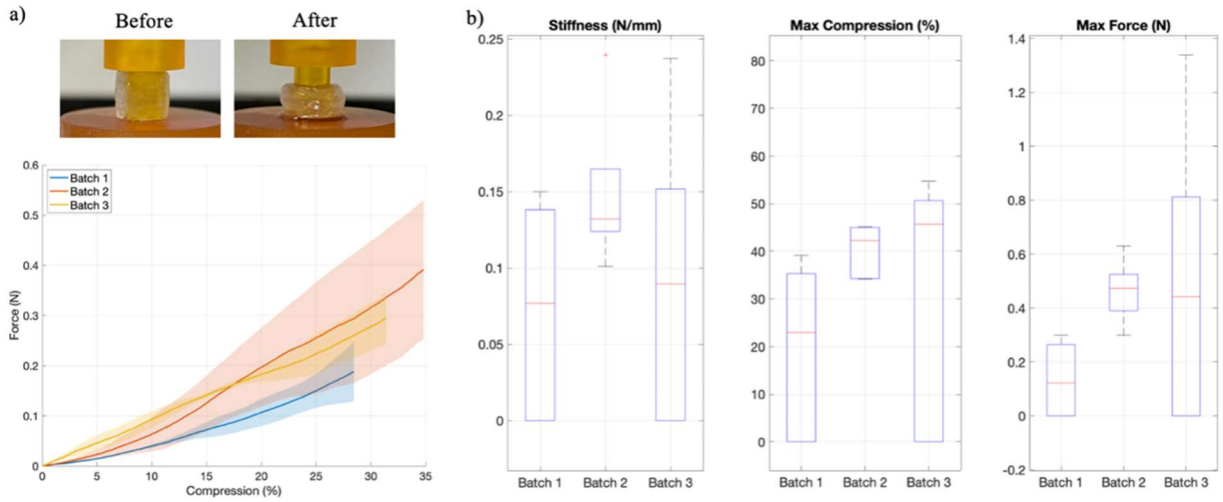
Introduction

The fabrication of mechanically stable, anatomically relevant vascular constructs remains challenging due to the complex geometry and anisotropic properties of blood vessels, which soft hydrogels struggle to replicate. The FRESH technique improves structural fidelity by supporting low-viscosity inks during deposition, yet standardized quantitative workflows are limited. Using alginate–gelatin blends as reproducible model inks, we established an engineering-focused pipeline combining optimized printing and mechanical testing to assess robustness and batch-to-batch consistency.

Methods

A sodium alginate–gelatin hydrogel was prepared as a reproducible model ink and printed using an optimized FRESH workflow, including a gelatin microparticle support bath and controlled extrusion through 0.4–0.6 mm nozzles. Post-printing stabilization combined thermal bath melting and Ca^{2+}-mediated reinforcement. Mechanical performance was quantified through confined compression and ring tensile tests across multiple batches, enabling evaluation of stiffness, failure behavior, and variability in printing, coating, and crosslinking.

Results



Optimizing the FRESH workflow yielded reproducible SA–GEL tubular constructs. For 6% SA, a 0.41 mm nozzle required ~50 kPa for stable extrusion, while 30 kPa caused collapse; 3% SA was unsuitable. Confined compression showed stiffness of 0.07–0.15 N/mm, maximum force 0.13–0.48 N, and compression 19–40% across four batches. Ring tensile tests gave 0.06–0.13 N/mm stiffness, failure strains of 60–130%, and forces of 0.4–1.2 N, confirming consistent axial and circumferential behavior.

Discussion

FRESH bioprinting overcomes filament spreading typical of soft hydrogels, enabling accurate lumenized geometries and supporting micro-CT–based evaluation. Integrating optimized printing with mechanical testing provided a quantitative, reproducible workflow. Constructs showed controlled axial and circumferential behavior (compression stiffness

0.07–0.15 N/mm; tensile stiffness 0.06–0.13 N/mm). Low inter-batch variability confirmed process robustness. Overall, this integrated strategy offers a reliable platform to guide parameter optimization and support future developments with advanced biomaterials and cellularized vascular models.

Impedance as a Novel Diagnostic Measure of Vascular Health and Disease

Mr Ali Farshad, Mr Md. Ashadujjaman, Prof. Abhay Ramachnadra Ph. D., Prof. Pranav Shrotriya Ph. D.

Iowa State University, Ames, Iowa, United States

Introduction

Vascular microstructure is important for its function and is known to change in disease (e.g. aortic aneurysm or aging) or during preservation. The influence of microstructure on intramural transport is not well understood. We use electrochemical impedance spectroscopy (EIS) as a non-destructive method to quantify transport within the wall, with electrical impedance serving as a surrogate measure of transport. The impedance characteristics of porcine vascular tissues are presented under three different conditions: 1) enhanced collagen cross-linking (using glutaraldehyde, representative of aging), 2) elastin damage (using elastase, representative of aortopathy), and 3) freezing. To demonstrate the versatility of the approach, results are presented for two vascular tissues of different sizes (aorta and innominate artery).

Methods

Fresh porcine aorta (AO) and innominate artery (IN) tissues were harvested from humanely euthanized animals used for meat; euthanization used approved methods. Tissues were examined under fresh conditions and then subjected to the three treatments (n = 5 treatments per tissue type). EIS measurements were performed in Hank's balanced salt solution using a four-electrode setup with Pt counter/working and Ag/AgCl reference/sense electrodes. Each sample was repeatably scanned three times to confirm the stability and reproducibility of the signals. Resistance was evaluated across four frequency ranges, and the distribution of relaxation times (DRT) analysis was used to interpret frequency-dependent features of the impedance.

Results

Multiple treatments showed changes in impedances across the frequency range. At 10,000 Hz, the average resistance of AO samples decreased by 33%±6.3% after glutaraldehyde treatment, 29%±16.5% after elastase treatment, and 13%±5.4% after freezing. These changes were statistically significant ($p<0.05$). Consistent reductions in impedance following treatments aligned with increased ionic accessibility caused by softening or

structural disruption. The distinct baseline differences between AO and IN tissues were maintained, and the DRT analysis revealed definitive treatment-dependent characteristics, suggesting that each treatment induced distinct alterations in the tissue matrix.

Discussion

The results demonstrate that EIS is sensitive to changes in structure and mechanics induced by various treatments. The stable and repeatable electrical signatures across treatments suggest that EIS could serve as a promising diagnostic measure of vascular health or disease.

Construction of Vascularized Three-Dimensional Hepatocyte Tissues Using Microfluidic Devices

Mr. Yen-Hsiang Huang, Dr. Tadahiro Yamashita, Prof. Ryo Sudo

Keio University, Yokohama, Kanagawa, Japan

Introduction

Advances in tissue engineering have enabled the construction of various tissues; however, generating complex three-dimensional (3D) tissues containing microvascular networks remains a major challenge. This study focuses on liver tissue engineering because the liver is one of the most important organs, owing to its vital functions such as detoxification. In the native liver, hepatocytes form parenchymal structures known as hepatic cords, while endothelial cells (ECs) form liver-specific microvessels, or sinusoids, between these cords. This highly organized architecture enables intimate interaction between hepatocytes and microvessels, which is indispensable for maintaining hepatic metabolic function. Therefore, constructing 3D hepatocyte tissues that incorporate microvascular networks—so-called vascularized hepatocyte tissues—is crucial for recapitulating native hepatic physiology in vitro.

Methods

We investigated two approaches for constructing vascularized hepatocyte tissues using microfluidic devices made of polydimethylsiloxane. In the first approach, hepatocyte spheroids containing fibroblasts, which serve as a source of pro-angiogenic factors, were formed and embedded within a hydrogel region of the microfluidic device. These spheroids were cocultured with ECs seeded in adjacent microchannels [1]. In the second approach, a cryogel scaffold containing fibroblasts was incorporated into a microfluidic device to generate a local paracrine-factor gradient [2]. Under these conditions, ECs successfully formed microvascular networks. Hepatocytes were subsequently introduced into the microchannels to construct 3D hepatocyte tissues interfacing with the microvascular networks.

Results

In the first approach, hepatocyte spheroids containing fibroblasts induced angiogenesis. ECs formed microvascular networks that extended toward and penetrated the spheroids. The resulting vascularized hepatic spheroids closely resembled hepatic sinusoids, with hepatocytes in intimate contact with the microvessels. These vascularized

spheroids exhibited significantly enhanced hepatic functions, including increased albumin secretion and urea synthesis.

In the second approach, microvascular networks formed under a local paracrine-factor gradient successfully integrated with 3D hepatocyte tissues. Functional perfusion through microvessels penetrating the 3D hepatocyte constructs was confirmed. Furthermore, hepatocyte proliferation was observed under this perfusion culture condition.

Discussion

These approaches demonstrate effective strategies for constructing perfusable 3D hepatocyte tissues and lay the groundwork for the future development of transplantable liver tissue in vitro.

Cellular Particles as Modular Building Blocks for Vascular Network Formation

Dr. Seiji Omata Assistant Professor, Mr. Akihiro Ueda, Mr. Kaito Tanaka, Dr. Yasuyuki Morita Professor

Kumamoto University, Kumamot, Kumamoto, Japan

Introduction

A major challenge in the development of regenerative tissues is the rational design of vascular networks within engineered constructs. In most current approaches, vascular cells are merely mixed into the tissue, resulting in random microvascular structures that reproduce only capillary-level networks. Conversely, when microfabrication techniques are used to recreate vascular architectures, it becomes difficult to adapt these predefined structures to injuries of varying shapes and scales. For these reasons, a method capable of simultaneously designing both capillaries and larger vessels is urgently needed. The present study aims to propose a highly transplantable design strategy based on a new concept termed "cellular particles".

Methods

In this approach, biodegradable particles are dispersed throughout a target regenerative tissue and gradually dissolve over time, thereby creating voids. We hypothesized that these voids would serve as initiation sites for angiogenic sprouting by vascular cells, ultimately leading to the formation of an integrated vascular network. To realize this concept, we fabricated “cellular particles” by attaching vascular-related cells to biodegradable polymer particles. The biodegradable particles, composed of polylactic-acid–based polymers, were generated with controlled diameters by dripping into microfluidic channels. Furthermore, to enhance cell adhesion while accelerating particle dissolution, the particles were engineered to be porous. Endothelial cells were used as the model vascular cell type and were successfully adhered to the particle carriers. These cellular particles were then embedded and cultured within collagen gels.

Results

To evaluate the behavior of endothelial-cell-laden particles within the collagen matrix, confocal laser microscopy was performed using CD31, an endothelial surface marker. The imaging confirmed the presence of numerous endothelial cells on the surface of the cellular particles, demonstrating successful seeding and retention within the gel. However,

after seven days of culture, no observable cellular infiltration into the surrounding matrix or formation of nascent vascular structures was detected.

Discussion

This study successfully established the foundational techniques required for fabricating and culturing cellular particles. We confirmed that the particles can be embedded directly into collagen gels and maintained for a seven-day culture period. To induce robust neovascularization, future work must incorporate macrophage-mediated extracellular-matrix remodeling to facilitate endothelial cell invasion and subsequent capillary formation.

Multilevel Characterization of Osteocyte Lacunar Microarchitecture in Healthy, Osteoporotic, and Post–COVID-19 Human Trabecular Bone

Dr. Seyedeh Fahimeh Hosseini[1], Dr. Isabella Poles[1], Dr. Eleonora D'Arnese[2], Prof. Laura Vergani[1], Dr. Federica Buccino[1]

[1]Politecnico di Milano University, Milan, Lombardy, Italy. [2]University of Edinburgh, Edinburgh, Scotland, United Kingdom

Introduction

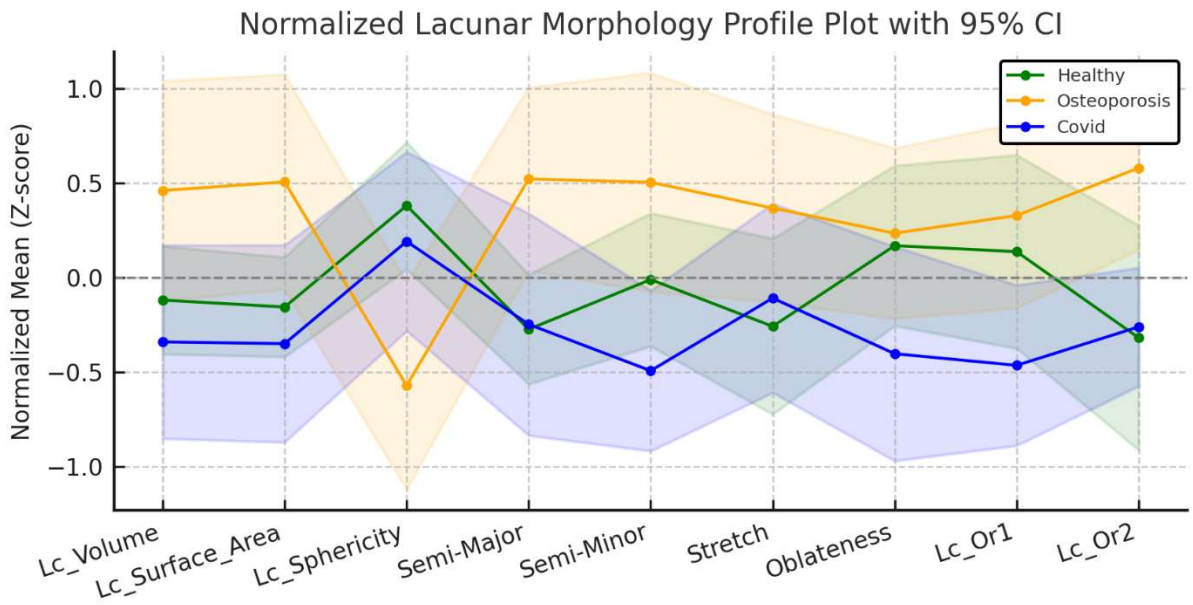
Osteocyte lacunae form the mechanosensory network of bone, regulating bone remodeling. Despite their central role, human evidence on pathology-driven lacunar alterations remains limited. This study investigates how pathological conditions reshape lacunar microarchitecture using synchrotron micro-CT, AI-based segmentation, and multilevel statistical modeling.

Methods

This cross-sectional study analyzed trabecular bone from ex vivo human femoral heads (FH) of healthy, osteoporotic, and COVID-19 patients undergoing total hip arthroplasty. Human FHs were collected at Galeazzi-Sant'Ambrogio Hospital (Milan, Italy) during 2021-2025. High-resolution synchrotron phase-contrast micro-CT images were preprocessed for 3D evaluation and segmented using a validated CNN based on the Keras VGG16 architecture [1]. This automated framework enabled the large-scale extraction of lacunar shape-orientation descriptors, including volume, surface area, sphericity, principal axes and their orientations, stretch, and oblateness. Given the hierarchical structure of the dataset, linear mixed-effects models (LMMs) were applied at the lacuna level, with age as a covariate and patient as a random effect. At the patient level, aggregated features were subsequently analyzed using covariate-adjusted MANOVA.

Results

In this study, bone samples from 48 female-only patients, divided into Healthy, Osteoporosis, and COVID-19 groups (n = 16 each, mean age = 72.0 ± 7.4, 77.8 ± 8.9, 68.1 ± 14.0 years, respectively), were analyzed. Bone volume fraction differed significantly across groups, with lower values in osteoporosis than in the healthy group ($p < 0.05$). LMMs of 8.96 million lacunae uncovered that lacunar volume, surface area, and semi-minor axis length were significantly larger in osteoporotic bone than in COVID-19 samples (all $p < 0.05$).



Minor-axis orientation (Lc_Or2) differed between osteoporosis and healthy ($p < 0.05$) and approached significance between osteoporosis and COVID-19 ($p < 0.1$), suggesting disease-specific alignment shifts.

At the patient level, MANOVA confirmed a significant overall group effect ($p < 0.05$), mainly driven by semi-minor axis length and near-significant sphericity, with the lowest sphericity in osteoporosis. The observed power (0.965) indicated high sensitivity to detect multivariate differences.

Discussion

This is a large-scale human study providing evidence that osteoporosis and COVID-19 leave quantifiable, disease-specific fingerprints on lacunar microarchitecture (figure). These morphological signatures probably reflect distinct remodeling microenvironments that will be investigated in further studies.

Characterizing ZIF-8 Degradation and Surface Topographies in Fibrous Scaffolds

Ms. Shu-Hsuan Chang, Dr. Pen-Hsiu Grace Chao

National Taiwan University, Taipei, Taiwan, Taiwan

Introduction

Nano- to micro-scale topographies enhance osteogenic differentiation [1]. By coating electrospun fibrous scaffolds with zeolite imidazolate framework-8 nanoparticle (ZIF-8 NP), we found the composite nanotopography promoted osteogenesis in mesenchymal stem cells (MSC) [2]. However ZIF-8 is unstable in cell culture medium such as DMEM [3]. It is unclear how the changing topography, as well as the released zinc ions, impact osteogenesis. In this study, we characterized ZIF-8 degradation in cell culture medium to delineate the chemical and topographical mechanisms.

Methods

Electrospun poly-L-lactide (PLA) fibrous scaffolds were fabricated as previously described [4]. To facilitate uniform coating, the scaffolds were wetted by brief ethanol (EtOH) treatment or sonication in ddH2O before in situ ZIF-8 synthesis [2]. Human bone marrow-derived MSCs were cultured in osteogenic medium on the scaffolds coated with collagen for 21 days and mineralization was assessed by Alizarin Red [5]. ZIF-8 degradation was monitored by measuring zinc ionic concentration with zincon [6].

Results

Pretreatment significantly impacted ZIF-8 NP size, where EtOH and sonication resulted in NP diameters of ~300 and ~90 nm, respectively (Fig A). The EtOH-treated scaffolds enhanced osteogenesis (Fig B). Release profile revealed that zinc concentration reached equilibrium within 20 hours of incubation (Fig C). Interestingly, scanning electron micrographs found persistent nanotopographies even after 5 days of incubation (Fig D).

Discussion

ZIF-8 NPs are widely studied for drug delivery applications for its biocompatibility and anti-bacterial properties. Zinc ions have also been shown to be osteogenic [7]. In this study, we found that zinc release from ZIF-8 NPs reaches equilibrium within one day. Since medium was refreshed every three days, cells might be exposed to zinc ions only at the initial stage of osteogenic induction. Current studies are ongoing to examine the effects of initial zinc

exposure, zinc ion dosage, and delineate the role of chemical and topographical cues on osteogenesis.

Biocompatibility of a Technical-Grade SLA Resin: Mechanical and Biological Evaluation of 3D print samples for Tissue Engineering

Mr. Vincenzo Marchese[1,2], Mr. Jose Ignacio Contreras[1], Dr. Carola Millan[1], Dr. Heidi Lynn Ploeg[2], Dr. Juan Francisco Vivanco[1]

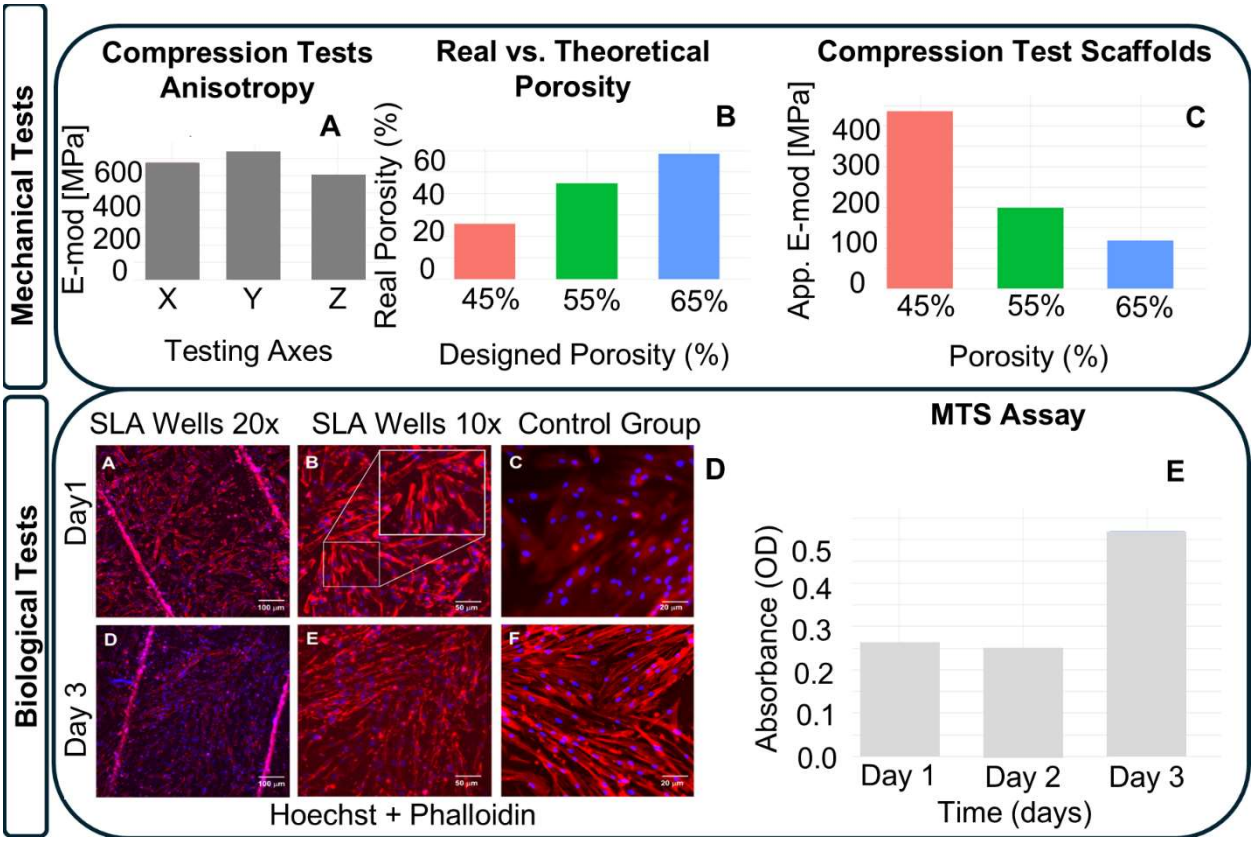
[1]Universidad Adolfo Ibañez, Viña del Mar, Valparaiso, Chile. [2]Queens University, Kingston, Ontario, Canada

Introduction

Osteoporosis increases fracture risk and highlights the need for improved scaffolds in bone tissue engineering. Current designs face limitations in geometry and material selection [1]. SLA printing offers precision and low-cost fabrication [2], but most resins are cytotoxic [3]. This study evaluated a resin in terms of mechanical performance and biological compatibility.

Methods

Specimens were printed using FormLabs 4B and Fast Model V1. Mechanical properties were assessed through compression testing of 10×10×10mm cubes for anisotropy (n=5) and porous scaffolds of 45%, 55%, and 65% (n=5). Biological assays used well-shaped specimens (5 mm diameter, 1.6 mm height, n=4). Human gingival stem cells were cultured in DMEM with SBF at 37 °C and 5% CO_2. Biocompatibility was evaluated through cell adhesion (fluorescence imaging) and viability using MTS assays on Days 1, 3, and 7.



Results

Compression testing revealed transversely isotropic behavior, with elastic modulus of 676±30.0MPa, 719±18.9MPa, and 605±26.8MPa for X, Y, and Z axes, with statistical significance in Z ($p<0.00001$). Porosity was 26%, 45% and 58% for the 45%, 55% and 65% groups respectively and apparent elastic modulus decreased with increasing porosity: 435±14.0MPa (45%), 199±12.5MPa (55%), and 118±17.3MPa (65%). Fluorescence imaging confirmed adhesion and proliferation, with nuclei increasing from ~1200 at Day 1 to 1700–2000 at Day 3. MTS activity rose from 0.26±0.13 at Day 1 to 0.52±0.174 at Day 7, supporting short-term adhesion and biocompatibility.

Discussion

Mechanical results confirmed anisotropy and an inverse relation between porosity and elastic modulus. The higher modulus at 45% porosity is explained by trapped resin, highlighting limitations of post-processing methods. Biological assays showed that MSC adhered and proliferated, suggesting non cytotoxicity. These results position the resin as an accessible model for in *vitro* evaluation. Limitations include short culture duration, single cell type, and assays restricted to wells rather than scaffolds. Future work will extend culture time, dead-live cytotoxicity and scaffolds tests, considering studies on effects of trapped uncured resin.

Mechanical and biological evaluation of functionally graded TPMS porous structures fabricated via SLA 3D printing

Mr. Vincenzo Marchese[1,2], Dr. Carola Millan[1], Dr. Juan Francisco Vivanco[1], Dr. Heidi Lynn Ploeg[2]

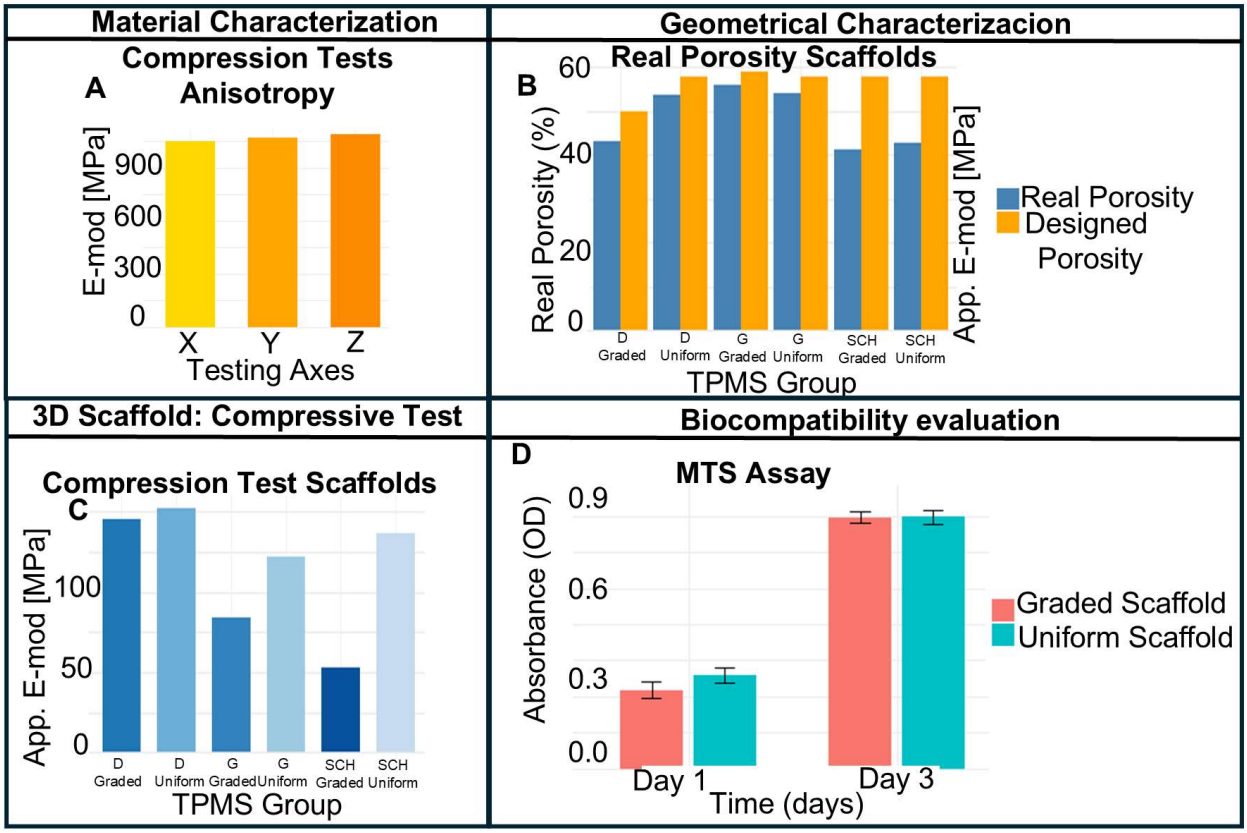
[1]Universidad Adolfo Ibañez, Viña del Mar, Valparaiso, Chile. [2]Queens University, Kingston, Ontario, Canada

Introduction

Osteoporosis increases fracture risk and underscores the need for improved scaffolds in bone tissue engineering [1]. Current scaffold designs face limitations such as poor cell distribution, low growth efficiency, and inefficient cell loading [2]. Triply Periodic Minimal Surface (TPMS) structures show promise with interconnected geometry [3]. Gradients enhance scaffold performance with porosity distribution [2]. This study evaluated the impact of a structural gradient in TPMS scaffolds mechanical and biological response.

Methods

Uniform and graded Gyroid, Diamond, and Schwarz-P scaffolds were fabricated with Biomed White Resin FormLabs. For compression tests, 10×10×10mm cubes (n=5) were used to analyze anisotropy, and porous TPMS scaffolds with 50–60% porosity (n=5). For biological assays, Gyroid scaffolds were tested. Human gingival stem cells were cultured in DMEM with SBF at 37 °C and 5% CO_2. Proliferation was assessed via MTS assays (Days 1, 3), and adhesion by fluorescent microscopy with phalloidin.



Results

Compression testing revealed isotropic mechanical behavior, with elastic modulus values of 1053±45.23, 1073±28.53, and 1089±40.61 MPa for the X, Y, and Z axes. Porosity was 54%/56% for Gyroid, 54%/43% for Diamond, and 43%/41% for Schwarz-P, uniform and graded respectively. Uniform scaffolds showed apparent elastic modulus of 122±22.4, 152±9.3, and 136±20.4 MPa for Gyroid, Diamond, and Schwarz-P, while gradients exhibited lower values: 84.5±7.18, 146±13.9, and 52.5±8.79 MPa. Biological assays improved initial cell distribution in gradients, but MTS assays showed no statistically significant differences, with OD rising from 0.39±0.029 and 0.32±0.032 on day 1 to 0.79±0.025 for both at day 3, indicating similar adhesion and early proliferation.

Discussion

Mechanical results show gradients reduce apparent elastic modulus. Schwarz-P proved most sensitive to structural changes, followed by Gyroid, while Diamond showed no variation compared to its uniform form, suggesting it is the best for modifications. Biologically, gradients may facilitate efficient initial cell loading, but quantitative assays showed no advantage in adhesion or proliferation during short-term. Future work will consider longer assays and cytotoxicity tests.

Regional Control for Monolithic Enthesis Engineering

MS Wen-Xuan Chen, Dr. Pen-hsiu Grace Chao

National Taiwan University, Taipei, Taiwan, Taiwan

Introduction

With distinctive zones of cell and matrix composition, the enthesis plays a crucial role in transferring mechanical loads from soft ligament/tendon to stiff bones while preventing stress concentration [1]. Restoration the structure and function of this interface is a major challenge. We previous optimized ligament tissue engineering with a growth factor supplementation regime using ligament fibroblasts (LF) [2]. In this study, we developed a monolithic construct composed of bone and ligament zones with mesenchymal stem cell (MSC) and LF. Using a physical barrier to confine cell seeding to defined scaffold regions, we created a co-culture system with spatially controlled bone and ligament development.

Methods

Human MSCs and porcine LFs were seeded on either sides of electrospun fibrous scaffolds with a temporary PDMS barrier to minimize mixing. In some studies, MSCs expressing Lifeact-mScarlet3 were used to track the initial seeding location and the subsequent cell migration. To optimize the chemical signals, osteogenic medium (OSM, supplemented with dexamethasone and β-glycerol phosphate) and ligamentogenic medium (LM, supplemented with bFGF and TGFβ), or mixed medium (MM) were investigated.

Results

The PDMS barrier successfully minimized cell mixing during seeding, as evidenced by the red MSCs only on one side of the scaffold (Figure A). After 2 weeks of culture, the MSCs were still restricted to one side, indicating successful regional control. This finding was supported by the restricted alizarin red positive region with osteogenic induction (Figure B). Looking into the effects of mixed chemical signal, we cultured MSCs and LF in MM and found significant, albeit slightly reduced, mineralization in the MSCs and no calcium deposition from the LF (Figure C).

Discussion

Spatial control of tissue organization has been a major challenge in organ engineering. While other fabrication approaches can generate complex structures, long term chemical signaling and specification remains an issue. We demonstrate regional control of undifferentiated and differentiated cell types allow long-term phenotypic specification

even in the mixed induction medium. Current studies are investigating ligament tissue development in the mixed medium and potential interactions between two cell types.

Images (Optional)

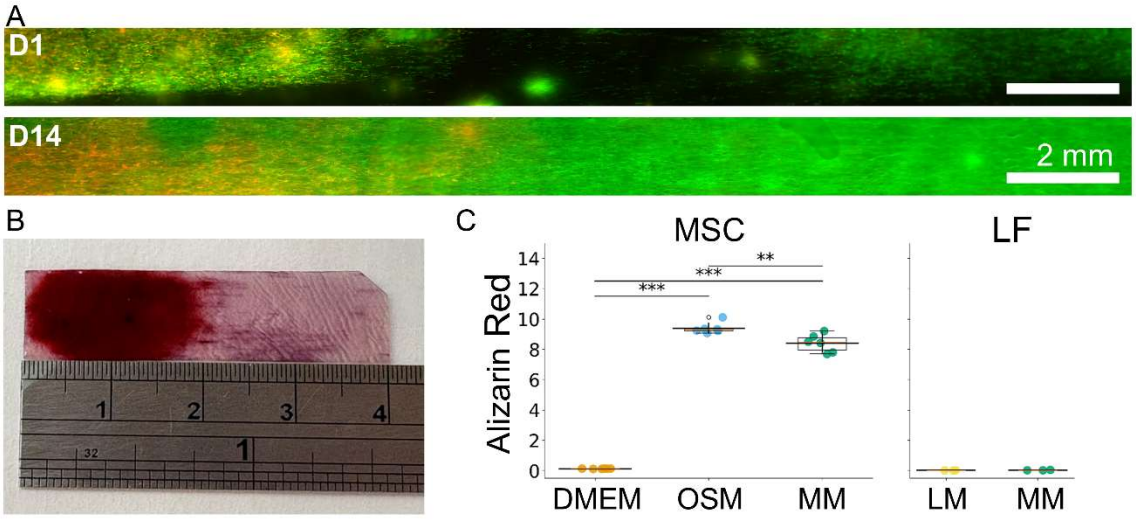

Figure (A) Regional control of cell distribution after cell seeding (D1) and after 2 weeks (D14). MSCs expressing mScarlet3 (red) were found only on the left side of the scaffold, while green indicate f-actin for all cells. **(B)** Alizarin red staining of MSC (left) and ligament fibroblast (right) coculture in OSM. **(C)** Effects of mixed osteogenic and ligamentogenic factors on MSC and LF calcium deposition.

Small Molecule Therapies to Rescue Gap Junctional Intercellular Communication to Overcome Stiffness-Induced Chemoresistance

Ms Charlotte Turner, Dr Raja Vadivelu, Dr Eoin McEvoy

University of Galway, Galway, Galway, Ireland

Introduction

Breast cancer (BC) is the leading cause of cancer death in women globally. Matrix stiffening, reduced cell proliferation, and a loss of functional gap junction (GJ) expression are associated with BC progression. In this study, we investigate how these factors could influence sensitivity to chemotherapy in BC and identify potential pathways to mitigate such chemoresistance.

Methods

T47D cells were cultured in supplemented RPMI and passaged once reaching 80% confluency. Low passage (LP) and high passage (HP) cells fall between P1-10 and P11-20 respectively. For spheroid culture, cells were seeded into gelatin-mTG hydrogels. Samples received 24-hour treatment with all-trans retinoic acid (ATRA), dipyridamole (DIP), or resveratrol (RES) in DMSO prior to doxorubicin (DOX). The parachute assay tracked calcein diffusion between connected cells to characterise GJ functionality. For immunofluorescence (IF), samples were stained with Cx43, E-cadherin, or N-cadherin primary antibodies and counterstained with DAPI and Phalloidin-FITC.

Results

Spheroids exhibited stiffness-dependent growth, with those encapsulated in stiff hydrogels (sfH) significantly smaller and more compact than spheroids in soft hydrogels (stH) (**Figure1.A**). Interestingly, stH spheroids reduced in size following treatment with DOX, while no significant differences were observed for sfH-spheroids (**Figure1.B**).

Cx43 expression and function which was significantly higher in LP compared to HP T47D cells. For all passages, Cx43 localization was highly concentrated to the cytoplasm and nuclear envelope. Following treatment with ATRA, DIP, and RES, Cx43 was significantly increased in later passages. ATRA (20μM) and DIP (60μM) pushed Cx43 expression to the membrane, specifically at the cell-cell interfaces (**Figure1.C-E**).

DOX treated sfH-spheroids decreased in size when treated in combination with ATRA, DIP, or RES compared to without (**Figure1.F**), potentially overcoming stiffness-induced chemoresistance.

Discussion

T47D cells cultured under higher mechanical stress developed into smaller, more compact spheroids, regulated via mechanosensitive pathways. Increased cell density and lower proliferation interfere with chemotherapy diffusion and sensitivity. As T47D cells mature through passages, they appear to lose GJ expression which may compound chemoresistance, but GJ assembly was overcome through treatment with small molecule drugs, particularly ATRA and DIP. Overall, we identified that combinational therapy to enhance gap junctional intercellular communication promoted chemotherapy diffusion and sensitivity in BC spheroids.

Use of Kinematic Variables for Missing Value Imputation of Athlete Rating of Perceived Exertion With Machine Learning Strategies

Dr Amarah Epp-Stobbe[1], Dr Ming-Chang Tsai[1], Dr Marc Klimstra[2,1]

[1]Canadian Sport Institute Pacific, Victoria, BC, Canada. [2]University of Victoria, Victoria, BC, Canada

Introduction

Managing athlete workloads, through rating of perceived exertion(RPE) or mechanical work calculated by GNSS, ensures safe, successful sport participation[1]. While GNSS is the ideal technology, its cost and limitations make RPE popular[1,2]. However, RPE utility relies on consistent reporting. Where missing, imputation strategies may mitigate RPE loss[1,3]. Daily-team-mean-substitution(DTMS), an easy-to-use strategy, is outperformed by methods like random forest(RF)[3-5]. Bayesian approaches are also promising, with unique advantages due to the inclusion of posterior distributions and prior beliefs[4]. However, Bayesian approaches including multivariate imputation by chained equations(MICE), have been limited in application on team sport workloads[2,4]. This investigation assesses RPE imputation using mechanical work, augmented by DTMS, RF, and MICE.

Methods

1002 datasets from 103 rugby sevens matches were analyzed. Athlete-worn GNSS collected playing-time, distance, and speed, with acceleration derived, from 22 female athletes. Mass, match-number, and opponent were collected pre-match; RPE post-match. Work was the cumulative sum of instantaneous absolute power multiplied by 0.1s-intervals. Data were imputed 100-times, predicting RPE using work, match-number, opponent, and player. RMSE, R^2, and accuracy were calculated. All model accuracies were tested across 5–30%missingness via ANOVA by model, missingness, and interaction, with a planned comparison evaluating differences. $RPE_{predicted}$ and RPE_{true} were compared using paired-sample equivalence tests.

Results

ANOVA found significant differences by model ($F(2,1782)=1457, p<0.05$), by missingness ($F(5,1782)=14205, p<0.05$), and interaction ($F(10,1782)=2323, p<0.05$). Planned comparison found all accuracies differed significantly($p<0.05$). Paired-samples equivalence tests found DTMS- and RF-$RPE_{predicted}$ equivalent to RPE_{true}($p<0.05$) but MICE-$RPE_{predicted}$ differed($p>0.05$).

Discussion

This investigation found MICE more accurate than RF and DTMS. RF demonstrated better R^2 and RMSE than MICE and DTMS[2-5]. Poor R^2 and accuracy affirm challenges in imputing RPE[2]. Equivalence testing suggested similarities between RPE_{true} and RF- and DTMS-RPEpredicted but not MICE-$RPE_{predicted}$, due to limited variability in predictors causing oversmoothing. The ANOVA and planned comparison indicated differences by model, inferring model selection remains an important consideration for practitioners.

Multimodal Prediction of Treatment Success in Degenerative Spondylolisthesis: Integrating Deep Learning–Derived Imaging Features and Clinical Data

Dr Andrea Cina[1,2], Dr Fabio Galbusera[1]

[1]Schulthess Klinik, Zurich, Zurich, Switzerland. [2]ETH Zurich, Zurich, Zurich, Switzerland

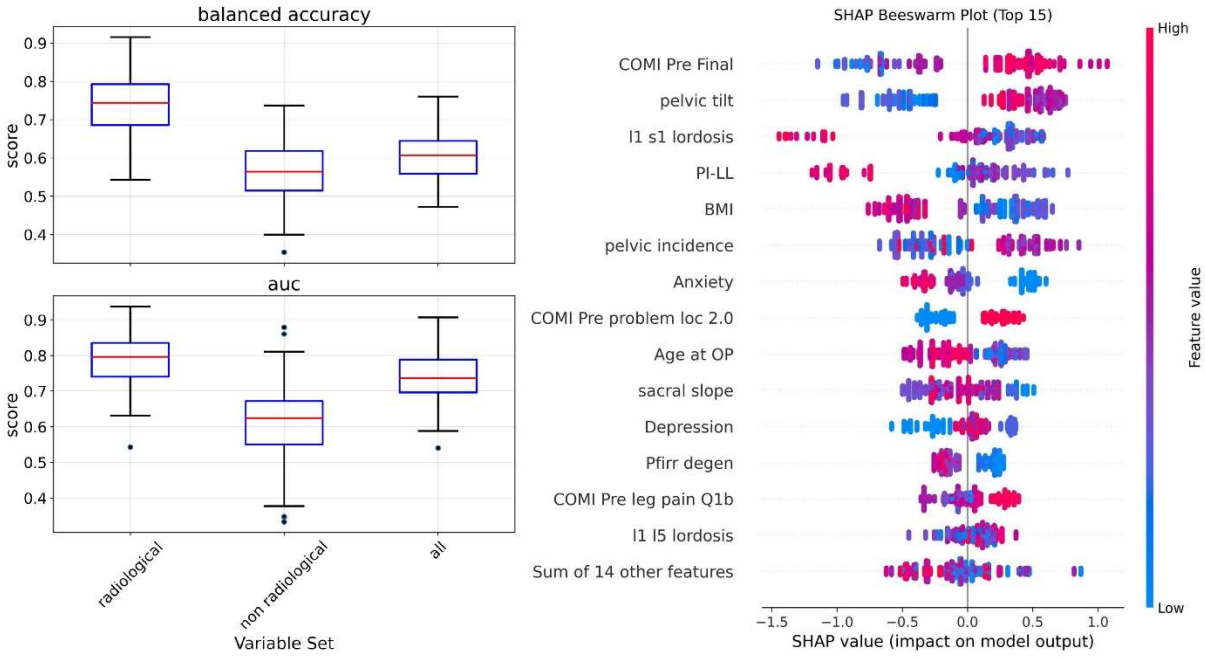
Introduction

Accurately predicting postoperative improvement in patients undergoing surgery for degenerative spondylolisthesis remains challenging. In low back pain research, achieving a ≥2.2-point reduction in the Core Outcome Measures Index (COMI)—the minimal clinically important change (MCIC)—defines treatment success. Existing predictive models rely mainly on demographic and questionnaire data [1]. We hypothesised that quantitative imaging biomarkers automatically extracted from preoperative radiographs and MRI could enhance the prediction of MCIC achievement at 1 year.

Methods

We retrospectively analysed 333 surgically treated patients. Baseline variables included age, sex, BMI, comorbidities, preoperative COMI, and imaging features. Two previously developed deep learning models were used to extract radiological findings from MRI and spinopelvic alignment parameters from standing radiographs. The outcome was the achievement of MCIC at 1-year follow-up. Three variable sets were compared: (1) demographics + radiological features; (2) demographics + questionnaire data; (3) all variables combined. An LGBM classifier was trained using 10-fold cross-validation, and performance was evaluated on an independent 20% test set. Balanced accuracy and AUC were estimated using 100 bootstrap resamplings. SHAP values were used for model interpretation.

Results



Models using radiological features achieved the highest performance, with a mean balanced accuracy of 0.738 ± 0.076 and an AUC of 0.787 ± 0.069. Questionnaire-based models performed substantially worse (balanced accuracy 0.564 ± 0.077, AUC 0.608 ± 0.110). Combining all variables improved performance relative to the questionnaire-only model but did not exceed the radiological model (balanced accuracy 0.603 ± 0.059, AUC 0.739 ± 0.074). SHAP analysis identified preoperative COMI, pelvic tilt, L1–S1 lordosis, PI–

LL mismatch, BMI, pelvic incidence, and psychological factors (anxiety and depression) as the strongest predictors of MCIC (Figure 1).

Discussion

Spinopelvic alignment parameters were more informative for predicting postoperative improvement than demographic or questionnaire-based variables. The absence of performance gains when combining all features likely reflects noise and redundancy introduced by weakly predictive clinical variables, which can lead to overfitting. The strong performance and balanced discrimination of the radiological model highlight the relevance of automated imaging-derived features for characterising surgical outcomes. These findings support incorporating multimodal imaging biomarkers into preoperative decision-support tools for degenerative spondylolisthesis. Future studies should explore larger cohorts.

Offset vision in virtual reality alters limb symmetry during a bilateral task

Mr. Taylor Wilson, Dr. Andy Karduna

University of Oregon, Eugene, Oregon, United States

Introduction

Virtual reality (VR) is increasingly used in research due to its ability to manipulate environments and sensory feedback. Our lab previously demonstrated that during a joint position sense task, participants primarily relied on incorrect visual information, undershooting a 90° shoulder-flexion target when given +8° offset vision (OV). It remains unclear whether individuals similarly rely on OV during a bilateral, moving limb-symmetry task. The present study examined the effects of right-hand OV while the left hand received accurate vision (AV) during a bilateral out-and-back reaching task. We hypothesized that right-hand OV would increase limb asymmetry (LA) compared with AV of the right hand.

Methods

Twenty healthy adults (13F/7M; 25.3 ± 6.6 yrs) were recruited. Exclusion criteria included recent upper-body pain or injury. Participants wore an HTC VIVE VR headset and arm-mounted trackers. A minimalist virtual environment displayed each hand as a black glove.

Participants performed ten repetitions of a bilateral reaching task, maintaining symmetry through the middle 80% of the movement (from ~90° elbow flexion to full extension). Four blocks were completed: AV for both hands, and three OV blocks where the right hand was visually shifted forward by 5, 7.5, or 10 cm with AV in the left-hand.

LA was calculated at the end point (80% elbow extension) of the 10th trial. A 1-RM ANOVA compared LA in the AV block against the three OV blocks, followed by Holm-corrected post-hoc tests.

Results

Block significantly affected LA ($p < .001$, $\eta^2 = 0.28$). Post-hoc tests indicated increases in LA as OV increased ($p < .01$; Cohen's $d = 0.69–1.61$). Means and standard deviations in LA per block are presented in Table 1. Interestingly, a 10-cm offset produced only a 3.7-cm increase in LA compared to the AV block.

Discussion

As hypothesized, OV of the right-hand increased LA, indicating a strong visual influence during a bilateral task. However, LA did not translate linearly to OV changes, suggesting proprioception from both limbs mitigates visual distortion. These findings contribute to a larger project examining how sensory availability of the opposite limb modulates reliance on OV, with future applications toward understanding age-related sensory integration in VR.

[3]Departamento Ciencias de la Salud, Pontificia Universidad Católica de Chile, Santiago, Santiago, Chile. [4]Department of Physiology and Pharmacology, The University of Toledo, Toledo, Ohio, United States

Introduction

A high-fat and high-sucrose diet (HFS) is one of the leading causes of obesity. Obesity often leads to reduced mobility, sedentary lifestyle, and musculoskeletal degeneration, such as fibrosis which has been linked to muscle inflammation [1]. Furthermore, in previous studies, we showed that muscles with primarily slow twitch fibers with a high aerobic capacity, were protected from degeneration in the presence of an HFS diet [2]. Based on these findings, we hypothesized that high aerobic capacity may offer protection to forelimb muscles composed of mixed fiber types in rats subjected to an HFS diet. We tested this hypothesis by quantifying muscle inflammation and fibrosis in rats with high aerobic capacity (HCR) and low aerobic capacity (LCR) following exposure to an HFS diet.

Methods

Results

In the Biceps Brachii, fibrosis significantly increased in both the LCR, and HCR rats fed the HFS diet, and the LCR rats had greater fibrosis than HCR rats [Figure 1]. The differences in fibrosis in the HCR and LCR rats, and the HFS and Chow diet were not associated with corresponding differences in the in macrophage content

Discussion

Greater fibrosis in LCR compared with HCR rats suggests a potential protective effect of high Greater fibrosis in the Biceps Brachii in LCR compared with HCR rats suggests a potential protective effect of high aerobic capacity against obesity-induced muscular maladaptation. These differences in fibrosis across groups was not associated with corresponding differences in macrophage content, thus excluding local inflammation at the end of the diet intervention as a cause for the differential fibrosis results. In future work, we will analyze mitochondrial function to determine how mitochondrial dysfunction and altered biogenesis may contribute to the differences in fibrosis across the experimental groups observed here.

Images (Optional)

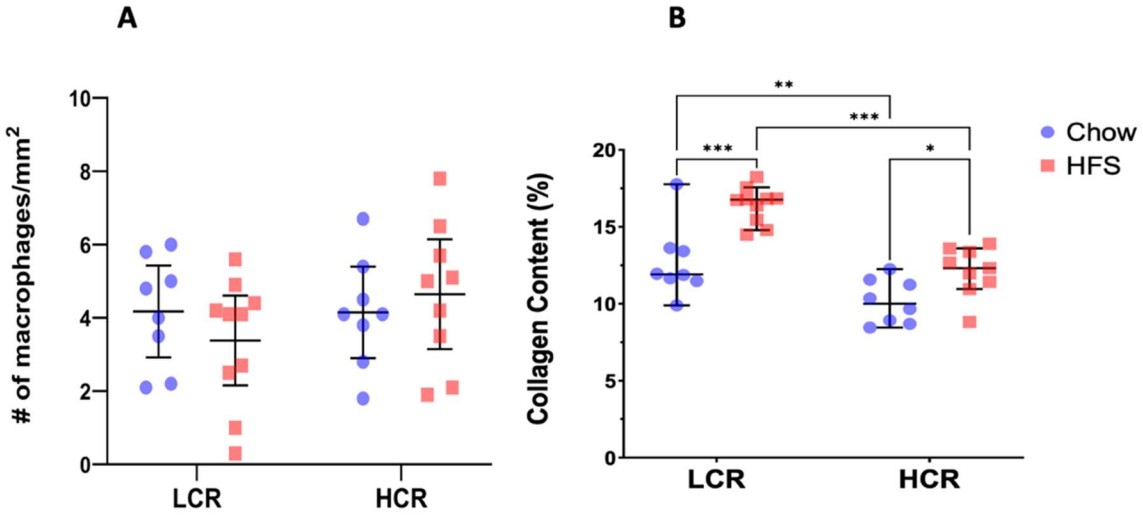

Figure 1: Macrophage (A) and Collagen (B) content in Biceps Brachii cross sections across four groups (HCR+chow; HCR+HFS; LCR+chow; LCR+HFS) (*p = 0.041, **p =0.009, ***p <0.001).

Toward Human-Like Motion in Musculoskeletal Simulation: Generative Adversarial Imitation from Observation (GAIfO)

Mr. Chihyeong Lee[1], Dr. Beom Chan Lee[2], Dr. Jooeun Ahn[1]

[1]Seoul National University, Seoul, Seoul, Korea, Republic of. [2]University of Houston, Houston, Texas, United States

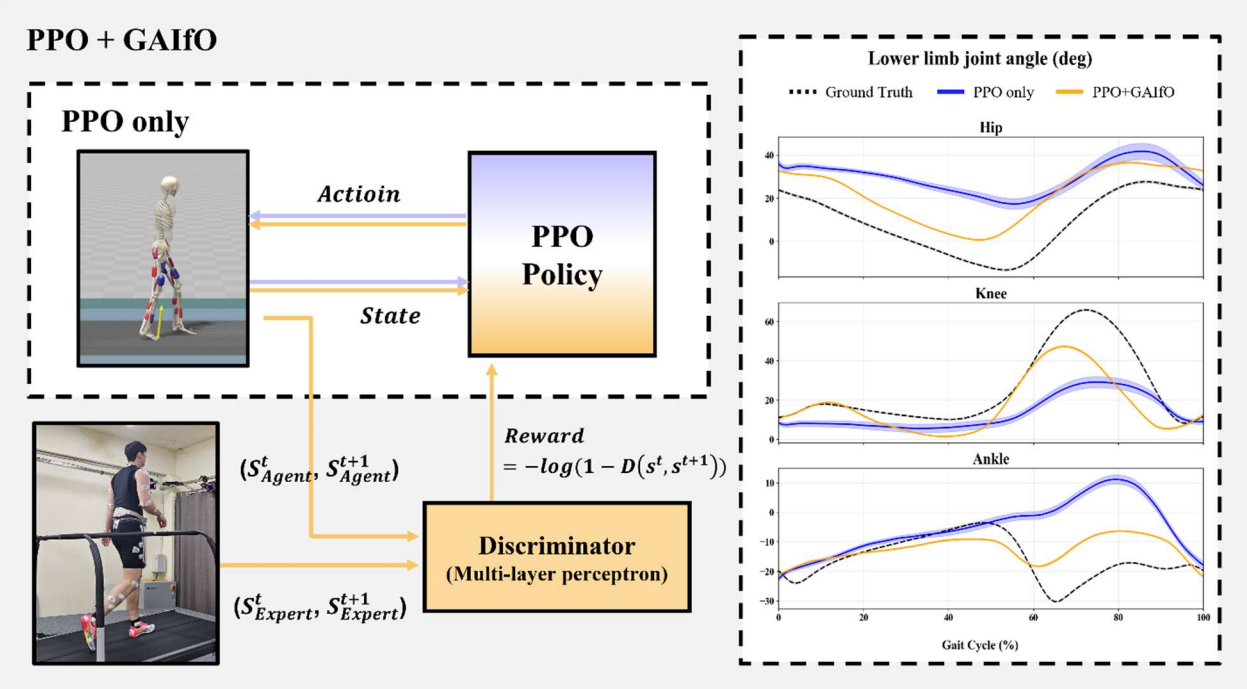
Introduction

Reinforcement learning (RL) enables musculoskeletal simulation without extensive experimentation. However, it often produces unnatural movements that exploit simulation physics rather than replicating human motion. Imitation learning can improve realism, yet these methods require action spaces such as joint torques, which cannot be collected in typical biomechanical studies [1]. GAIfO addresses this limitation by learning solely from observable state transitions, allowing the use of experimentally measurable data [2]. Therefore, this study explored whether incorporating GAIfO into an RL framework could guide a musculoskeletal agent toward more human-like gait.

Methods

Twenty-four healthy adults walked on a treadmill at their preferred speed (1.0 ± 0.1m/s). Hip, knee, and ankle angular velocities were extracted to train a GAIfO discriminator. A musculoskeletal model in SCONE with the Hyfydy physics engine walked on a treadmill moving at 1.0 m/s. One agent was trained using Proximal Policy Optimization (PPO) alone, and another was trained using PPO combined with GAIfO. Their gait patterns were compared against experimental data using joint kinematics and symmetry differences.

Results



Across fifty 20-second rollouts, PPO+GAIfO achieved higher mean reward, longer episode duration, and a substantially lower fall rate (90% vs 16%) compared to PPO only. PPO+GAIfO also exhibited lower root-mean-square error with experimental joint angles (Hip: 22.2° vs 13.5°, Knee: 17.1° vs 12.7°, Ankle: 16.1° vs 7.4°) and produced more symmetric lower-limb movement (Hip: 26% vs 83%, Knee: 9% vs 99%, Ankle: 56% vs 72%).

Range-of-motion analysis showed significant deviations across all joints for PPO, whereas PPO+GAIfO matched knee and ankle ROM without significant differences.

Discussion

Overall, the results highlight that GAIfO effectively leverages experiment-derived information to improve motion realism, guiding simulation agents toward more natural and symmetric movement patterns. GAIfO does not simply mimic recorded movements but instead shapes the agent's behavior toward human-like strategies while maintaining task objectives. These findings indicate that the PPO+GAIfO framework captures coordination characteristics that PPO alone fails to reproduce. The framework therefore provides evidence that it can be effectively applied to musculoskeletal models to generate realistic movement using only experiment-derived data.

Machine Learning–based Assessment of Triceps Muscle Fatigue Using Mechanomyographic Signals

Ms Raneda Kerfi[1], Dr Coralie Privet-Thieulin[1,2], Dr Hassan Soubra[1]

[1]LyRIDS, ECE research center, Lyon, Rhône-Alpes, France. [2]Laboratory of Tribology and Dynamic Systems, Lyon, Rhône-Alpes, France

Dr Coralie Privet-Thieulin

Introduction

Muscle fatigue assessment is crucial in sports, rehabilitation, and injury prevention. Conventional methods are accurate but often costly, invasive, and impractical for daily use. Inertial Measurement Units (IMUs), which record mechanomyographic (MMG) signals via acceleration and angular velocity, provide a portable and low-cost alternative. Yet, triceps brachii fatigue remains largely unexplored. This study proposes a quantitative approach to detect triceps fatigue using inertial signals during controlled upper-limb exercises.

Methods

Fifty participants were recruited in two groups:
(1) Thirty-four subjects performed two 1-minute exercise phases separated by 30 seconds of rest.
(2) Sixteen subjects repeated the exercise until muscular failure.
A triaxial IMU (MPU6050), placed over the triceps, recorded accelerometer (AX, AY, AZ) and gyroscope signals. Data processing included timestamp harmonization, segmentation into labeled phases, and extraction of amplitude, movement frequency, and signal averages, along with computation of the acceleration norm.
Two classification models were developed—Random Forest and Long Short-Term Memory (LSTM) neural networks—to distinguish Exercise vs. Rest and to attempt differentiation between Phase 1 and Phase 2 (pre- vs. post-fatigue).

Results

Descriptive analyses showed a consistent decrease in movement frequency and number of repetitions from Phase 1 to Phase 2, particularly on the vertical axis (AZ), along with a

general reduction in amplitude across subjects. A decrease in mean acceleration values was also observed during late-fatigue stages, most notably on AZ.

The Random Forest model achieved 81% accuracy (recall 92% for Exercise) for Exercise vs. Rest classification. The LSTM achieved 84% validation accuracy, demonstrating improved sensitivity to temporal variations. Both models showed limited ability to distinguish Phase 1 from Phase 2 (≈ 50% accuracy), reflecting the subtlety of early fatigue patterns.

Discussion

IMU-derived MMG signals show strong potential for non-invasive fatigue monitoring. While the identification of active vs. resting periods is robust, detecting early fatigue requires additional features, improved stabilization methods, or enhanced temporal modeling. Future work should refine acquisition protocols and explore more advanced neural architectures.

Prediction of Human Cortical Bone Work-of-Fracture Based on Bone Collagen Denaturation and Machine Learning

Mr. Corin Seelemann, Dr. Daniel Dapaah, Prof Charbel Azzi, Prof Thomas Willett

University of Waterloo, Waterloo, Ontario, Canada

Introduction

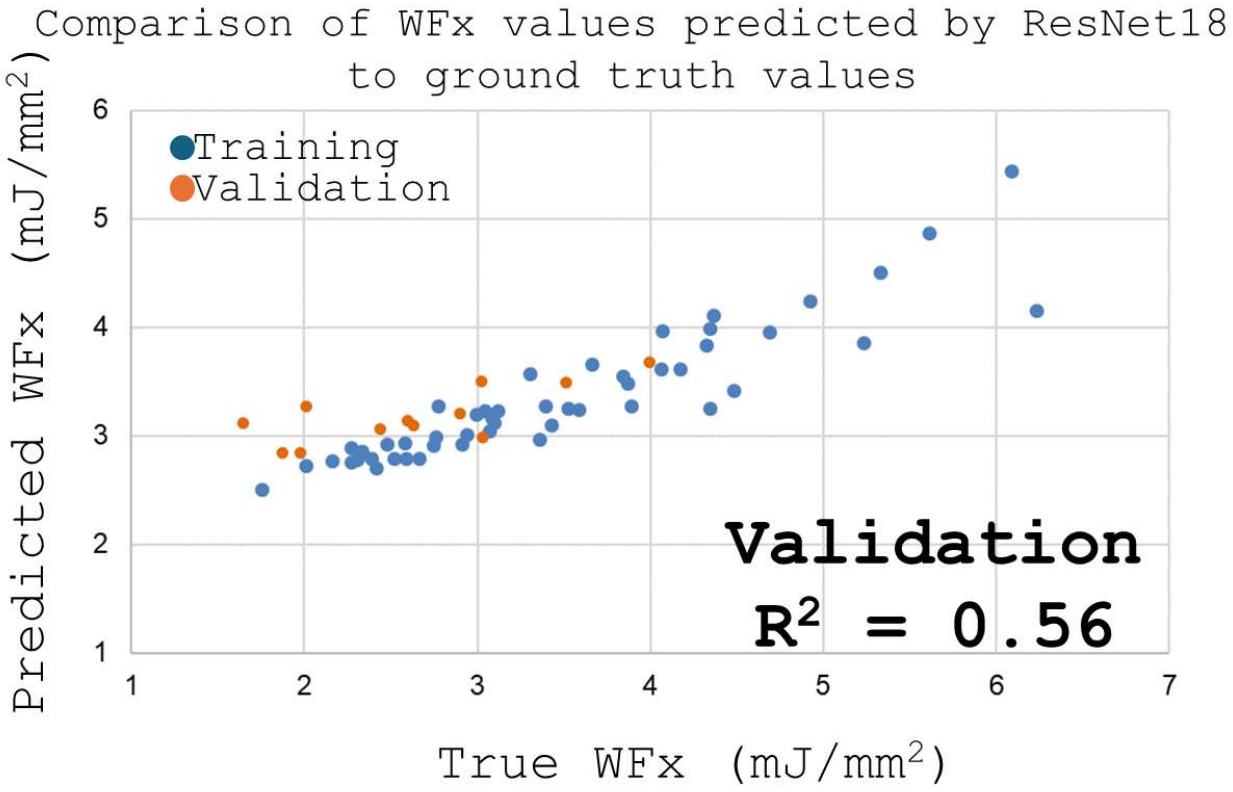
The determinants of bone fracture resistance and the mechanisms of its loss are not fully understood. Factors such as oxidative damage or porosity partially degrade fracture resistance. A challenge is bone's hierarchical structure which provides multiscale toughening mechanisms, notably the denaturation of bone collagen as an energy sink during fracture. Our prior work correlating fluorescently labelled collagen hybridizing peptides (F-CHP) staining intensity to work-of-fracture (WFx) showed weak correlation (R^2=0.13). Recent research has fractographically predicted mechanical behavior of engineering materials using machine learning (ML) [1,2]. Here we apply these methods to determine WFx from F-CHP stained bone fracture surfaces. To our knowledge, quantitative fractography has not been used to predict WFx of human cortical bone.

Methods

Notched cortical bone beams were machined from 60 femora from a diverse set of human donors. These were fractured at quasi-static rates and WFx was calculated [3]. Fracture surfaces were imaged as per our prior work [4].

We developed a novel, fracture-surface–specific preprocessing and learning pipeline for confocal F-CHP images, combining per patch intensity normalization to remove background bias, patch-based texture sampling, and a ResNet18 model trained with donor-separated validation to quantitatively predict WFx from a single post-fracture image.

Results



The best training conditions resulted in an R^2 value of 0.56 for the validation data set. Comparatively linear regression using F-CHP staining only achieved an R^2 of 0.13.

Discussion

The complexity of bone tissue makes understanding the mechanisms of bone tissue quality and its loss difficult. Here, the morphology and collagen denaturation signal of a fracture surface predicted the work-of-fracture required for fracture. The R^2 of 0.56 shows greater correlation with fracture resistance than a single Raman biomarker (R^2 of 0.47)[5].

This suggests that microstructure and collagen denaturation patterns encoded on the fracture surface capture micro-scale toughening mechanisms that determine WFx. This motivates the development of new models to elucidate the determinants of bone tissue quality.

Uncertainty-Aware Cardiovascular Flow Reconstruction Using a Latent Diffusion Model

Dr. Dana Lynn Lavacot, Dr. Fanwei Kong

Washington University in St. Louis, St. Louis, MO, United States

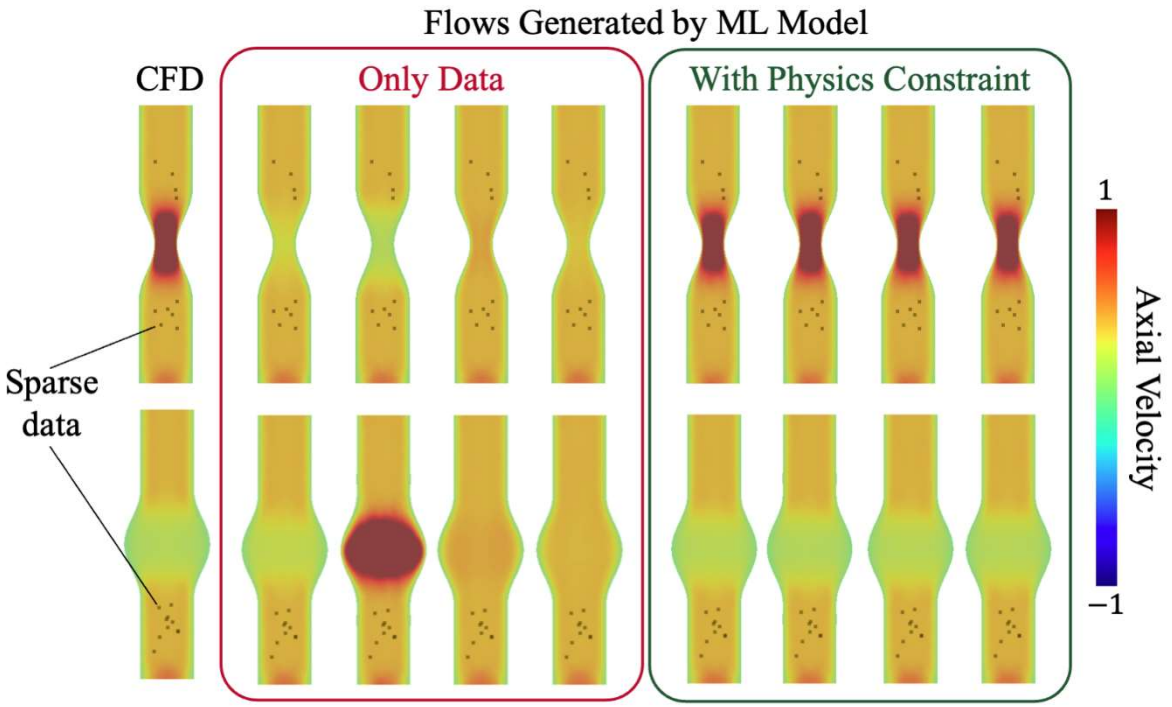
Introduction

Echocardiography (echo) is a medical imaging technique that is widely used in clinical settings due to its accessibility, non-invasiveness, and ability to provide real-time visualization of cardiovascular structure and flow at the bedside. However, echo data is often noisy and limited, making it challenging to interpret and use for diagnosis. Thus, inherent to echo measurements are uncertainties in flow quantities and geometry characterization. Advances in machine learning, such as diffusion models, show potential in enhancing echo data within uncertainty-aware frameworks.

Methods

We utilize a framework based on the latent diffusion model of [1], which leverages a conditional neural field autodecoder so that the model learns and generates in the latent space. We guide generation to reconstruct flow fields that are consistent with echo measurements and physics. As a proof of concept, we demonstrate the framework for the simplified problem of idealized blood vessels with varying degrees of stenosis and aneurysm.

Results



We find that the diffusion model can conditionally generate physically-reasonable flow fields given limited measurements from the original simulations. We find that when the measurements are plausibly from multiple blood vessel shapes, the model generates a wide distribution of flows, most of which are not physically consistent with the geometry. By enforcing physics constraints, we can collapse the generated distribution to the original flow.

Discussion

From this proof of concept, we find that diffusion models are a promising framework for cardiovascular flow reconstruction from clinical data. When we apply this framework to the full cardiac problem, we expect to be able to quantify uncertainties through analysis of the

generated distributions. In our ongoing work, we are investigating the performance of the diffusion model for more complex and more realistic geometries. Ultimately, we will use a generative model [2] to create various realistic cardiac geometries for training a diffusion model that can be applied in clinical settings.

Images (Optional)

Mapping the Age-Related Constriction of Gait Strategies via Semi-Supervised Deep Learning

Ms Diana C. Martinez[1], PhD Diego F. Villegas[1], PhD Aaron D. Likens[2]

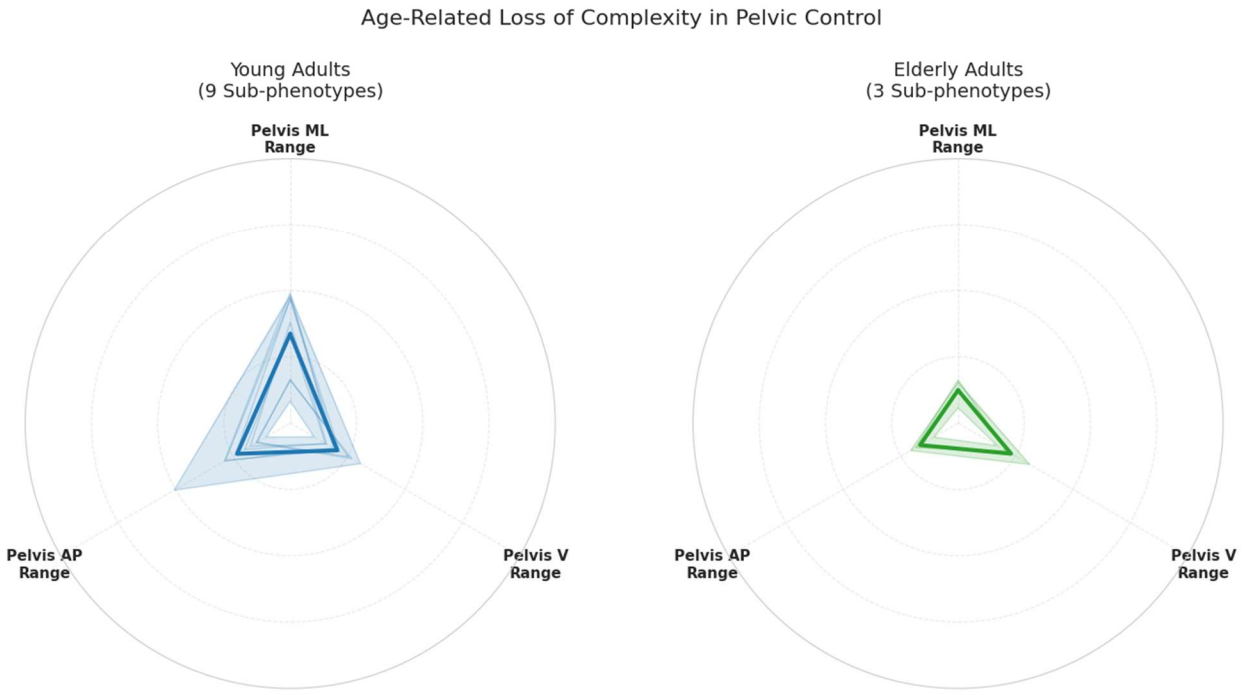
[1]1School of Mechanical Engineering, Universidad Industrial de Santander, Bucaramanga, Santander, Colombia. [2]Division of Biomechanics and Research Development, Department of Biomechanics and Center for Research in Human Movement Variability, University of Nebraska at Omaha, Omaha, Nebraska, United States

Introduction

Recent advances in gait rehabilitation and prosthetic control suggest that restoring functional mobility depends not only on targeting discrete kinematic metrics, but also on the inherent robustness of human locomotion [1]. According to the "loss of physiological complexity" hypothesis [2], aging reduces the adaptive capacity of physiological systems. Based on this finding, we hypothesize that mapping the intrinsic organization of gait strategies using semi-supervised deep learning could reveal distinct gait subphenotypes and quantify the motor diversity that underpins healthy gait adaptability.

Methods

~460,000 gait cycles from the open-access NONAN GaitPrint database [3-5], containing full-body IMU kinematics (321 variables) from young (19–35 years), middle-aged (36–55 years), and older adults (≥56 years) were analyzed. A semi-supervised bidirectional long short-term memory (BiLSTM) autoencoder (AE) was trained to learn compact gait representations. Subsequently, Hierarchical Density-Based Spatial Clustering of Applications with Noise (HDBSCAN) was applied to identify distinct data-driven subclusters, with separability assessed via cluster purity. Explainability followed a two-stage approach: (1) a gradient-boosting proxy classifier identified the primary kinematic discriminators (validated by SHAP scores), and (2) macro-profiles were computed to characterize the coordination strategies underlying each subphenotype by quantifying relative changes in dynamic range.



Results

The explainability framework identified tri-axial pelvis accelerations as the key discriminators with high fidelity (Proxy Accuracy: 81.7%; SHAP scores > 0.38). HDBSCAN identified 20 subclusters with 100% age-group purity. An inverse relationship between age and phenotype diversity was observed: young adults expressed nine distinct subphenotypes, revealing a rich repertoire of pelvic and hip strategies. Middle-aged adults formed eight transitional subclusters, while older adults consolidated into only three stereotyped subclusters [Figure 1]. Quantitative profiling of these older adult phenotypes revealed a systemic "stiffening" strategy: macro-profiles showed a 24.0% reduction in tri-axial pelvic acceleration amplitude compared to young adults.

Discussion

These findings reveal distinct gait substructures that closely aligned with physiological aging. The age-related reduction in subphenotypes validates the loss-of-complexity hypothesis, reflecting a shift toward fewer, more constrained coordination strategies for controlling the center of mass. Quantifying this constriction of the locomotor solution space provides a data-driven foundation for tools with the potential to assess gait adaptability through changes in the motor repertoire.

Deep Learning Enables Prediction of Bilateral Joint Kinetics of Walking in Young and Older Adults Before, During, and After Functional Electrical Stimulation of Plantar Flexors

Mr. Dylan M. Page MS[1], Ms. Ningzhen Zhao MS[1], Ms. Arianna S. Monteiro[1], Mr. Changseob Song MS[2], Dr. Inseung Kang PhD[2], Dr. Owen N. Beck PhD[1], Dr. Nicholas P. Fey PhD[1]

[1]The University of Texas at Austin, Austin, TX, United States. [2]Carnegie Mellon University, Pittsburgh, PA, United States

Introduction

Biological joint moment estimators have been used to inform assistive technologies [1]. However, data-driven technique performance can suffer outside of the training dataset, including untrained walking patterns from older adults using neuromodulation interventions. We developed temporal convolutional networks (TCNs) that predict walking lower-limb joint kinetics across age groups and functional electrical stimulation (FES) conditions.

Methods

10 young (21.6±2.2 yrs) and 8 older (77.8±5.7 yrs) adults performed treadmill walking trials before, during, and after FES applied bilaterally over soleus muscles during late-stance [2]. Moments and power of hip, knee, and ankle joints and inertial measurement unit (IMU) signals of the pelvis, thigh, shank, and foot were computed bilaterally. Two TCNs with temporal dilations used IMU signal inputs to predict sagittal plane joint kinetics. The networks were evaluated using leave-one-subject-out cross-validation. Additional within-participant networks were trained and tested. Linear mixed effects models were used to fit Root Mean Square Error (RMSE) and included age group, FES condition, and joint, $\alpha=0.05$.

Results

The cross-validated networks resulted in average RMSE of 0.231±0.130 Nm/kg and 0.363±0.189 W/kg. The cross-validated network predicted joint kinetics worse than within-participants networks (RMSE=0.061±0.054 Nm/kg, $p<0.001$; RMSE=0.139±0.154 W/kg, $p<0.001$). Moment RMSE increased during FES ($\beta=0.020$, $p=0.027$). Young adults had greater power RMSE ($\beta=0.123$, $p=0.032$), and hip power RMSE was lower than ankle ($\beta=-0.068$, $p=0.014$). All other covariates showed no difference.

Discussion

The networks demonstrated robustness across age groups for moments and FES conditions for power. Moment error was higher during FES as expected as FES alters joint work distribution. Power error was unexpectedly lower for older adults. Our user- and neuromodulation-agnostic networks, when tested on *older* adults, performed similarly (0.15 Nm/kg RMSE) as prior studies [1] that predict hip and knee moments during 22 ambulation tasks in control subjects, with considerably less training data. Our networks predictions of lower-limb joint kinetics across FES conditions offer an opportunity to use this approach to better identify neuromotor adaptation. Next, we will optimize hyperparameters and expand the dataset to improve prediction performance.

Images (Optional)

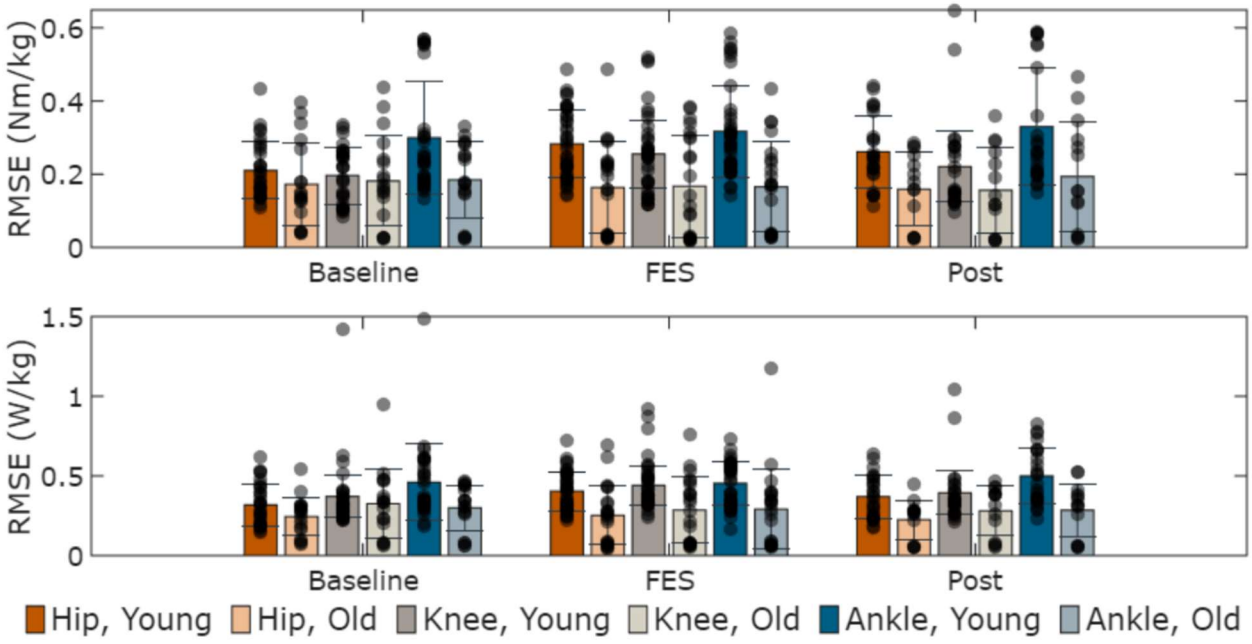

Figure 1. The networks show robust predictions across age groups in joint moments and FES condition in joint power. Panel A shows moment RMSE and panel B shows power RMSE. Bars indicate means, error bars represent standard deviations, and black points show individual values.

AutoSSM: Nonlinear Statistical Shape Modelling via a Variational Autoencoding Framework

Ir. Edwin Tay, Dr. ir. Nazli Tümer, Prof.dr. Amir Zadpoor

Delft University of Technology (TU Delft), Delft, Zuid-Holland, Netherlands

Ir. Edwin Tay

Dr. ir. Nazli Tümer

Introduction

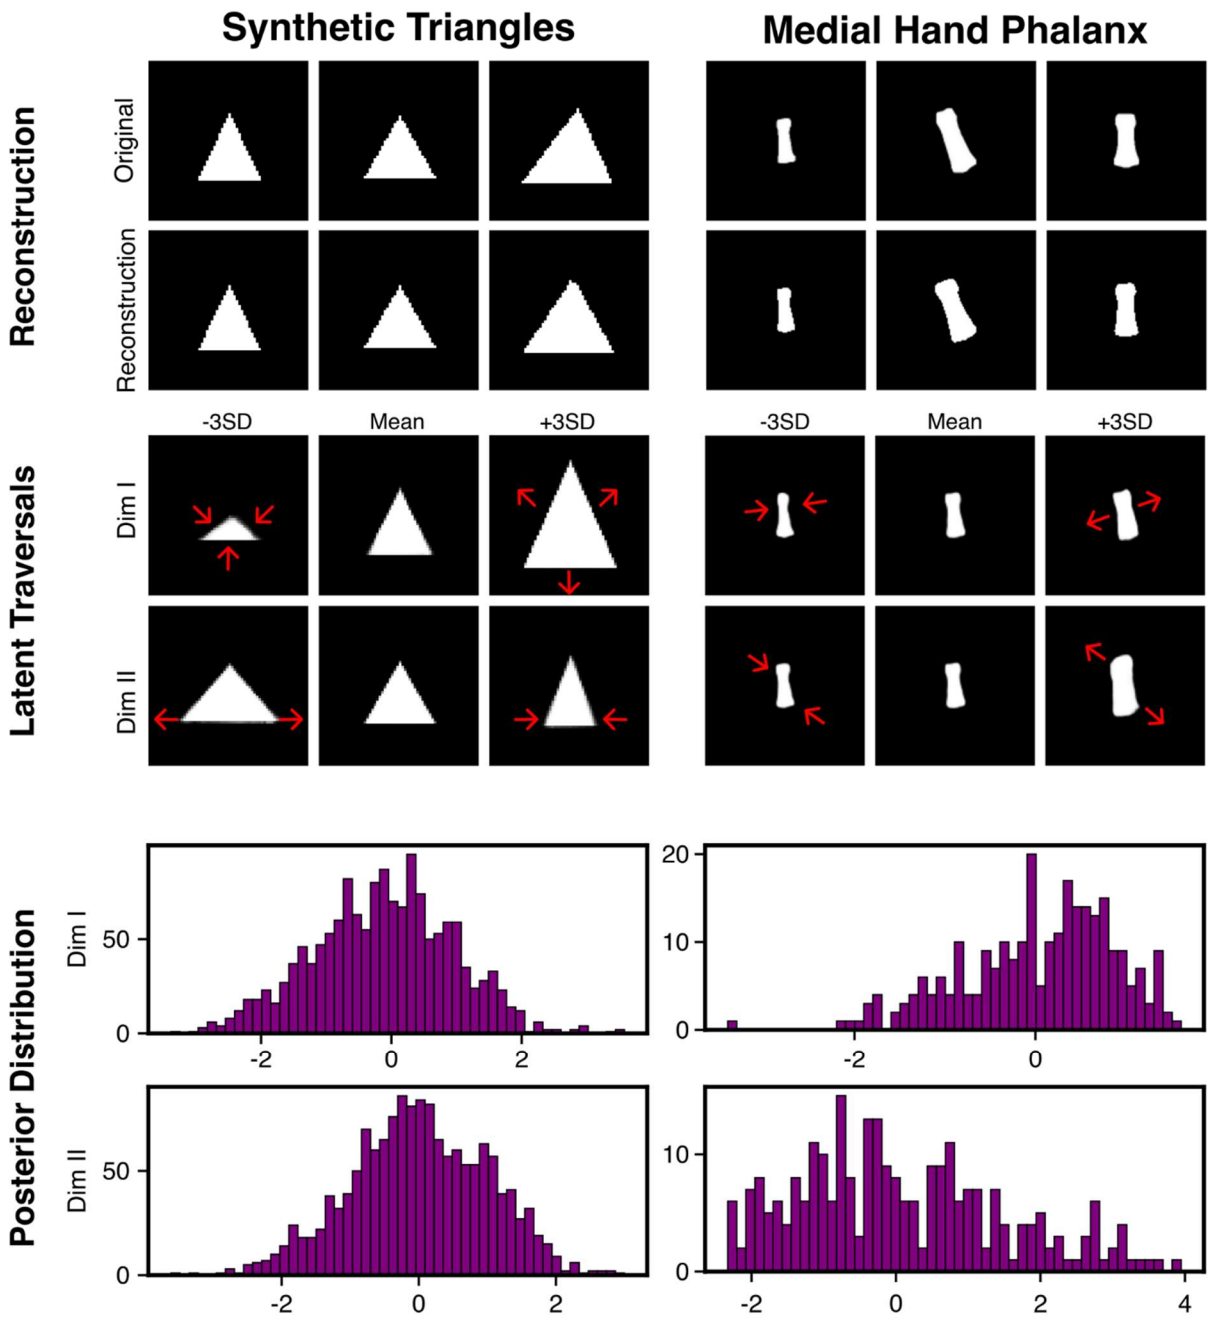
Dynamic growth and adaptation processes, from the cellular to the organ-scale, result in an expansive envelope of possible shape variation. These inherently nonlinear processes culminate in similarly nonlinear shape variations, resulting in a complex underlying shape space. Nevertheless, characterizing this time-varying shape space and deepening our understanding of physiological and pathological shape development can support many clinical applications, such as diagnosis and prognosis.

Existing methods often rely on processes that linearize inherently nonlinear data and use rule-based heuristic pipelines for discretization, which can lead to information loss. We propose that deep learning-based frameworks offer a more viable path towards nonlinear shape models that account for biological growth and development.

Methods

We developed an AutoSSM framework that amalgamates advances in variational autoencoders (VAEs), multi-scale modules, latent space disentanglement, and contrastive learning. Together, these components enable unsupervised learning and the structuring of shape spaces via latent variables. Wherein, each variable represents a unique and rich dimension of spatial variability. We demonstrate the efficacy of our framework via synthetic (generated shapes) and biological data (medial phalanges).

Results



Our Inception-based VAE generates high fidelity reconstructions (Jaccard = 0.949±0.042, Dice = 0.9733±0.023). Through disentanglement and self-supervision, the resulting

encoded latent variables capture distinct dimensions of spatial variation, closely aligning with those identified by traditional PCA-based SSMs. Each dimension can then be considered a probabilistic prior which, taken together, constitutes the overall shape space. Consequently, traversing and randomly sampling from the learned posteriors of each dimension provides physiologically valid shapes constrained within our learned shape space.

Discussion

Initial results demonstrate the feasibility of our AutoSSM framework for unsupervised learning of the underlying shape space. This is done without linearizing inherently nonlinear data (*i.e.,* biological growth and variation). Our framework further avoids heuristic, rule-based preprocessing pipelines, and each learned latent dimension captures richer, more expressive aspects of shape variation. Nevertheless, further work is necessary to develop a comprehensive evaluation of the underlying shape space identified via our framework. Regardless, our framework can also be further extended to explore the encoding of textural information for holistic shape and appearance modelling, and for applications to alternative shape representation media.

Performance Assessment of Machine Learning Algorithms for Hop Classification and Functional Profiling of 1,878 Hop Tests

Miss Eleonora Cabai MS[1,2], Dr. Jorge Chahla MD, PhD[3], Dr. Leonardo Metsavaht MD, PhD[4], Dr. Gustavo Leporace PhD, MSc[4], Dr. Jonathan Gustafson PhD[2]

[1]Politecnico di Milano, Milan, Milan, Italy. [2]Rush University Medical Center, Chicago, Illinois, United States. [3]Midwest Orthopaedics at Rush, Chicago, Illinois, United States. [4]Instituto Brasil de Tecnologias da Saúde (IBTS), Rio de Janeiro, Rio de Janeiro, Brazil

Introduction

Machine learning (ML) has shown significant potential for biomechanical subgroup classification [1], providing a valuable tool to personalize clinical decision-making [2]. However, no consensus exists regarding the optimal ML approach. This study investigates the performance of multiple algorithms to identify the optimal configuration for accurate subgroup classification given biomechanical data from 1,878 horizontal hop landing tests.

Methods

The dataset consisted of 24 biomechanical features (trunk/pelvis/hip/knee/ankle kinematics) extracted from the horizontal hop test of 1,878 subjects, collected at a private motion analysis institute, and grouped into 6 functional profiles. We used these data to evaluate the classification accuracy (80-20 train-test split) of five algorithms: Gaussian Naive Bayes (GNB), Multi-Layer Perceptron (MLP), Random Forest (RF), Support Vector Machines (SVM), and Deep Learning Neural Networks (DL). Our approach involved: (1) random state optimization to identify the best configuration, (2) performance evaluation with the best random state, and (3) recursive feature elimination to determine the optimal feature subset. Model performance was assessed using weighted average metrics, including accuracy, precision, recall, and F1-score to account for potential class imbalances.

Results

SVM and GNB exhibited the lowest performance across all configurations, with average accuracies of 80.6% ± 2.5% (Table 1). RF and DL demonstrated robust performance with average accuracy scores of 83.1% ± 1.4% and 86.2% ± 1.5% respectively. MLP showed the best performance, achieving an average accuracy of 87.7% ± 1.7%. The confusion matrices revealed that some subgroups with unique movement strategies at the knee and ankle

were more challenging to classify than others. The recursive feature elimination process identified minimal redundancy in the feature set.

Discussion

We successfully identified an optimal configuration for subgroup classification of horizontal hop landing tests using ML. The variation in performance across different models and random states highlights the importance of model selection and parameter optimization, particularly with the high variance in human-related data. The recursive feature elimination identified the importance of all the 24 features for hop classification. This ML-based approach can serve as a foundation for future studies aiming to establish functional classifications to support clinical decision-making in orthopedics.

Building the Foundations for AI-Based Diagnostic Models of Human Movement Using Real-World Video

Ms. Ellie Thompson, Mr. Shanren Yang, Mr. Mahan Bagheri, Dr. Max Donelan

Simon Fraser University, Burnaby, BC, Canada

Introduction

Differences in how people move can make a task efficient, unstable, or painful, yet identifying these issues remain challenging. Movement analysis often relies on subjective observation, introducing variability across coaches, clinicians, and therapists. Most individuals receive feedback from a single expert, limiting opportunities to compare and validate assessments. While artificial intelligence (AI) now matches expert performance in static diagnostic tasks, human movement is dynamic, multi-joint, and difficult to describe consistently. We developed a camera-agonistic system that integrates an AI-based video analysis tool with a real-world video collection and coach review platform. This system provides the foundational components for future high-throughput, AI-driven movement diagnostics.

Methods

We developed a web platform that enables athletes to upload videos from mobile devices and certified coaches to review them. The platform supports structured feedback through time-stamped comments, voice-to-text transcription, and tagging tools. Separately, we built a custom AI-based tool using Python infrastructure that analyzes uploaded videos to identify movement type and extract key frames representing major movement phases. Building on existing multimodal embeddings, we map video content and coach feedback into a shared semantic space, bringing aligned pairs closer together and pushing mismatched pairs apart. During the pilot period, 16 athletes submitted 144 videos, contributing to our goal of 300 videos for initial model training.

Results

Athletes successfully uploaded videos through the platform, confirming its reliability for real-world data collection. We selected the bar muscle-up—a movement requiring coordination and control—as the model task. The automated analysis software accurately detected attempts and extracted clean, representative frames from each video. Coaches

provided high-quality feedback using the review platform, with voice-to-text tools improving efficiency. Using these annotations, we generated early prompts that enabled the system to produce draft feedback from video input. Initial qualitative review showed alignment between the system-generated feedback and coach-identified movement issues.

Discussion

These pilot findings demonstrate the feasibility of integrating real-world video collection, automated movement analysis, semantic evaluation, and expert coaching into an AI-driven diagnostic system. The tools we established provide a foundation for high-throughput, consistent movement assessment applicable to athletic performance, rehabilitation, and injury-prevention.

A Principled Validation Framework for Explainable AI in Gait Analysis: Sensitivity, Faithfulness, and Cross-Method Coherence

Mr Ching Hang Chiu[1], Ms Elodie Drew[2], Mr Alpesh Kothari[1,3], Dr Julie A. Stebbins[1,3], Prof Amy B. Zavatsky[4], Dr Philippe C. Dixon[2]

[1]NDORMS, University of Oxford, Oxford, Oxfordshire, United Kingdom. [2]Department of Kinesiology and Physical Education, McGill University, Montreal, Quebec, Canada. [3]Oxford Gait Laboratory, Oxford University Hospitals NHS Foundation Trust, Oxford, Oxfordshire, United Kingdom. [4]Department of Engineering Science, University of Oxford, Oxford, Oxfordshire, United Kingdom

Introduction

Machine learning provides powerful tools for analysing complex gait patterns, yet its opaque decision-making mechanisms hinder clinical trust. While post-hoc explainable artificial intelligence (XAI) can identify features driving model decisions, its fragility to noise raises concerns about biomechanical validity. We propose here a validation framework to evaluate XAI across three dimensions: sensitivity (whether highlighted features influence model output), faithfulness (whether explanations reflect learned representations), and coherence (cross-method consistency) [1,2]. The framework is demonstrated on a task with a known discriminative feature to establish its reliability and support its extension to more subtle applications.

Methods

Kinematic data from 18 idiopathic toe walking (ITW) and 18 typically developing (TD) children (20 cycles per subject; pelvis/hip all planes, knee/ankle sagittal; normalised to 101 timepoints) were analysed. A 1D Convolutional Neural Network (CNN) was trained with five-fold subject-stratified cross-validation to classify ITW vs TD gait. Attribution maps, showing which parts of the input contributed to the model's decision, were derived from 6 XAI techniques: Saliency, Input×Gradient, Integrated Gradients, Guided Backprop, DeepLIFT, and GradientSHAP. Sensitivity was assessed via relevance-guided masking (removing the top 5–50% attributed features) and measuring associated AUROC decline. Faithfulness was assessed through progressive weight- and label-randomisation, with attribution similarity drop quantified using Pearson correlation. Coherence was examined by changes in global attribution similarity after removing each method. Validated attributions were then ensemble-averaged and qualitatively compared with 1D Statistical Parametric Mapping (1d-SPM) effect-size heatmaps representing ITW–TD group differences.

Results

The CNN model achieved high performance (AUROC: 0.99 ± 0.02). Sensitivity testing confirmed that all methods identified functionally relevant features. Faithfulness tests showed that Guided Backprop failed to degrade under weight-randomisation and that Saliency was unstable across retraining with no label-randomisation, indicating unfaithful attributions. Coherence analysis likewise showed that both methods weakened global similarity, leading to their exclusion. XAI validation was further supported by XAI–SPM agreement (Fig 1), with both marking the ankle sagittal plane as highest-importance.

Discussion

This framework distinguished plausible from artefactual explanations. Methods that passed sensitivity but failed faithfulness produced relevant yet non-discriminative attributions driven by generic input sensitivity.

Images (Optional)

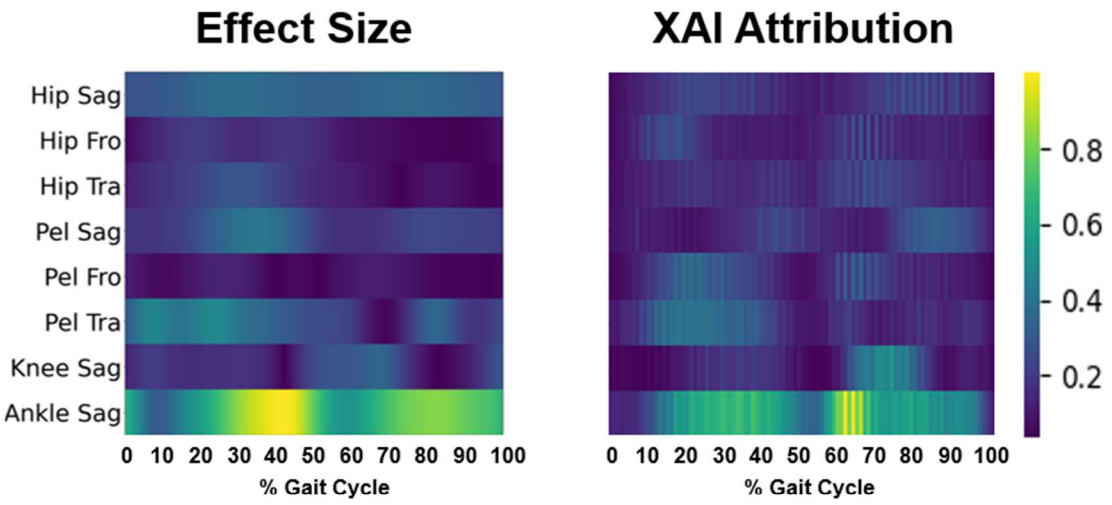

Figure 1. Heatmaps showing (left) 1D-SPM effect sizes for ITW–TD group differences and (right) ensemble-averaged XAI attributions from validated explainability methods. *Both analyses highlight ankle sagittal kinematics as the dominant region of discriminative information, supporting the biomechanical validity of the XAI explanations.*

Advancing Real-Time and Automated Inertial Sensor Analysis Across Biomechanics Applications with Time-Series Transformers

Mr. Gerard Aristizábal Pla[1], Prof. Michael Potter[2], Prof. Wouter Hoogkamer[3], Prof. Kurt Beschorner[1]

[1]University of Pittsburgh, Pittsburgh, Pennsylvania, United States. [2]Francis Marion University, Florence, South Carolina, United States. [3]University of Massachusetts Amherst, Amherst, Massachusetts, United States

Introduction

Real-time and automated inertial measurement unit (IMU) analysis is critical because many biomechanics applications require immediate feedback, minimal manual intervention, and continuous monitoring outside laboratory settings. Transformers meet these requirements and are versatile across context, but have not been applied extensively to IMU data. We evaluated a time-series transformer (TST) model across five methodologically and application-diverse tasks: gait event detection, stride length estimation, human activity recognition, and freezing of gait detection.

Methods

Five TST models (4 attention heads, 3 layers) were trained and cross-validated across distinct IMU datasets. For gait event detection, 17 subjects performed walking, jogging, running, and sprinting trials with shoe-mounted IMUs. For contact time validation, 20 participants ascended and descended three outdoor staircases at varying speeds with shoe-mounted IMUs [1]. Stride-length estimation used sprint trials from 17 subjects [2]. Human activity recognition involved 30 participants performing six activities with a pelvis-mounted IMU [3]. Freezing-of-gait detection used data from 35 individuals with Parkinson's disease completing 2-minute walking tests with shank-mounted IMUs [4]. Each model processed sliding windows of IMU data, producing either frame-wise probabilities, window-level probabilities, or stride-length estimates. Training used Adam optimization, gradient clipping, task-specific loss functions, and strict leave-one-subject-out validation. Performance was evaluated using F1-score, mean absolute error, mean bias or area under the receiver operating characteristic curve, averaged across folds, as appropriate.

Results

TST models achieved strong performance that matched or exceeded heuristic approaches (Table 1, where bold indicates best performance).

Discussion

TST models offer an efficient and fully automated way to process IMU signals. Unlike heuristic methods, TST models learn temporal patterns directly from raw data without assumptions. Their probabilistic, window-based design supports real-time inference, making TST models a scalable solution for automated gait analysis in biomechanics applications. Future work will explore developing a single unified Transformer capable of handling all tasks within one model.

Reliability assessment of a neural network-based ecological framework for remote gait analysis in Parkinson's Disease

Mr. Giulio Rigoni[1], Mr. Oier Zazpe[1,2], Ms. Fabiola Spolaor[1], Prof. Damiano Varagnolo[1], Prof. Daniele Volpe[3], Prof. Zimi Sawacha[1]

[1]University of Padova, Padova, Veneto, Italy. [2]Mondragon Unibertsitatea, Mondragòn, Basque country, Spain. [3]Fresco Parkinson Foundation Villa Margherita, Vicenza, Veneto, Italy

Introduction

Global physiotherapy demand is rising, driven by aging populations and the increasing prevalence of neurodegenerative conditions like Parkinson's disease (PD). With growing complexity in treating neurological patients in traditional facilities, remote rehabilitation services are emerging as promising options, alongside methodologies for remote assessment of treatment effects. This study proposes a neural network (NN)-based framework to assess gait alterations in PD individuals through both kinematics (i.e., spatio-temporal and joint kinematics) and kinetics (ground reaction forces, GRF) relying only on video data.

Methods

We developed a NN-based approach that, from markerless-based (i.e., Pose2Sim [1]) anatomical landmarks (ALs) trajectories, identifies the stance phase and estimates three-dimensional GRFs through two NNs: 1. a Spatio-Temporal Graph Convolutional Network (ST-GCN); 2. a modified image-based NN [2]. A proprietary training dataset of 401 gait cycles from 39 healthy adults (45.40 ± 20.47 Years, 24.58 ± 3.57 kg/m^2) and 26 PD subjects (70.74 ± 7.56 Years, 25.78 ± 3.39 kg/m^2) was applied. For validation, gait data of 10 PD individuals (73.50 ± 6.64 years; BMI 25.39 ± 1.73 kg/m^2) not included in training were used. An 8-camera Vicon system, two Bertec force plates and two GoPro Hero7 cameras (sagittal and frontal) were used. Inverse kinematics was performed in OpenSim from AL trajectories obtained via Pose2Sim and marker-based data. GRFs were estimated through the two NNs using markerless AL trajectories and compared with force plate data through RMS, coefficient of multiple correlation and 1D-SPM [3].

Results

While large differences emerged between markerless and marker-based inverse kinematics (RMS>6.78°, **Figure 1.1**), both GRF predictors showed good agreement with the

experimental measures, particularly for the vertical and mediolateral components (**Figure 1.3**).

Noticeably, stance phase identification showed good accuracy (97.29%, **Figure.1.2**).

Discussion

The two ecological approaches show potential for remotely monitoring PD individuals, paving the way for gait analysis on individuals with pathological conditions using only common, off-the-shelf cameras.

Neural Network With Cross-Domain Knowledge Transfer From Force Plates to Wearable Insoles for the Estimation of 3D Ground Reaction Force components.

MSc Gloria Scanagatta[1,2], Dr Miel Willem[1], Dr Bryce A Killen[1], Prof Ilse Jonkers[1]

[1]KU Leuven, Leuven, Vlaams-Brabant, Belgium. [2]Università degli studi di Padova, Padova, Padova, Italy

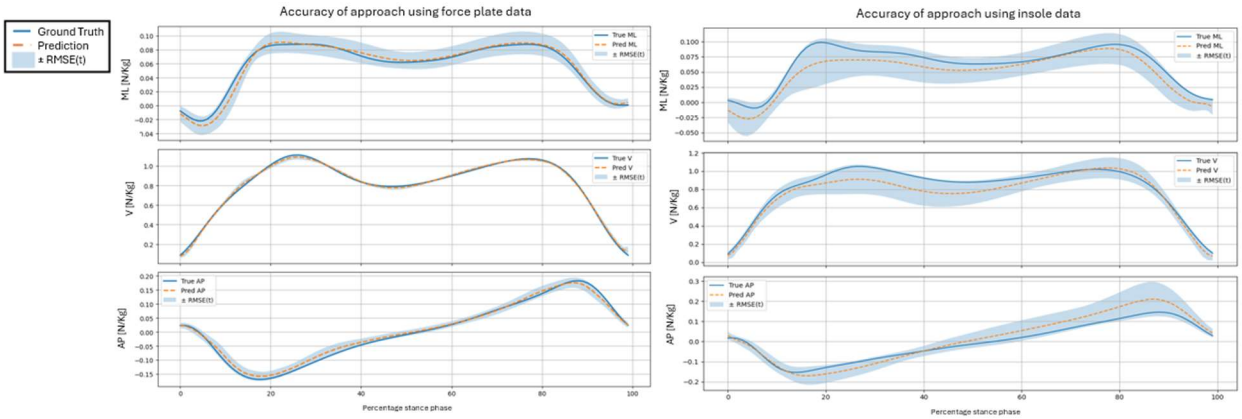
Introduction

Accurately measuring ground reaction forces (GRFs) remains a major challenge in out-of-lab human movement analysis. This study proposes a deep learning framework capable of estimating three-dimensional GRFs from pressure insole data with high accuracy, enabling reliable force measurement in real-world settings.

Methods

Force platform (FP) data were recorded in a total of 36 participants (healthy and osteoarthritic) while walking on an instrumented treadmill at self-selected pace, afterwards 2 heathy subjects were acquired with sychronized data from FP and insoles. Data was preprocessed in MATLAB to segment stance phases, filter signals (Butterworth filter), and compute resultant force vectors for model training. A multilayer BiLSTM neural network with concatenate attention layer, global features, was developed and trained using supervised learning on gold standard FP measurements. The model was trained with a weighted Huber loss, given the high variability and limited amplitude of the Medio-Lateral(ML) and Antero-Posterior(AP) components of the GRFs during stance. Recurrent layers were selected to preserve temporal dependencies and reconstruct GRF waveforms. A patient-aware split was applied to create training, validation, and independent test sets. Final trained weights were deployed in an inference-only network on pressure insoles data and evaluated against the ground truth FP data.

Results



The network achieved excellent performance for FP data, achieveing for the vertical component, RMSE = 1.56 ± 0.35 %BW, NRMSE = 1.53 ± 0.31%, and correlation = 0.9983 ± 0.0007. When applied to insole data, errors slightly increased but remained robust, with NRMSE values below 19% and correlations above 0.90 for all three components. The vertical component showed the best generalization (NRMSE = 11.47 ± 1.66% and

correlation = 0.9542 ± 0.0093). Qualitative analysis (Figure 1), demonstrates that the network accurately learns the GRF pattern and maintains strong cross-domain generalizability.

Discussion

These results indicate the proposed deep learning approach generalizes effectively to unseen subjects and to data acquired from different modalities. It reaches accuracy levels consistent with in-domain validation studies found in the literature, despite no adaptation to the insoles domain. This work provides strong evidence that pressure insoles, combined with advanced neural network models, can serve as a reliable tool for estimating GRFs outside laboratory environments.

MoveDB: Toward a Scalable Biomechanics Database Platform for Reproducible Research

Mr. Hudson Burke

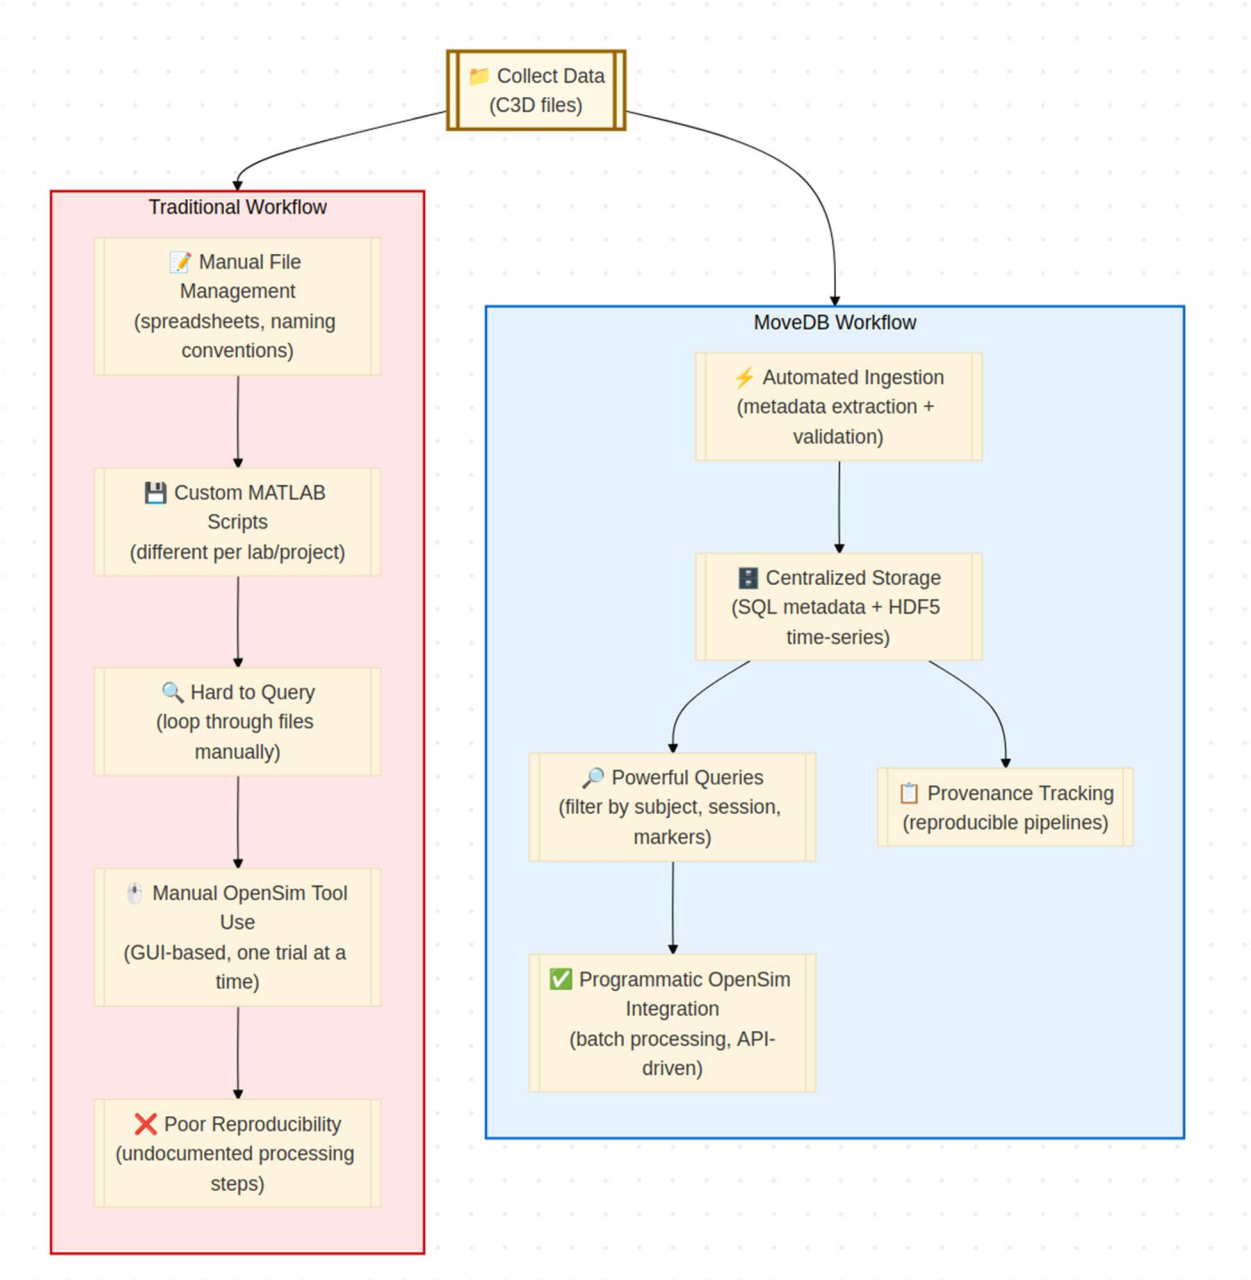
University of Virginia, Charlottesville, Virginia, United States

Introduction

One of the major challenges facing modern biomechanics research is a cohesive strategy to handle "Big Data". At the American Society for Biomechanics 2025 meeting, a majority voted that biomechanics was not prepared or capable of properly utilizing datasets at scale. Studies generate large volumes of complex data from motion capture, force plates, electromyography, and wearable sensors. However, the lack of standardized platforms hinders reproducibility and collaboration. MoveDB is an open source software platform addressing these challenges by providing scalable tools for data management, analysis, and sharing

Methods

Predominantly, the biomechanics community uses MATLAB for data analysis. While familiar and capable, MATLAB requires a license, which can be a barrier for collaboration, and as a closed-source platform with limited package management, it can lead to issues with reproducibility. Biomechanics datasets are also predominantly file-based, with C3D files being the most common format for motion capture data and OpenSim analyses relying on a wide variety of specific file types. Thus, MoveDB was developed using Python to leverage its strengths in data science, free and open source ecosystem, and portability. The core components of MoveDB include SQL for efficient querying of metadata, HDF5 for scalable management of time series data, EZC3D for reading C3D files, and OpenSim's Python API for biomechanical modeling and simulation.



Results

The platform supports efficient data ingestion, allowing users to upload C3D files and automatically extract relevant metadata. Once ingested, users can perform complex queries to filter datasets based on various criteria, such as subject demographics, experimental conditions, or specific markers, and then utilize OpenSim's Python API to run batch simulations and analyses programmatically. MoveDB also enables flexible deployment options, from local installations for individual researchers to cloud-based solutions for larger collaborations.

Discussion

MoveDB is currently in active development, and community involvement is essential for its success. The project is open source, and we invite biomechanics researchers to contribute to the development of MoveDB by providing feedback, suggesting features, and participating in testing. By working together, we can create a robust and scalable platform that meets the needs of the biomechanics community and advances the field as a whole.

Improving Energy Expenditure Estimation From a Single Wrist IMU by Learning Musculoskeletal Joint Kinematics

M. Sc. Ilias Masmoudi[1], Dr. med. Elisabetta Gazzerro[2], Prof. Dr. Anne Koelewijn[1]

[1]Chair of Autonomous Systems and Mechatronics, Department of Electrical Engineering, Friedrich-Alexander-Universität Erlangen-Nürnberg (FAU), Erlangen, Bavaria, Germany. [2]Unit of Muscle Research, Experimental and Clinical Research Center Charité Universitätsmedizin and Max Delbrück Research Center, Berlin, Berlin, Germany

Introduction

Accurately estimating energy expenditure from wearable sensors is important for biomechanics, rehabilitation, and ambulatory monitoring. However, upper-limb energy expenditure estimation using a single wearable remains underexplored. We ask whether inferring internal joint kinematics from a single wrist inertial measurement unit (IMU) can improve estimates of upper-limb metabolic energy expenditure, by providing an intermediate, physiologically informed representation linking sparse external signals to muscle energetics.

Methods

Using the OpenSim MoBL-ARMS model (7 DOF, 50 musculotendon actuators) [1,2], we generated 5-s joint-angle trajectories by sampling sums of sinusoids with added Gaussian noise and randomized biases to produce diverse, plausible motions. A virtual wrist IMU with realistic noise produced accelerometer and gyroscope signals. Computed muscle control produced time-varying muscle excitations, and total metabolic energy expenditure was computed with the Umberger model [3]. Signals were resampled to 50 Hz and segmented into overlapping 1.0 s windows (10% overlap); each window was labeled by mean metabolic energy expenditure. Shoulder and elbow angles and angular velocities served as ground-truth kinematics. We trained four time-series neural networks: IMU-only → energy-expenditure, measured-kinematics-only → energy-expenditure, IMU + measured kinematics → energy-expenditure, and a two-stage pipeline: (1) IMU → predicted kinematics, (2) IMU + predicted kinematics → energy-expenditure. Performance was evaluated by test mean absolute percentage error (MAPE) on held-out runs.

Results

Test MAPE on held-out runs was: IMU-only 32.6%, Kinematics-only 26.6%, IMU+Kinematics 18.1%, and Two-Stage 19.3%. Incorporating measured joint kinematics reduced error by 44.5% relative to IMU alone, and the two-stage approach achieved comparable accuracy.

Discussion

Augmenting minimal wearable data with musculoskeletal joint kinematics substantially improves simulated upper-limb energy expenditure estimation. A learned kinematics estimator from a single wrist IMU can bridge sparse wearable signals and internal muscle energetics, enabling more accurate, low-burden monitoring. The study is limited to simulations and depends on model assumptions. Next steps include experimental validation with human participants, investigation of inter-individual variability and personalization, and assessment of real-time deployment.

Assessing the Performance of Deep Learning 3D Reconstruction Models of the Pelvis from Bi-Planar X-Rays using Spinopelvic Parameters

Ms. Isabella Tierney, Ms. Marie De Mey, Mr. Jeffrey Lee, Dr. Stewart McLachlin, Dr. John McPhee

University of Waterloo, Waterloo, Ontario, Canada

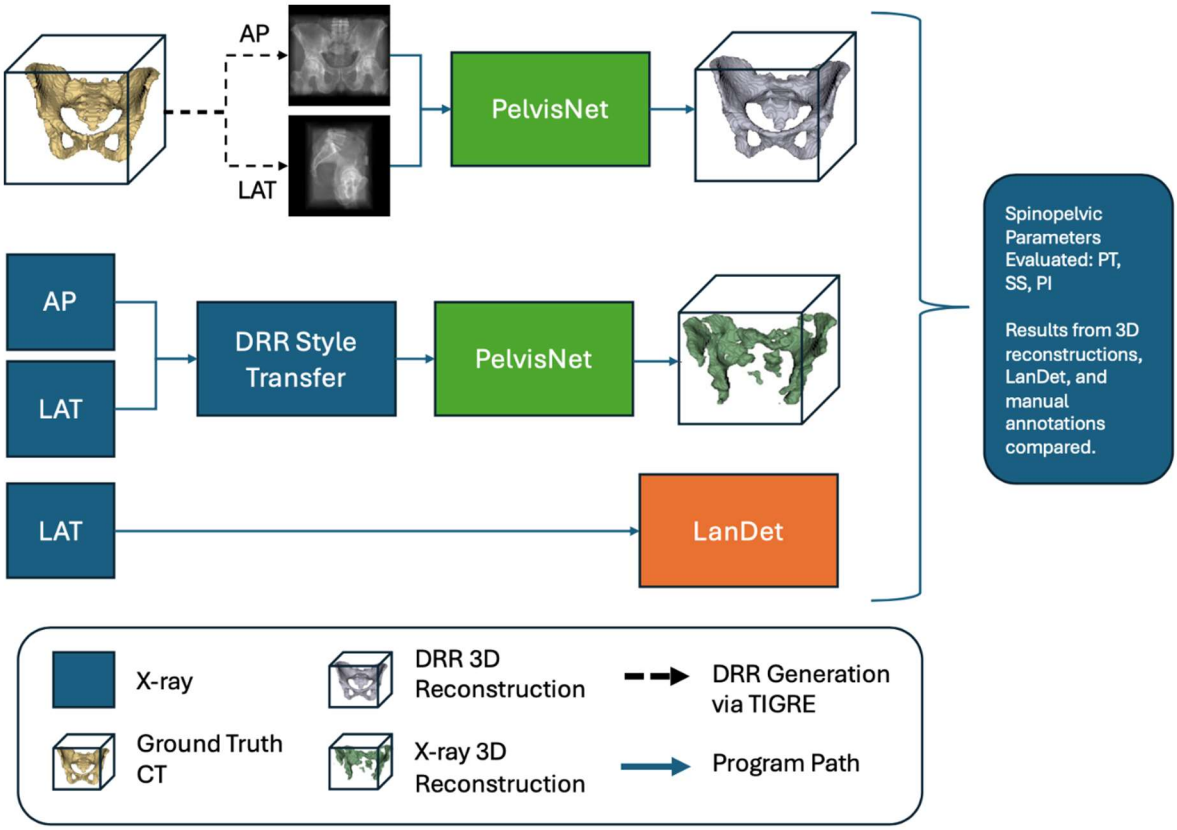
Introduction

Preoperative planning using 3D pelvis reconstructions from computed tomography (CT) scans currently outperforms 2D X-ray preoperative planning in prosthetic matching and implant positioning. With advances in deep learning (DL), recent work aims to generate 3D pelvis reconstructions from bi-planar X-rays. However, due to the absence of publicly available paired X-ray and ground truth CT datasets, most studies generate synthetic X-rays using digitally reconstructed radiograph (DRR) techniques. However, 3D reconstruction models solely trained on DRRs may limit clinical translation, due to differences in appearance compared to real X-rays. To demonstrate, we created a paired bi-planar DRR/CT dataset using CTPelvic1k and TIGRE and our Attention U-Net model (PelvisNet) achieved a Dice score of 75.2%; however, when real X-rays were tested on the model the results were poor (Figure 1).

Methods

This study investigates the methods needed to generate accurate 3D reconstructions from X-rays. Since these X-rays do not have a corresponding ground truth CT scan, DL evaluation metrics cannot be used to assess the performance. Instead, the 3D reconstructions from both the X-rays and DRRs will be evaluated based on measurements of spinopelvic parameters such as pelvic incidence (PI), sacral slope (SS), and pelvic tilt (PT) using automatic 3D landmark detection methods [1-2].

To gauge the results from both DRR and X-ray reconstructions, an automated spinopelvic detection method for lateral X-rays, LanDet, with an accuracy of 98% for PT, will be used as the standard [3]. Methods for the translation of X-rays to be used on DRR trained models include style transfer using Cycle-CAN [4] and cropping/sampling methods.



Results

Preliminary results are encouraging; final results will be included in the WCB presentation.

Discussion

To our knowledge, this will be the first study to evaluate 3D pelvic reconstruction models on X-rays using spinopelvic parameters, offering significant potential to improve and increase accessibility for pre-operative surgical planning.

Kinematics-Based Technique Clustering of Freestyle Swimmers

PhD student Itay Coifman, MsC. May Hakim, Prof. Gera Weiss, Prof. Raziel Riemer

Ben-Gurion University of the Negev, Beer-Sheva, Israel, Israel

Introduction

Swimmers adapt their stroke mechanics based on race distance, individual strength, and physiological capacities. These adaptations may involve variations in limb motion(i.e, tchequnie), stroke rate, and stroke length, allowing athletes to optimize performance across different event demands[1,2]. The wrist trajectory is affected by the movement of the entire body and limbs. Therefore was used for the classification of swimming techniques by applying unsupervised clustering using wrist motion.

Methods

Motion of skeletal joints and keypoints (17) data were extracted from side-view videos of 155 swimmers (55 female) freestyle trials (n=254) using a custom human pose estimation pipeline [3]. The analysis focused on standardized wrist trajectories (see figure 1) to isolate the technique from differences in anthropometry, stroke rate. The distance between two trajectories was defined by using Dynamic Time Warping (DTW) combined with a term that accounts for the time displacements between two wrapped trajectories to measure the spatial and temporal distances. The K-Medoids algorithm was applied to this matrix to identify the movement archetypes. The number of clusters was determined using K that maximizes the silhouette score.

Results

The algorithm identified two distinct clusters, with statistically significant differences. Group-A(54%) was characterized by a Deep Push trajectory (depth μ=67.0), an early push phase (starting at μ=41.1%), faster trial times (μ=14.5s/ 25m), less time underwater (71.7%), and a higher stroke rate (μ=55.5 cycles/min). Group-B exhibited a Shallow Push trajectory (depth μ=56.93), a late push phase(starting at μ=49.8%), slower trial times (μ=15.4s/25m), more time underwater(75.0%), and a lower stroke rate (μ=45.3 cycles/min).

Discussion

Applying trajectory clustering to joint kinematics successfully distinguished swimmers by performance level. The distinct separation between profiles confirms that wrist displacement is a sufficient proxy for technical efficiency. The "Deep Push" group engaged

propulsion earlier and deeper (indicated by the higher normalized L value), correlating with higher velocity. These findings suggest that wrist trajectories are highly correlated with other key indicators of technique assessment. This enables coaches to use simplified guidelines for explaining different techniques.

Development of a Data Warehouse System for Storage, Analysis, and Downstream Applied Research with Multimodal Biomechanics and Injury Assessment Datasets Using Open Source Tools – Architecture and Proof of Concept

Dr. Mitchell Abrams PhD, Dr. Jason Luck PhD

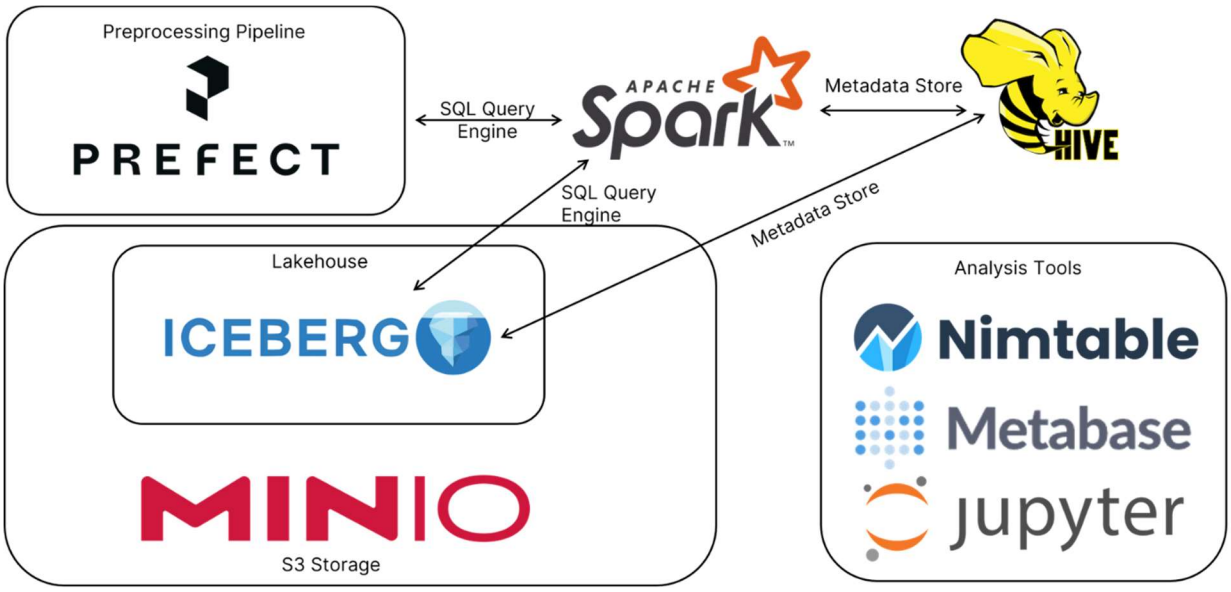
Duke University, Durham, North Carolina, United States

Introduction

Biomechanics research groups rely on increasingly multimodal data in their projects. For example, one study could incorporate wearable data sources, survey data, laboratory testing, and video footage. While linking data sources by subject or collection session is feasible in small-scale studies, when scaling data collection efforts to hundreds or thousands of participants across multiple years and research sites, data aggregation and cross-referencing can become cumbersome, time consuming and computationally expensive. We develop here a framework for a robust, extensible technology stack using open source tools, facilitating data intake, processing, and analysis by researchers of multiple skill levels.

Methods

A technical stack consisting of Apache Iceberg (data lakehouse), MinIO (S3 object storage), Apache Spark + Hive (querying and metadata storage), Prefect (data processing workflows), Jupyter, Nimtable and Metabase (data analysis) was developed (see Figure). Docker containers running these services were deployed on a secure university server. For proof-of-concept analysis, a subset of data from an ongoing study was used. Wearable in-ear sensor data from youth football players (n=4; triaxial accelerometer and angular rate; Duke DASHR) was compared with weekly self-reported athletic activity contact exposure questionnaires (AACEQ) across 20 data collection sessions. Raw data were uploaded to the MinIO object store for staging, and preprocessed with Prefect (DASHR) and Jupyter notebooks (AACEQ). Jupyter and Metabase were used for analysis. Coarse event detection identified potential head acceleration events [HAE] (>10g). Events were considered on days where the athlete reported they participated in football-related activities, and had body-to-body contact, with or without head contact of another player or the ground.



Results

On days with reported contact exposure, athletes sustained 353 potential HAE, averaging 17.7 events per athlete per day. On six days with reported contact, no HAE were detected in the wearable data.

Discussion

Deploying a robust technical stack enables and streamlines the application of data science methods to multimodal data sources. This sample analysis is easily completed in under an hour following data intake, and is readily extended with machine learning, AI, or other complex techniques. Using this system in a multi-site study would facilitate exploration of injury mechanisms and broader research questions.

[5]Division of Cardiovascular Medicine, Hospital of the University of Pennsylvania, Philadelphia, PA, United States. [6]Department of Bioengineering, University of Pennsylvania, Philadelphia, PA, United States

Introduction

Understanding the natural variability and aging of aortic anatomy is essential for improving diagnosis, treatment planning, and computational modelling of thoracic aorta disease. Statistical shape modelling (SSM) provides a framework to quantify population-level geometric variation and identify factors driving aortic morphology differences. In this work, we developed a SSM of the healthy thoracic aorta to characterise its main modes of variation and assess how subject characteristics influence aortic geometry.

Methods

A subset of 1484 healthy individuals (aged 47-82 years; 50% male) was selected from the UK Biobank, and their aortas were segmented with a convolutional neural network [1]. After mesh extraction, spatial alignment and establishing point-to-point correspondence, principal component analysis (PCA) was applied to extract the dominant modes of anatomical variation in the population.

A multivariate analysis of covariance (MANCOVA) evaluated the combined effect of age, systolic & diastolic blood pressure, height, weight, and sex on the shape modes. Additionally, linear regression related PCA shape coefficients to these characteristics, enabling interpretation of how each factor influences aspects of aortic shape variation.

Results
