Dating Laboratory, The Norwegian Institute of Technology,
N-7034 Trondheim-NTH

Received December 17, 1974

The mean apparent radiocarbon ages of marine shells, collected alive before the initiation of atomic bomb testing, and also before the main input of dead carbon derived from fossil fuels, are found to be 440 yr for the coast of Norway, 510 yr for Spitsbergen, and 750 yr for Ellesmere Island, Arctic Canada. The relationship between these apparent ages and the oceanic circulation pattern, is discussed. Also possible variations of the apparent ages back in time are discussed.

INTRODUCTION

As is well known, present day seawater and living marine organisms assume an apparent radiocarbon age due to the circulation of carbon in nature. The processes involved were recently discussed by Mangerud (1972), and will not be repeated here. An important point is that apparent ages measured today can vary from 200 to 300 yr to more than 2500 yr, depending on the history of the relevant water masses. Therefore, for the correction of radiocarbon dates of marine specimens, the apparent age of the water masses in which the dated organism lived must be estimated.

Since 1962 atomic bomb testing has completely disturbed the natural ^{14}C activity; the use of fossil fuel in this century has also influenced the activity, but in the opposite direction. We have therefore employed museum specimens of shells, collected before 1926, the majority being collected much earlier. In compilation of published results we have used only dates from marine shells collected before 1940.

In the present study recent marine shells from the North Sea, the coast of Norway, Bear Island, Spitsbergen, and

Ellesmere Island (Arctic Canada) are dated.

All samples were from the collections in the Zoological Museum, University of Bergen. Shells from Ellesmere Island were collected by the second Norwegian Fram-expedition, the others by various Norwegian scientists. Their ^{14}C activity was measured by the Radiological Dating Laboratory in Trondheim, and the $^{13}\text{C}/^{12}\text{C}$ ratio by R. Ryhage, Karolinska Institutet, Stockholm.

Methods

All the molluscs had been collected alive, some of them possibly being stored in alcohol for a short time after collection. Later they were kept in dry storage in boxes in a closed drawer. Contamination during storage (Olsson *et al.*, 1968) is negligible for carbonate shells of such young samples.

Pretreatment of samples in the ^{14}C -laboratory involves washing and scrubbing of shell surfaces followed by a thorough rinse in distilled water. On average 12% by weight of the samples was removed by hydrochloric acid leaching.

^{14}C activity was measured in not less

^aDated shells. Latitude and longitude can be ca. 2' in error. The parameters are calculated according to formulas given in Mangerud 1972. $\delta^{14}\text{C}$, Δ and apparent age refers to year of collection and are also corrected for the industrial effect (Fig. 1). The latter correction causes the small differences for the samples T-951 to T-960, compared with the results given by Mangerud (1972, Table 4) and Nydal et al. (1972, pp. 448-450).

ACKNOWLEDGMENTS

We both wish to express our gratitude to Dr. Johanne Kjennerud for providing the shells from the museum, Mr. Fred Skogseth for assistance in the laboratory, Dr. Brian Robins for correcting our English, and cand. real. Inge Aarseth, cand. real Kjell Bjørklund, and cand. real. Tore Vorren for their critical reading of the manuscript. The work was financially supported by The Norwegian Research Council for Science and the Humanities (NAVF).

ADDENDUM

After this manuscript was submitted, further measurements of the ^{14}C -activity of recent marine shells from Denmark, Iceland, and Western Greenland were published in: Krog, H. and Tauber, H. (1974). C-14 chronology of Late- and Post-glacial marine deposits in North Jutland. *Danmarks geologiske Undersøgelse*, Årbog 1973, pp. 93-105. Copenhagen.
