# ON THE GROWTH OF SOLE IN THE NORTH SEA 

by<br>F.A. van Beek<br>Netherlands Institute for Fishery Investigations<br>P.O. Box 68, 1970 AB IJmuiden<br>The Netherlands

#### Abstract

Changes in length at age, weight at age, condition factor and ovary weight of North Sea sole were investigated from Dutch market samples in the period 1957-1986. A considerable increase of length at age and condition factor and consequently weight at age in males and females were observed in the period 1965-1973. The increase in growth started in all age groups simultaneously. In the period after 1973 these parameters remained at a high level for age groups 3-7. Length- and weight at age in older animals show a further increase until 1986. The percentage of ovary weight has not changed significantly over the whole period. The surplus production has been calculated for an early and a recent period. A comparison has been made with the surplus production of North Sea plaice. From the differences between both production plots and differences in the migration behaviour of both species it is concluded that it is likely that the factor(s) responsible for the growth increase only occur in the southern North Sea.

## Introduction

Changes in growth have been observed in many commercial species and many areas. In 1976 DE VEEN described significant changes in the biological parameters in the North Sea sole (Solea solea L.) observed in the years 1951-1973 and tried to relate them to changes in environmental factors. The only significant factors found were with fishing effort and with indices of the disturbance of bottom layers by active gears.

DE VEEN's paper was based on data from research vessel sampling for the years 19511965 and the annual sampling programmes in the Dutch fish markets in the years 19571973. He demonstrated a similar increase in growth in the period 1968-1973 in four substocks and found no significant differences between the substocks in this period.

The Dutch fish market sampling programmes continued after 1973. The present paper reports on further developments of growth in the North Sea sole stock. No distinction has been made between sub-stocks. In order to compare the developments of the stock after 1973 with the period covered by DE VEEN the whole market sampling data base, for the period 1957-1986 was reanalysed.

Changes in length at age, weight at age, condition factors and gonad weight were studied on second quarter data only as in this period soles of all age groups aggregate in coastal waters for spawning and biological sampling was intensified in this period every year.

## the data

Soles landed in the Dutch fish markets are gutted and are presented in 5 size categories. The biological sampling is based on this stratification. In each size category a number of fish are taken at random and sex, length, weight, gonad weight and maturity stage (females only) and age (otolith) were recorded. The sampled weights are raised to the total landings by size category for each quarter. In this way quarterly length distributions per age group are obtained for each category. Thereafter the categories were combined.

In the years before 1962 the Dutch fishery for sole in the North Sea was predominantly carried out with otter trawls. After 1961 the otter trawls were gradually replaced by beam trawls. Since 1969 the majority of the Dutch catch is landed by beam trawls. The market samples considered in this paper therefore originate from both type of gears.

In this paper only ages 2-14 were considered as older age groups occur infrequently in the the market samples.

Mean length at age were obtained as the average of the length distribution per age group weighted in each quarter.

The condition factor of each fish was calculated as $C=W / L^{3}$ where $W$ is the life weight. A conversion factor gutted/life weight of 1.11 was applied in all years. A mean condition factor per age group was calculated as the average from all sampled fish.

Mean weight at age was calculated from the length distribution per age group and the mean condition factor of that age group and was weighted over catch numbers in the length distribution.

Ovary weights were determined in the second quarter only. In this paper only ovary weights of stage 4 and 5 in April were considered, because they represent pre-spawning fish with a seasonal maximum in average weight..

For the calculation of the surplus production of females the data were slightly modeled. Assuming no significant growth in length during spawning time, mean length at age in the second quarter were considered representative for the period just before spawning (end of the first quarter) and just after spawning (beginning of third quarter). Weight at age before (W1,age) and after spawning (W3,age) were calculated from a smoothed second quarter length at age, using the BERTALANFFY growth equation (in BEVERTON \& HOLT,1957), and first and third quarter condition factors. The total growth of an age group was calculated as the difference in weight before spawning and the weight of the preceding age group after spawning (W1,age-W3,age-1). The reproduction of the age group was estimated from the calculated pre-spawning weights ( Wl, age) and the percentages of ovary weights (constants per age group) stages 4 and 5 in April. Both growth and reproduction were plotted against the mean weight ((W1, age +W 3 , age-1)/2).

## Results

Tables 1a and 1 b give the numbers of fish sampled per age group in each year. The level of sampling was not the same each year. In the earliest years (1957-1961) sampling was rather poor. In 1962, 1969 and 1974 sampling was intensified in steps and in 1980 it was reduced again to its present level. The numbers sampled per age group each year depends also on year class strength. Therefore abundant year classes are better sampled than average and poor ones. Also, in general the younger age groups are better sampled because they occur in more than one size category in the fish market. Sometimes a size category contains only 1 year class. The oldest fish are predominantly found in the largest size class which contain many year classes.

The data for age 3 must be considered with caution, because this age group is not fully recruited in the fishery in the earlier years and might also be influenced by small changes in the used mesh size.

Tables $2 a$ and $2 b$ give the mean length at age in the 2 nd quarter for males and females respectively. These data are plotted in Figure 1a and 1b. In these plots observations based on less than 3 fish are omitted because they are highly variable.

Length at age is variable, but at the same level in the years 1957-1965 in all age groups. The large fluctuations in the earlier years in the older age groups are mainly due to poor sampling. In the period after 1965 mean length at age starts to increase each year for all age groups simultaneously and in both sexes. This yearly increase in mean length at age stops around 1973 in the age groups 3-7 and the new higher level remains until 1986 except for 4 and 5 year old males where it tends to decrease again in the latter period. In age groups 8 14 the increase continues also after 1973 but is lower than in the previous period.

Weight at age data for the 2nd quarter are shown in tables 3 a and 3 b and figures 2 a and 2 b . Also here observations based on less than 3 fish are omitted in the plots. The trends in weight at age are similar as described for length at age.

Tables 4 a and 4 b show the condition factors per age group for both sexes. Figure 3 shows the condition factors for each age group in the 4 different quarters (averages over the period 1971-1986). The condition factors in females are higher than in males.

In females, the condition factor is lowest after spawning in the third quarter. It increases during the third, fourth and first quarter by somatic growth and the development of the ovaries. The seasonal pattern of changes in the condition factor of males is different from the females. The condition factors are lowest in the second and third quarter and highest in the fourth quarter. In contrast to the females they decrease in the first quarter.

Figure 4 shows the trends of the condition factors in the second quarter with time. Yearly fluctuations in the condition factors of males and females show a similar pattern. These fluctuation are probably caused by different growing conditions each year. However, also differences in the stratification of the samples in the second quarter might have influenced these fluctuations. In the period 1961-1971 the condition factors in both males and females increased continuously. After this period they remained at a more or less constant level, lower than in 1971 but higher than the period before the increase.

The percentage ovary weight of the total body weight (stages 4 and 5) in April shows some trends in time but has not changed over the whole period (figure 5). There are short periods with increasing and decreasing trends. In the periods 1966-1970 and 1973-1982 the
relative ovary weight decreases in all age groups. In the first period this decrease is much stronger $(30-40 \%)$ than in the latter $(10-15 \%)$. In the intermediate years there is a strong increase. The fluctuations in the years before 1969 are partly caused by poor sampling. Figure 5 shows that the percentage ovary weight increases with age.

Figure 6 shows the surplus production of females in the periods 1958-1962 and 19821986. The average annual growth ( Y -axis) was plotted against the average weight of the fish during the year (X-axis). Each point represents an age group. The figure shows that the growth in all age groups group was higher in the latter period. The reproduction relative to the weight of the fish in both periods did not change.

## Discussion

The annual growth of fish in weight results from an intake of energy by feeding. This energy is used for metabolic processes, increase in length, increase in condition factor and reproduction. Changes in growth can be described by changes in increase of length, condition factor and reproduction.

Within the considered years, a continuous increase of weight at age has been observed in male and female sole in the period 1965-1973 in all age groups simultaneously. In the period after 1973 no systematic changes in weight at age have been observed in ages 3-7. The weights in these age groups have remained fairly constant at the high 1973 level, except for 4 and 5 year old males which showed a gradually decrease until 1986. This decrease is not observed in females. In the period after 1973 the weights of age groups 8 and older continued to increase. The observed increase in weight at age results from an increase in length at age and an increase in the condition factor in the same period. DE VEEN (1976) mentions the period 1968-1973 in which the increase of growth occurred. From the available data it is difficult to determine the exact year in which it started because of the high annual fluctuation particularly in the first years.

The increase in weight at age from the earlier period (1958-1962) compared to the most recent period (1982-1986) for both males and females is about 54\% for age groups 4-14. About $10 \%$ of the increase in weight is caused by the higher condition factor, the other $44 \%$ results from the increase in length.

The seasonal changes in condition factors are most pronounced in females as the development of the ovary, which amounts to about $6-12 \%$ of the total body weight in April, and the ripening of the eggs and spawning process take more energy than sperm production in males. The higher level of the condition factor in females is probably also related to a higher energy demand for reproduction. As most of the 2 year olds and some of the 3 and 4 year old females will not become mature (VAN BEEK, 1985), the seasonal change in condition factor for these age groups is less pronounced and the value is lower. The condition factors of males in the youngest age groups are not biassed by the occurrence of immature fish, as was the case in females, because all males of age 2 and older are mature (unpublished data from 1985 April survey in the South Eastern North Sea).

In contrast to the females the condition factors of males decrease in the first quarter. The most likely explanation for this phenomena is that the loss weight is caused by the need of energy for metabolic processes in the first quarter. In females this loss is camouflaged by an increase of weight of the developing ovary and ripening of the eggs.

Egg production itself, has not been measured in the marked samples. However, changes in the egg production will be reflected in changes in the percentage ovary weight in spawning time. The decrease of the percentage ovary weight of the total body weight in the years 1966-1970 and the increase in the following years coincide with a period where overall growth in sole increases. Therefore it seems unlikely that those factors, responsible for the growth increase, are the same factors which influence the allocation of energy which will be used for reproduction. Over the whole period 1966-1986 the percentage ovary weight has not changed significantly and seems not related to the changes in the observed weights of the fish.

The fact that the increase in growth rate started in all age groups simultaneously suggests that an external factor, influencing the growth rate must be responsible. The effect of this factor has continued to increase until 1973. After 1973 this factor has not disappeared but the effects of it do not further increase the growth rate of sole. DE VEEN has attempted to correlate these changes with environmental factors such as the density of the sole stock, temperature in the growth season, eutrophication, and fishing effort. He found that of these factors significant correlations were only found with fishing effort and with indices of the disturbance of the bottom layers by active gears, in particular beam trawls. DE GROOT \& APELDOORN (1971) studied the effects of beam trawling on the zoobenthos and demonstrated considerable damage to bottom organisms. DE VEEN suggests that the disturbance of bottom with tickler chains increase the availability of injured molluscs and polychaetes, which are the major food for soles.

No attempt was made to repeat these correlations. However, it must be considered that since 1971 beam trawl effort of Belgium and The Netherlands doubled and tripled respectively. Although some of the increase of effort is exerted to areas outside the distribution of sole, most of the increase is made on the sole fishing grounds. However, after 1973 no further increase in growth has only been observed in age groups 8 and older. It seems reasonable to assume that availability of food is a major factor in the growth increase. If disturbance of the bottom is a significant factor three possibilities remain; 1) The increase of effort after 1973 has exerted to areas where predominantly older soles occur. 2) Further increase in effort after 1973 does not increase the availability of food. 3) Taking in account the limits of other environmental factors, the growth parameters of sole have reached a biological limit in 1973 and the increase of weight at age in the years thereafter are caused by the cumulative effects of the period 1965-1973 with a superimposed maximum growth in the years after 1973. The first possibility does not seem likely. No information is available to verify the other two possibilities. Also natural changes in the abundance of zoobenthos, may be interfering with disturbance of the bottom, could be responsible for changes in the availability of food. However, time series of the abundance of zoobenthos are lacking.

In general, a great proportion of energy in young female soles, accumulated by feeding, is allocated to somatic growth. At older ages an increasing proportion is used for reproduction at the expense of somatic growth. This is demonstrated in figure 6. The surplus production plot (figure 6) shows the annual growth in two periods where weight at age was fairly stable. The period 1958-1962 is representative for the situation before the increase of growth occurred. The period 1982-1986 represents the situation after the major growth increase. As discussed above, the percentage of ovary weight did not change systematical during and after the growth increase (data were only available for the period 1966-1986) and it is assumed that that no changes occurred before 1966. The figure shows that the surplus production of sole has increased in small and large animals but that the amount of production used for the reproduction has not changed.

RIJNSDORP \& VAN BEEK (1987) report on an increase of mean length at age in the late sixties and early seventies in young plaice. This increase did not occur in older plaice. They also present a comparable surplus production plots (figure 7) for the periods 1957-1965 and 1975-1980. In plaice the surplus production has increased in the latter period in smaller animals only and remained the same or showed a slight decrease in the larger animals.

They suggest that the differences between sole and place are possibly related to differences in the distribution of both species. The younger age groups of plaice are predominantly distributed on the same feeding grounds as sole in the Southern North Sea. Older plaice migrate in summer to feeding grounds in the Central and Northern North Sea, while older soles remain in the Southern North Sea. They suggest that the factor(s) responsible for the increase of growth in sole and plaice occur in the Southern North Sea and only that soles are exposed to these factors during their whole life and plaice only in their first years.
